Potential kidney donors with asymptomatic microscopic hematuria: histopathological findings & outcomes

Ehab Hammad, Aleid Ahassan, Tariq Ali, Ibrahim Aehab, Almanea Hadeel.
Kidney & Pancreas Transplantation, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia.

Background: Microscopic hematuria is not uncommon in potential kidney donors. After excluding urological causes, most of these donors require kidney biopsy to exclude glomerular lesions. We evaluated biopsy findings among donors with isolated microscopic hematuria and assessed short-term outcomes of their prospective recipients.
Methods: kidney donors between January 2010 and January 2015 who had microscopic hematuria which was not due to urological causes were included in the study. All of them underwent native kidney biopsies which were examined by light microscopy, immunofluorescence and electron microscopy. Donor characteristics pre-donation were compared between abnormal biopsy and normal biopsy groups. Short-term outcomes of our donors were compared to 27 age & sex matched non hematuric donors 3 month post donation.
Results: Out of 750 donors, 27donors (3.6%) were found to have isolated microscopic hematuria (IMH) and underwent kidney biopsy. Mean age of these donors was 32.6±8.Nineteen donors had 1+ hematuria, 6 donors had 2 + and 2 donors had 3+ hematuria or more in urine dipstick. All of them had a minimum of 3 red blood cells/high power filed on urine microscopy. Eight (29.6%) biopsies showed histopathological abnormalities of which, thin basement membrane disease (n=6, 22.2%) was the commonest cause followed by IgA nephropathy (n=2, 7.4 %). Donors with abnormal biopsy findings were excluded from donation. The remaining donors (n=19, 70.4%) had no significant pathology and were permitted to donate. Except for 2donors (7.4%) who were excluded due to other medical/recipient related issues. There was no significant difference in short-term outcomes between hematuric donors accepted for donation and non hematuric donors group 3 month post donation. The recipients of kidneys from donors with microscopic hematuria with no histopathological abnormalities had a mean SBP of 121 ± 9.5, mean DBP 74 ±8.5 and mean serum creatinine of (75.6µmol/l±21.3) at three month follow up. Their last urine analysis confirmed absence of hematuria in 6 of them, 3 showed +ve dipstick and microscopic hematuria.
Conclusions: Our study showed that 29.6 % of our donors with isolated microscopic hematuria had abnormal histopathology on renal biopsy. Isolated asymptomatic microscopic hematuria justifies extensive work up including renal biopsy to identify donors who may have underlying renal pathology.

320.2

Comparison of the rate of decline of GFR and 1. 5 and 10 year outcomes of live kidney donors – UK cohort study

Nithya Krishnan[1], Lisa Bradbury[2], Graham Lipkin[3], Neil Raymond[1].
[1]Renal Unit, University Hospitals Coventry & Warwickshire NHS Trust, Coventry, United Kingdom; [2]Statistics, National Health Services Blood & Transplant, Bristol, United Kingdom; [3]Renal Unit, University Hospitals Birmingham, Birmingham, United Kingdom.

It is important to have a better understanding of the long term outcomes and risks of kidney donation. We compared the rate of decline of GFR levels and 1, 5 and 10 year outcomes of live kidney donors. From January 1, 2001 until December 31, 2013 inclusive, all live kidney donors in the U.K, were included in the study. December 31, 2014 was considered the study end, meaning that all patients had at least one year of follow-up. A total of 9750 live donor records were available; out of which 9229 had GFR measured at baseline.
The baseline GFR was divided into 3 groups – 1. Meeting the British transplant guidelines' recommended levels (n= 9047). 2. Up to 5 mls/min/m2 less than the recommended levels (n=121) and 3. More than 5 mls/min/m2 less than the recommended levels (n=52). The mean (M) and standard deviation (SD) of the rate of decline of GFR (mls/min/m2) in years 1, 5 & 10 for group 1, 2 and 3 are 35.37 (15.21), 7.65 (3.6) and 4.34(2.02) ; 19.80 (11.36). 3.03 (1.8) 1.46 (0.63); 6.41(22.58). 0.46 (5.62), 0.75 (0.21) respectively. Using 1 year GFR as baseline the rate of change was +0.63 (2.55) in 5 and -0.07 (1.73) at 10 years. Morbidity outcomes at years 1, 5 and 10 were not significantly different between the 3 groups . None of the 173 donors in groups 2 & 3 had died during the 10 year follow-up period in comparison to 48 in Group 1.
Analysing by dividing group 1 into 10 year age bands from <30 to 70+, showed a decline in GFR of 34.4(17.9) to 25(13.4) in 1, 7.1(3.7) to 6.4(2.5) in 5 and 4.1(2) to 3.9 (0.8) in 10 years. Using GFR at year 1 as baseline, showed an increase of 0.9(3) to 0.8 (2.2) in 5 and a very minimal decline about in 10 years. Adjusted Multiple linear logistic regression analysis showed that that females had a lower rate of decline at 1 year, -0.83 (-1.49 to 0.18), P=0.013. but the effect was not significant at year 5 or 10.
Thus, there is a significant decline in GFR at 1 year, more so for men. However, the rate of decline after 1 year is almost similar to that of the general population. Though the rate of decline is lesser in lower baseline groups the numbers are too small to draw definitive conclusions.

320.3

Acute operative complications and 1, 5, & 10 year outcomes in living donors by type of live donor nephrectomy

Nithya Krishnan[1], Lisa Bradbury[2], Neil Raymond[1].
[1]Renal Unit, University Hospitals Coventry & Warwickshire NHS Trust, Coventry, United Kingdom; [2]Statistics, National Health Services Blood & Transplant, Bristol, United Kingdom.

Introduction: Living kidney donation has significantly improved recipient and graft survival world wide. With a move to increase these numbers further, it becomes mandatory to have a better understanding of the short and long term outcomes and risks of kidney donation.
Aim: To investigate occurrence of acute operative complications and 1,5,& 10 year outcomes in living donors by type of nephrectomy
Methods: National Health Service and Blood and Transplant, U.K (NHSBT), obtains informed consent from all patients undergoing a transplant in the UK for continuing data collection and subsequent analyses. The study protocol was reviewed and passed by the Renal Registry (RR) projects advisory group, UK. From January 1, 2001 until December 31, 2013 inclusive, all live kidney donors were included in the study. No formal sample size estimate was produced for the study; all eligible patients records were used. December 31, 2014 was considered the study end, meaning that all patients had at least one year of follow-up. Datasets, based on regular returns from individual transplant centres across the UK, were obtained from NHSBT.
Results: A total of 9750 live donor records were available. Nephrectomy type was available for 9602 donors; Open 3132 (33%), Pure laproscopic - 3886 (38%) and hand assisted laproscopic– 2802 (29%). We analysed the incidence of operative complications; splenectomy, reoperation required, organ perforation, operative haemorrhage, pneumonia, pneumothorax, pulmonary embolism, wound infection, DVT, other complications and a combined variable for any one or more complication.
Statistically significant differences was were noted for the incidence of reoperation (41/2794, P=0.018), organ perforation (44/2802, P=0.032), wound Infection (60/ 2796, P=0.018), other complication (323/2793, P<0.0001), any one or more complications (402/2802 P<0.0001) in the hand assisted laproscopic group when compared to the other 2 groups. Incidence of operative haemorrhage (64/3122, P<0.0001) and pneumothorax (46/3130, P<0.0001) were higher in open nephrectomies. Pure laproscopic nephrectomy yielded the least complications.
One, 5 and 10 year outcomes were analysed using logistic regression methods to facilitate adjustment for donor age, gender and operative complications. At one year, there was significantly more wound pain in the open group in comparison to both the laparoscopic groups P=0.001. Incisional and operation related hernia was more in the hand assisted laparoscopic group P=0.048. Other operation related conditions was more in the laparoscopic groups, especially pure, compared to the open group P=0.024. At five years (n= 6011) wound pain remained significant with more wound pain in open nephrectomy group: 9/2814 vs. 0/ 2282 P=0.007. At 10 years (n=1863) there were only 2 donors with wound pain, both in the open group. Also all laparoscopic procedures were “pure”, as the hand assisted procedures only started in 2007 in the U.K.
Conclusions: Though there were small numbers of complications overall, significant differences were identified with most complications seen in hand assisted laproscopic nephrectomies and least in pure laproscopic operations. Wound pain remained significant in long term outcomes and was mainly related to open nephrectomy.

320.4

The Percentage of CD19 positive cells in lymphocytes can predict acute antibody-mediated rejection after administration of rituximab in ABO-incompatible kidney transplantation

Takayuki Hirose, Daiki Iwami, Hajime Sasaki, Haruka Higuchi, Ken Morita, Nobuo Shinohara.
Renal and Genitourinary Surgery, Hokkaido University, Sapporo, Japan.

Introduction: Administration of rituximab to ABO-incompatible kidney transplant recipients has been recognized as effective and safe. Although a single dose of rituximab at 375 mg/m^2 is known to lead to B-cell depletion, the dosage of immunosuppressants should be reduced because it may cause excessive immunosuppression and the risk of infection[1],[2]. However, the appropriate dosage and whether the B-cell population should be monitored after administration remain to be determined.
Materials and Methods: Forty-four consecutive ABO-incompatible kidney recipients (28 men and 16 women) were enrolled in this retrospective study. They were treated with rituximab (65–400 mg/body) 2 to 4 weeks before transplantation, followed by plasmapheresis and intravenous immunoglobulin as desensitization therapy. They were given basiliximab as induction therapy and maintained with triple immunosuppressants. The mean age at transplantation was 50.3 ± 15.4 years, and the mean pretransplant dialysis period was 2.8 ± 3.8 years. The percentage of CD19-positive cells in lymphocytes (%CD19) and CD19-positive cell count after administration of rituximab were examined just before transplantation. These recipients were divided into 2 groups according to pretransplant %CD19 as follows: low %CD19 group, <1% (n = 34) and high %CD19 group, ≥1% (n = 10). The relationship between %CD19 and the incidence of acute antibody-mediated rejection (AAMR) was evaluated.
Results: AAMR was observed in 6 recipients whose pretransplant %CD19 were significantly higher than that of recipients without AAMR (3.1% vs 0.6%; $p = 0.004$). Neither CD19$^+$ cell count nor rituximab dosage significantly changed according to AAMR incidence. The incidence of AAMR was significantly higher in the high %CD19 group than in the low %CD19 group (40.0% vs 5.9%, $p = 0.006$). One of 2 recipients who developed AAMR in the low %CD19 group had not been treated with plasmapheresis because of low anti-ABO IgG titer before desensitization. Serum creatinine level was significantly higher in the high %CD19 group than in the low %CD19 group (1.64 ± 0.16 mg/dL vs 1.22 ± 0.06 mg/dL, $p = 0.005$), although all rejection cases were resolved by anti-rejection therapy and no graft loss occurred.

	High %CD19 (n=10)	Low %CD19 (n=34)	*p* value
AMR (%; n)	40.0 % (n=4)	5.9% (n=2)	0.006 *
S-Cr (mg/dl)	1.64 ± 0.16	1.22 ± 0.06	0.005 †

Table. Comparison of graft outcome between high %CD19 group and low %CD19 group
High %CD19 group: %CD19 of lymphocytes ≥1%, low %CD19 group: %CD19 <1%
*: Chi-square, †: *t*-test

Conclusion: High levels of %CD19 after rituximab administration in ABO-incompatible kidney transplant recipients may indicate insufficient depletion of B cells that can lead to AAMR. Measurement of %CD19 may be useful identifying patients who need additional administration of rituximab.

ABO incompatible renal transplantation without splenectomy or anti-CD20 treatment: Comparison with ABO compatible renal transplant

Amit Sharma[1], Harinderjit S.Gill[1], Apra Kalra[2], Priyadarshi Ranjan[3], Divya Singh[4], Rupinderjit Kaur[1], Monika Rana[1], Neha Bahari[1].
[1]Nephrology, Dialysis and Kidney Transplant, Fortis Hospital, Mohali, Punjab, India; [2]Transfusion Medicine, Fortis Hospital, Mohali, Punjab, India; [3]Urology and Kidney Transplant Surgery, Fortis Hospital, Mohali, Punjab, India; [4]Radiodiagnosis, Prime Diagnostic and Heart Institute, Chandigarh, India.

Introduction: ABO-incompatible (ABOi) renal transplant has diminished the gap between demand and supply of kidneys for patients with end stage renal disease (ESRD). It involves preconditioning the patient by lowering the isoagglutinin titers and preventing further rise. The study was conducted to assess the feasibility of performing ABOi renal transplant without the use of Anti CD20 antibody or splenectomy and comparison of outcome with ABO compatible (ABOc) transplants.
Methods: This study was conducted from January 2014 to August 2015. A total of 116 patients were divided into two groups based on ABOi or ABOc donors. Patients received Tacrolimus, Mycophenolate mofetil and Prednisolone, started 10 days (ABOi) and 2 days (ABOc) prior to transplant. Plasmapheresis and intravenous immunoglobulin was given until isoagglutinin titer <1:4 was obtained on the date of transplantation in ABOi cases. All patients received induction immunosuppression: Thymoglobulin (1 mg/kg/day for 3 days) for ABOi and ABOc with HLA mismatch >3/6 and Basiliximab 20 mg (2 doses) in remaining. In ABOi transplant, isoagglutinin titers were regularly monitored postoperatively and plasmapheresis was done preemptively if they increased to >1:8 in first week post transplant and >1:16 in 2nd and 3rd week post transplant). Patient and allograft survival; 1-, 3-, 6-, 9-, 12-, and 18-month renal function; infectious complications; and incidence of rejection were evaluated.
Results: 75% of the ABOi and 81% of ABOc recipients were males. Mean±Standard Deviation (SD) age of the ABOi recipients was 40.12±11.59 years (39.79±14.41 years in ABOc). Median isoagglutinin titer at start was 1:32 (1:16 to 1:256). Mean plasmapheresis required were 3. In ABOi group, Mean±SD creatinine levels were 1.26±0.29 mg/dL at 6 months, 1.34±0.37 mg/dL at 12 months and 1.36±0.33 mg/dL at 18 months (1.24±0.36 mg/dL, 1.21±0.33 mg/dL and 1.23±0.34 mg/dL respectively in ABOc group).

Table 1: Patient Characteristics of ABO incompatible (ABOi) and compatible (ABOc) transplant groups

		ABOi (n=16)	ABOc (n=100)
Donor	Age (Mean ±SD) in years	48.25 ± 13.14	48.9 ± 11.73
	Females	43.75%	61%
Recipient	Age (Mean ±SD) in years	40.12 ± 11.59	39.79 ± 14.41
	Females	25%	19%
S. Creatinine (Mean ±SD) mg%	At discharge	1.37 ± .46	1.33 ± .48
	At 1 month	1.25 ± .30	1.26 ± .35
	At 3 month	1.26 ± .30	1.24 ± .35
	At 6 month	1.26 ± .29	1.24 ± .36
	At 9 month	1.34 ± .37	1.21 ± .33
	At 12 month	1.36 ± .33	1.23 ± .34
	At 18 month	1.47 ± .34	1.26 ± .35
Graft Survival At 1 year		87.5%	97%
Patient survival At 1 year		87.5%	97%
Rejection episodes	AMR	12.5% (2/16)	0%
	ACR	6.25% (1/16)	1%
Infections	UTI in first 12 weeks	0%	9%
	Parvovirus	0%	2%
	Fungal Septicemia	12.5% (2/16)	2%
	CMV	0%	2%

Discussion: No significant difference between post transplant serum creatinine observed in the 2 groups. In ABOi group, 3 episodes of antibody mediated rejection (AMR) & 1 acute cellular rejection (ACR) occured which were successfully treated. No AMR seen in ABOc group. Two patients succumbed to fungal sepsis in th ABOi group.
Conclusions: This study suggests that successful ABOi renal transplantation is possible without the use of splenectomy or Anti-CD20 treatment but AMR episodes as well as fungal sepsis are significantly high in the ABOi group.

HLA identical renal transplants. Immunologically privileged why do they fail?

S. Adibul Hasan Rizvi[1], Muhammad Mubarak[2], Tahir Aziz[3], Ejaz Ahmed[3], Fazal Akhtar[3], Mirza Naqi Zafar[2], Anwar Naqvi[1].
[1]Urology and Transplantation, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [2]Pathology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [3]Nephrology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan.

Objectives: HLA identical transplant are immunologically privileged and thus have the best graft survival in both deceased and living donor transplants. Superior survival yet the graft fail. This paper describes the causes of graft failure in HLA identical transplants in the getting of a develop country.
Patient and Methods: Between 1992 and 2012, 3749 live related transplant were performed at our center. Of these 3749, 756 (20%) were HLA identical transplants. Immunosuppression was by triple drug regimen CyA/AZA or Tacrolimus/MMF with steroid. All dysfunction were confirmed by biopsy. Each recipient is followed life long where all treatment is provided free including immunosuppression drugs.
Result: In the follow-up period of 1 to 20 years, 160 (21%) of the 756 identical graft were lost with 5, 10, 15 years survival rates of 85%, 68% and 60% respectively. A comparison of those who lost grafts (Group A) (n=160) vs those who maintained function (Group B) (n=596) showed that in Group A donors were older 35±9 vs 32±9 (p0.001), more female 46% vs 33% (p0.031), more recipients were female 25% vs 18% (p0.03) and hypertensive 60% vs 49% (<p0.04), acute rejection rates were higher 13% vs 4.8% (p0.001), increased cyclosporine toxicity in biopsy 14% vs 11% (p0.20) and high recurrence of original disease 9% vs 4% (p0.03) as compared to Group B. Of the 160 grafts lost 24% were functioning but lost due to death of recipient, 7% lost due to recurrence, 7% lost due to infection in the graft, 6% lost due to acute rejection and 50% were lost due to chronic rejection.
Conclusion: HLA identical grafts have superior survival due to immunological privilege. Unfortunately 30% grafts are lost due to infection and 7% due to recurrence of disease. Old age of donors, female gender and hypertension and cyclosporine toxicity are the other causes leading to chronic graft loss.

320.7

Retroperitoneal versus intraperitoneal hand assisted laparoscopic donor nephrectomy: a case matched study

Zubir Ahmed, Pankaj Chandak, Raphael Uwechue, Nicos Kessaris, NIzam Mamode.
Transplantation, Guy's Hospital, London, United Kingdom.

Introduction: Although hand assisted laparoscopic donor nephrectomy has become a standard of care for living kidney procurement in most centres it is not clear if a retroperitoneal approach offers any advantage over an intraperitoneal approach. Recent RCT data has been published on the subject but the results have been biased by small patient numbers and significant demographic and operative heterogeneity between groups. We therefore conducted a case matched study of retroperitoneal versus intraperitoneal HALDN.
Methods: 61 retroperitoneal HALDNs were matched with 2:1 with 122 intraperitoneal HALDNs for age, sex, laterality, multiplicity of arteries and obesity status (BMI > 30) using a propensity matching score approach using Stata SE 12. Outcomes assessed were Clavien grade 2, 3 and 4 complications, infective episodes, readmission, need for reoperation, postoperative hospital stay, creatinine change at Day 30 and development of incisional hernia.
Results: The mean age of the cohort was 44.1 years (SD11) with 52.5% female. The mean length of surgery was greater in the retroperitoneal cohort (225 mins v 200 mins, p=0.001). Hospital stay (4.2 v 3.9 days p=0.11) and readmission rates (9.1 v 9.6% p=0.12) were similar. Incidence of postoperative surgical site infection (9.9% v 10.1% p=0.1) and the occurrence of minor complications (Clavien 2) were also equivalent (16.3 v 17.3% p=0.45). The abdominal reoperation rate was lower in the retroperitoneal group (1.6% v 3.3% p=0.009) as was the rate of incisional hernia development at one year (0% v 5% p=0.08). Day 2 peak CRP levels were less in the retroperitoneal group (111 v 123 p=0.035). Creatinine rise at day 30 was also similar (+34 v +37 p =0.35).
Discussion: Retroperitoneal HALDN has similar minor complication outcomes compared to the intraperitoneal approach with similar lengths of hospital stay and readmission rates. However there is evidence from this study that it may exhibit a reduced systemic inflammatory response (as measured by Day 2 CRP) and also reduce more serious surgical complications and thereby reduce the need for reoperation.

320.8

Different sensitivity of rituximab-treatment to B-cells between ABO-incompatible kidney and liver transplantation

Asuka Tanaka, Hiroshi Morimoto, Kentaro Ide, Yuka Tanaka, Kohei Ishiyama, Masahiro Ohira, Hiroyuki Tahara, Hideki Ohdan.
Department of Surgery, Division of Frontier Medical Science, Programs for Biomedical Research, Hiroshima University, Hiroshima, Japan.

The use of ABO-incompatible (ABO-I) donor organs is a possible solution for the shortage of donor organs for transplantation; however, naturally occurring antibodies (Abs) against blood group A or B (A/B) carbohydrate determinants in sera are a major impediment to achieving successful transplantation. Therefore, in ABO-I transplant, plasmapheresis or plasma exchange, splenectomy, and/or anti-B-cell immunosuppressant treatment are widely adopted and improved graft and patient survivals to the level comparable to ABO-compatible (ABO-C). In addition to these modalities, the prophylactic use of rituximab, a monoclonal chimeric human-murine anti-CD20 Ab that depletes B-cells by complement-dependent cytotoxicity (CDC), Ab-dependent cell-mediated cytotoxicity (ADCC), and stimulation of apoptosis, is currently indispensable to achieving successful ABO-I KT and LT. A desensitization protocol with rituximab is currently widely used for kidney transplantation (KT) and liver transplantation (LT) across the ABO-I barrier. However, it remains to be elucidated whether rituximab is equally effective for B-cell and T-cell immune responses in both KT and LT recipients. To clarify these effects of rituximab, we enrolled 46 KT recipients (18 ABO-I recipients 28 ABO-C recipients) and 77 LT recipients (14 ABO-I recipients ABO-C recipients) in this study. Both ABO-I KT and LT recipients were preconditioned prior to surgery with a common desensitization protocol that consisted of a single dose of rituximab and subsequent daily internal use of calcineurin inhibitor (CNI) and mycophenolate mofetil (MMF). The basic immunosuppressive regimen after KT comprised CsA, MMF, and methylprednisolone (MP) with gradually tapering doses, and Basiliximab was administered at the time of transplantation and on postoperative day 4. After LT, the basic immunosuppressive regimen comprised TAC and MP at gradually tapering doses. Only in ABO-I LT, MMF is added to the regimen. The proportion of peripheral blood B-cells was determined at the perioperative period. T-cell responses to allo stimulation were evaluated by a mixed lymphocyte reaction (MLR) assay. One week after rituximab administration, the proportion of peripheral B-cells in all of the ABO-I KT recipients decreased below 0.1%. In contrast, that in some of the ABO-I LT recipients remained above 0.1% at this time point. Eventually, B-cells were undetectable in both groups by week 2. And, B-cells remained below the detection limit throughout the first year in the ABO-I KT recipients, whereas they reappeared in the periphery after 6 months in the ABO-I LT recipients. Although the difference was not statistically significant, during the first year after transplant, alloreactive T-cell responses tended to be lower than those in the ABO-C group.
In conclusion,this study indicates that rituximab has differing B-cell sensitivity between KT and LT recipients and a minimal effect on the alloreactive T-cell responses in KT and LT recipients.

Immunosuppressive myeloid cells in patients given combined kidney and hematopoietic cell transplants in a tolerance protocol with TLI and ATG conditioning

Kent Jensen[1], John Scandling[3], Stephan Busque[2], Judy Shizuru[4], Robert Lowsky[4], Ani Saraswathula[1], Kevin Sheehan[4], Asha Shori[2], Edgar Engleman[5], Samuel Strober[1].
[1]Medicine - Immunology & Rheumatology, Stanford University School of Medicine, Stanford, CA, United States; [2]Medicine - Surgery, Stanford University School of Medicine, Stanford, CA, United States; [3]Medicine - Nephrology, Stanford University School of Medicine, Stanford, CA, United States; [4]Medicine - Blood and Marrow Transplantation, Stanford University School of Medicine, Stanford, CA, United States; [5]Medicine - Pathology, Stanford University School of Medicine, Stanford, CA, United States.

In preclinical murine models of mixed chimerism and tolerance induction, combined organ and hematopoietic cell transplantation using total lymphoid irradiation (TLI) and anti-thymocyte globulin (ATG) conditioning results in changes in the percentages of innate and adaptive immune cells. These changes include an increase in CD11b+Gr-1+MHCII- myeloid derived suppressor cells (MDSCs), and CD8+CD11c+MHCII+ dendritic cells (DCs), as well as a decrease in T and B cells. Murine MDSCs and DCs exhibited increased production of arginase-1 and IDO respectively, suppressed the MLR, and were required for induction of tolerance. Here, we studied the changes in myeloid cells in the blood of 10 patients given combined HLA matched or mismatched kidney and hematopoietic cell transplants following TLI and ATG conditioning. We found that in the first 4 months post transplant, there was a profound depletion of T cells in the blood of HLA matched and mismatched patients but no significant change in the absolute cell number of Lin-CD11bhiDRlo MDSCs, CD11bhiCD14+DR+monocytes, or CD11bloCD14-DR+ DCs. The ratio of myeloid to T cells significantly changed to favor the myeloid cells during the first four months post transplant, but returned to pre-transplant values between 6 to 12 months post transplant. Similar changes were found in patients regardless of whether they developed mixed chimerism. In addition, the myeloid cells developed a significantly increased ability to suppress the activation and proliferation of autologous, purified, anti-CD3/-CD28 microbead-stimulated, pre-transplant T cells when co-cultured in vitro. The suppression was most pronounced when pre-transplant versus early (1.5-4 month) post transplant MDSCs were compared. MDSC suppression was associated with increased production of arginase-1. The suppressive capacity of the myeloid cells returned to pre-transplant values 6 to 12 months post transplant. Subsets of DCs were studied to compare the percentages of pre-transplant myeloid versus plasmacytoid DCs among all DCs to percentages measured at serial time points through 24 months post transplant. Since the balance of myeloid DC subsets changed in the preclinical model following transplantation to favor the CD8+ DC subset, we also determined the percentages of myeloid DC subsets (CD16+, CD1c+ and CD141+). There were no significant changes in the percentage of myeloid versus plasmacytoid DCs or among subsets of myeloid DCs after transplantation in our patients. In conclusion, there was a transient change in the balance of T cells and myeloid cells in the blood of our patients following transplantation to favor the myeloid cells. The latter cells developed immune suppressive activity that promotes tolerance to the transplanted kidney in a manner that mirror our preclinical murine studies.

Treatment of large plasma volumes using specific immunoadsorption to desensitize ABO-incompatible kidney-transplant candidates

Lionel Rostaing[1,5,6], Asma Allal[1], Arnaud Del Bello[1], Federico Sallusto[2], Laure Esposito[1], Nicolas Doumerc[2], Bénédicte Debiol[3], Audrey Delas[4], Xavier Game[2,6], Nassim Kamar[1,6,7].
[1]Néphrologie, Dialyse et Transplantation d'Organes, CHU Rangueil, Toulouse, France; [2]Urologie, Andrologie et Transplantation d'Organes , CHU Rangueil, Toulouse, France; [3]Etablissement Français du Sang de Midi-Pyrénées, CHU Purpan, Toulouse, France; [4]Laboratoire d'Histologie, CHU Rangueil, Toulouse, France; [5]INSERM U563 - IFR -BMT , CHU Purpan, Toulouse, France; [6]Université Toulouse III - Paul Sabatier, Faculté de Médecine de Rangueil , Toulouse, France; [7]INSERM U1043 - IFR-BMT, CHU Purpan, Toulouse, France.

Background: ABO-incompatible (ABOi) kidney transplantation has very good long-term results, i.e., similar to those observed for living-kidney ABO-compatible transplantation. This is because patients are desensitized at pretransplant using apheresis and rituximab therapy, associated with tacrolimus-based immunosuppression.
Methods: This prospective single-center study evaluated 12 consecutive patients (6 males), aged 40 (23–59) years. Incompatibilities were A into 0 (8), B into 0 (3), and AB into 0 (1). Efficacy of a single, pre-transplant (Day –1), specific immunoadsorption session was evaluated using Glycosorb® columns (anti-A or anti-B; Glycorex Sweden) to treat large volumes of plasma, i.e., up to 18 L. Pretransplant desensitization relied on rituximab (D –30), tacrolimus, mycophenolic acid, and steroids (all started on D –13), and a single session of specific immunoadsorption on D –1. For every patient, immunoadsorption was coupled in tandem with a hemodialysis session.
Results: Overall, 15 L (11–18) of plasma were treated per patient, i.e., 0.2 (0.11–0.36 L/kg). Isoagglutinin titers were 1/16 (1/5–1/64) before the procedure, decreasing after 6 hours to 1/5 (1/1–1/16; p=0.008), and to 1/2 (1/1–1/8; p=0.05) at completion of the session. The next day, i.e., the day of transplantation, there was no rebound of isoagglutinins [1/4 (1/1–1/5); p=ns]. The procedure was well tolerated with no side effects and no significant changes in hemoglobin level, platelet counts, fibrinogen, or albumin levels.
Conclusion: For ABOi kidney transplantation, a single, longer, specific immunoadsorption session was very efficient at 1 day pre-transplantation with no rebound. However, these results should be confirmed when isoagglutinin titers are higher (≥120).

"Paired Kidney Exchange" program – single Czech institution experience with 50 paired transplants since 2011

Jiri Fronek[1], Libor Janousek[1], Renata Zamecnikova[1], Pavel Chromy[3], Ondrej Viklicky[2], Tomas Marada[1].
[1]Transplant Surgery, IKEM, Prague, Czech Republic; [2]Department of Nephrology, IKEM, Prague, Czech Republic; [3]IT Department, IKEM, Prague, Czech Republic.

Introduction: Kidney paired donation has been at first performed at our institution in 2003. Until 2011 only four 2-way exchanges were performed. Since 2011 the kidney exchange started at our institution as coordinated program. All the incompatible pairs are collected prospectively in the database. The matching run is performed every three monts with on average 20 pairs included for matching.
Methods: There were in total 58 paired live kidney transplants (KTx) performed in Czech since 2003, of those 50 since 2011, those we assessed. There were five 2-way, three 3-way, two 4-way, two 5-way, one 6-way and one 7-way domino kidney paired exchanges performed, two altruistic samaritan donors entered the scheme. There were 9 cases of re-transplant, of those seven second, one third and one forth KTx. Two surgeons perfomed all the transplants, one did all the mininvasive nephrectomies using Hand Assisted Retroperitoneoscopic (HARS) live donor nephrectomy technique.
Results: Mean recipient age was 46.4 years (SD 10.9), mean SCr one month after transplant was 123 umol/l (SD 41), equivalent of 1.39 mg/dl (SD 0.46). There was one case of delayed graft function due to early rejection observed. The program did help some 50 patients so far.
Conclusions: Kidney paired donation program can be run with success even at single institution, this limits some of the highly sensitised patients as well as blood group 0 recipients. Also, the bigger is the group for matching, the higher might bet the number of transplants. Possible cooperation within European centres would help to treat more patients with the best treatment modality – live donor kidney transplantation.

Management of plasma cells rich acute rejections- role of proteasome inhibitors

Khawar Abbas[1], Tahir Aziz[2], Mirza Naqi Zafar[3], Muhammed Mubarak[4], Adib ul Hassan Rizvi[5].
[1]Transplant Immunology, Sindh Institute Of Urlogy and transplantation, Karachi, Pakistan; [2]Nephrology, Sindh Institute Of Urlogy and transplantation, Karachi, Pakistan; [3]Transplant Immunology, Sindh Institute Of Urlogy and transplantation, Karachi, Pakistan; [4]Histopathology, Sindh Institute Of Urlogy and transplantation, Karachi, Pakistan; [5]Urology, Sindh Institute Of Urlogy and transplantation, Karachi, Pakistan.

Introduction: Plasma cells acute rejection (PCAR) appears to be poorly responsive to anti-rejection therapy and showing poor prognosis for survival of the renal allograft. This paper describes outcome of PCAR after proteasome inhibition therapy.
Patients and Method: Plasma cell acute rejection (PCAR) was diagnosed using Banff 2007 classification of renal allograft pathology and its revision including Banff 2013 update. Ten patients received proteasome inhibition based therapy (1.3mg/m2) for their PCAR. Each patient's also received two doses of Rituximab (375mg/m2), 14 doses of anti -thymocyte globulin (ATG) (1.6mg/kg) and 10 session of Plasmapheresis. Historic pre-transplant and sera at PCAR were tested for the presence of human leukocyte antigen (HLA) antibodies for HLA class I and Class II by Luminex (one Lambda, Canoga Park, CA, USA)according to manufacturer's instruction. We used the value of 1000 mean fluorescence intensity (MFI) as a cutoff for positive results.
Results: PCAR had had occurred 3.1±2.55 yr after transplant. The percentage of plasma cells was 47.8 ±12.2. Donor specific antibodies (DSAs) were found in all 10 cases, Class I in 20% and class II in 80%. Mean Post treatment serum creatinine improved from 4.90±2.75 to 3.30±1.58 mg/dl. The mean HLA class I and class II DSA MFI decreased from 4018± 126.57 to 706±430 and 5355±2921 to 1332±1203 respectively. One and two year graft survival was 90%.
Conclusion: Proteasome based therapy is effective in patients with PCAR, reducing both plasma cells and DSA with improvements in serum creatinine. In all 10% of the grafts were lost within the first year of PCAR.

320.13

The importance of renal biopsy in candidate living donors with proteinuria

Handan Özdemir[1], Gökce Özdemir[1], Aysen Terzi[1], Nurhan Özdemir[2], Merih Tepeoglu[1], Gökhan Moray[3], Mehmet Haberal[3].
[1]Pathology, Baskent University, Ankara, Turkey; [2]Nephrology, Baskent University, Ankara, Turkey; [3]Transplant Surgery, Baskent University, Ankara, Turkey.

Due to organ shortage and difficulties for availability of cadaveric donors, living donor transplantation is an important choice for having allograft. Whereas donors with hematuria and proteinuria consist of complex living donors and these donors requires careful evaluation for future renal risk.
The aim of this study is two-fold; first to investigate the importance of proteinuria in the determination of renal pathology in donors, and second to find out the importance of renal biopsy in the selection of donor for transplantation.
Only 679 donors whom were underwent donor evaluation process between 2000 and 2013 were included in the study. Among 679 donors only 70 showed proteinuria. Serial 24-hour urine protein and microalbumin were examined in all these donors and all of them underwent renal biopsy. Renal biopsies were examined under light, immunofluorescence and electron microscopy.
The mean 24-hour urine protein and microalbumin were found 438±302 mg/day and 103,6±235 mg/day respectively in 70 cases. Among 70 cases with proteinuria, only 21 (30%) had chance to become a donor after biopsy (Group 1). Biopsy findings of these 21 cases were found to be nonspecific. Remaining 49 cases were taken out of donor list because of their biopsy and/or clinical findings (Group 2). In group 2, the biopsy diagnosis was FSGS in 17, IgA nephropathy in 8, MPGN in 4, IgM nephropathy in 3, and tubulointerstitial nephritis in 2, hypertensive nephropathy in 2, membranous glomerulonephritis in 1, minimal change disease in 1, lupus nephritis in 1 and nonspecific biopsy findings in 10 cases. A significant difference was found between group 1 (284,8±114 mg/day) and group 2 (503±333 mg/day) in regards of 24-hour urine protein ($p<0.01$). In addition significant differences was noted between group 1 (34,2±59,2 mg/day) and group 2 (143±275,4 mg/dl) in regards of 24-hour urine microalbumin ($p<0.01$). Statistically no significant difference was found between two groups in regards of creatinine clearance. Only 16 patients also showed microscopic hematuria in addition to proteinuria. All 16 cases were included to group 2.
In conclusion proteinuria should be assessed as a standard part of the donor evaluation process. We suggested that proteinuria greater than 300 mg is a marker of glomerular pathology and renal disease. We also concluded that microalbuminuria determination may be a more reliable marker of renal disease and the presence of microalbuminuria should preclude donation.

321.1

Risk of acute cardiovascular complications following pancreas transplantation

Jim Kim[1], Joshua Schulman-Marcus[2], Anthony C.Watkins[1], Thangamani Muthukumar[2], Dmitriy Feldman[2], Rajesh Swaminathan[2], Luke Kim[2], Choli Hartono[2].
[1]Surgery, Weill Cornell Medicine, New York, United States;
[2]Medicine, Weill Cornell Medicine, New York, United States.

Introduction: Type 1 diabetes mellitus (T1DM) and chronic kidney disease (CKD) are known independent risk factors for cardiovascular (CV) disease. To date, the association between in-hospital CV complications following pancreas and kidney transplants has primarily been described only in smaller single-center studies. We therefore analyzed a large nationally representative database to assess composite CV morbidities in patients who had a simultaneous pancreas and kidney transplant (SPK) compared with pancreas transplant alone (PTA), and pancreas after kidney transplant (PAK). Our aim is to gain insight into early CV complications following pancreas transplantation and in patients who have CKD and end-stage renal disease (ESRD).
Materials and Methods: We conducted a serial, cross-sectional analysis of the Nationwide Inpatient Sample (NIS) for patients who underwent pancreas transplantation in the US from 2003 to 2012 (weighted n = 13,399). Multivariate logistic regression analysis was performed to examine the odds of CV complications as well as in-hospital mortality in SPK (weighted n = 8,613) compared to PTA and PAK (weighted n = 4,786).
Results: After adjusting for age, sex, race and co-morbidities, SPK patients had an overall increased risk of CV complications versus either PTA or PAK; OR = 1.38 [95% CI (1.14-1.68), p < 0.001]. Subgroup analysis demonstrated an equivalent risk of myocardial infarction, but a six-fold increased risk for stroke following SPK (see Figure). Atrial fibrillation/flutter and congestive heart failure were also increased after SPK.

	Univariate Analysis		Multivariate Analysis	
Complications	Odds Ratio [95% C.I.]	P value	Odds Ratio [95% C.I.]	P value
Stroke	4.65 [1.78-12.12]	0.002	**6.45 [2.15-19.11]**	**0.001**
Myocardial infarction	1.21 [0.92-1.60]	0.17	0.99 [0.68-1.44]	0.96
Atrial fibrillation/ flutter	0.95 [0.69-1.32]	0.78	1.62 [1.05-2.50]	0.03
Congestive heart failure	1.56 [1.24-1.95]	<0.001	1.33 [1.01-1.75]	0.04
All-cause CV complications	1.44 [1.22-1.69]	< 0.001	**1.38 [1.14-1.68]**	**0.001**
Death	0.40 [0.30-0.53]	<0.001	0.59 [0.40-0.871]	0.01

Discussion: Pancreas transplantation restores long-term physiologic control of euglycemia in patients with T1DM and subsequently leads to improvements in secondary complications, including CV disease. SPK and PAK are potential therapeutic options for Type 1 diabetics who have concomitant ESRD. To our knowledge, this study represents the largest pooled analysis of pancreas transplants examining differences in postoperative CV complications, namely the increased risk in patients undergoing pancreas transplant in conjunction with a kidney transplant (SPK) versus those who did not have ESRD at the time of their pancreas transplant (PTA and PAK). Undoubtedly, patient selection differences exist between the groups, but given the overlapping comorbidities, the effects of uremia appear to be a significant risk factor for CV complications following pancreas transplantation. We report multiple novel findings, including a six-fold increased risk for stroke following SPK versus pancreas alone (PTA+PAK).

Conclusion: Despite rigorous pretransplant evaluation, acute complications from CV disease may still cause considerable morbidity and mortality. ESRD is a significant risk factor for all-cause CV morbidity in patients undergoing pancreas transplantation. Further research is needed to elucidate the underlying mechanisms and to identify potential preventative measures.

321.2

Postoperative monitoring and diagnosis of common surgical complications following pancreas transplantation by microdialysis catheters

Gisle Kjøsen[1], Rune Horneland[2], Ole Øyen[2], Einar M.Aandahl[2,4], Kari G.Dahl[2], Andreas Barratt-Due[1,5], Sören Pischke[1,5], Gisli Björn Bergmann[1], Tor Inge Tønnessen[1,3], Håkon Haugaa[1].
[1]Dept. of Anaesthesiology, Oslo University Hospital, Oslo, Norway; [2]Dept. of Transplantation Medicine, Section for Transplant Surgery, Oslo University Hospital, Oslo, Norway; [3]Institute of Clinical Medicine, Oslo University Hospital, Oslo, Norway; [4]The Biotechnology Institute, Oslo University Hospital, Oslo, Norway; [5]Dept. of Immunology and Transfusion Medicine, Oslo University Hospital, Oslo, Norway.

Introduction: The complication rate after pancreas transplantation (PTx) is very high, with venous thromboses, bleeding and enteric anastomosis leakages being the most commonly occurring events that lead to early graft loss. There is currently a lack of reliable methods to uncover complications at an early stage. By the time the blood sugar increases, the grafts are in most cases irreversibly damaged, and can only infrequently be saved. In an ongoing study, we investigate whether microdialysis catheters are able to detect complications post-PTx. In this case report we describe the successful detection of venous thrombi and anastomotic leakage by microdialysis catheters.
Method: Four diabetic patients underwent technically similar solitary pancreas transplantations. A common aortic patch with both the coeliac trunk and the superior mesenteric artery was anastomosed "end-to-side" to the common iliac artery on the right side and an elongated portal vein was anastomosed "end-to-side" to the inferior caval vein. The enteric anastomosis was performed by a side-to-side duodeno-dudenostomy. At the end of surgery, two microdialysis catheters were placed on the anterior and posterior pancreatic surface. We measured glucose, lactate, pyruvate and glycerol bedside, sampled every 1-2 hours postoperatively.
Results: All patients had uncomplicated initial postoperative courses. On the third postoperative day however, we experienced elevations in lactate and lactate/pyruvate ratio in two patients. Doppler ultrasounds showed well-circulated grafts, but supplemental CT scans revealed venous thrombi in both patients. They underwent immediate angiographic intervention, and the thrombi were successfully removed. The patients were discharged on the 14th and 10th postoperative day, respectively. They have both had normal control CT scans after discharge, and remain insulin-free nine months post-PTx.

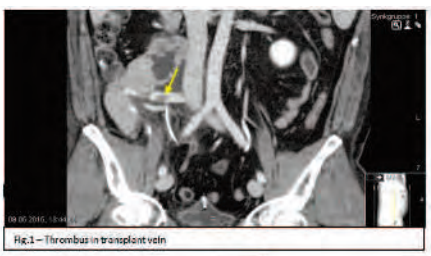

Fig.1 – Thrombus in transplant vein

Fig.2 – Venous echo, thrombus in transplant vein

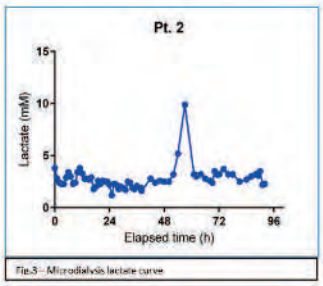

Fig.3 – Microdialysis lactate curve

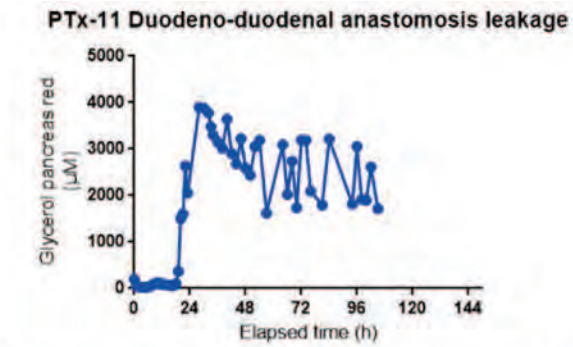
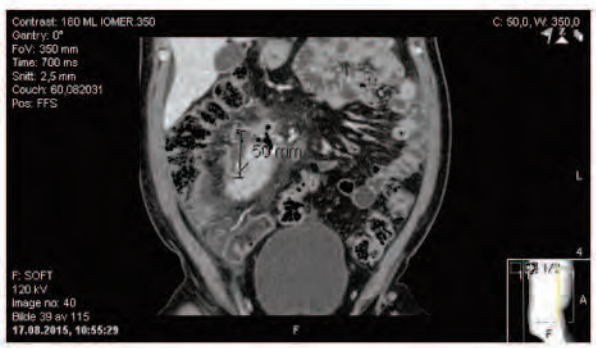
Another patient had a 36-fold increase in microdialysis glycerol 20 hours postoperatively, but apart from this remained clinically well. He was discharged on the 10th postoperative day, but was readmitted on the 16th postoperative day with an abscess in relation to the enteric anastomosis. He was discharged after 5 days of IV antibiotics, without any intervention.
The last patient had elevated microdialysis glycerol in excess of 1000µm from the first measurement. This was accompanied by an amylase count of 21000 U/L measured in drainage fluid. He was otherwise clinically well, and was transferred to the medical ward on postoperative day 8. Six days later signs of infection developed, and a CT showed a peripancreatic abscess. The abscess was treated by percutaneous, ultrasound-guided drainage and IV antibiotics. The patient was discharged on the 28th postoperative day.





Conclusion: Monitoring pancreas transplants with microdialysis catheters appear to detect early complications like anastomotic leakage and ischemia at an early stage, and may potentially improve graft survival.

321.3

Longitudinal assessment of oral glucose tolerance test parameters for the prediction of pancreas transplant dysfunction

Emmanuel Morelon[1], Pascaline Alix[4], Fanny Buron[1], Sophie Reffet[2], Maria Brunet[1], Olivier Thaunat[1], Ricardo Codas[1], Lionel Badet[1], Fitsum Guebre[3].
[1]Transplantation, Hospices Civils de Lyon, Lyon, France;
[2]Endocrinology, Hospices Civils de Lyon, Pierre Bénite, France;
[3]Nephrology and Transplantation, CHU Grenoble, Grenoble, France;
[4]Nephrology, Hospices Civils de Lyon, Lyon, France.

Introduction: In patients with type 1 diabetes and end-stage renal disease, simultaneous pancreas-kidney transplantation (SPK) is the treatment of choice to improve glycemic control and prevent the development of secondary complication of diabetes. The management of pancreatic transplantation in the long term is limited by a lack of clinically relevant markers of graft dysfunction. Oral glucose tolerance test (OGTT) is performed to monitor pancreas graft function. The aim of our study was to focus on longitudinal assessment of insulin secretion and sensitivity data that can be derived from OGTT and to study their performance for the prediction of pancreas graft failure in the long term.
Patients and Methods: Between 2004 and 2013, patients with pancreas transplantation were retrospectively analyzed from the clinical database of the transplantation department, Edouard Herriot Hospital, Lyon, France. Clinical parameters, fasting blood glucose, HbA1c and OGTT were analysed at baseline, 3 months and every year after pancreas transplantation. Patients who lose their pancreas transplant within the first 3 months post transplantation were excluded from the analysis. Pancreas graft loss was defined as re-introduction of insulin therapy or anti-diabetic oral agents.
Results: 204 pancreatic graft recipients (6 PTA, 191 SPK, 7 PAK) were analyzed. Patient and pancreas graft survival at 10 years were 94.8% and 73.7% respectively. 28 patients lose their pancreas graft after a median of 31 months for vascular thrombosis (21.2%), pancreas necrosis (3%), biopsy proven acute rejection (24.2%), diabetes reccurrence (9.1%), lymphoma (3%) and unknown reason (24.2%). After 1 year post transplantation, 2 hour glucose from the OGTT and area under the curve for glucose were the most predictive for pancreas graft failure whereas Matsuda index, HOMA-IR and QUICKI, best predicted graft dysfunction after 2 years post transplantation. Fasting plasma glucose, HbA1c and OGTT at 3 months were not able to predict graft failure.
Discussion: Our study confirms the interest of the OGTT performed one year after pancreatic transplantation for the identification of patients at risk for pancreas graft loss. The relevance of complementary explorations (graft biopsy, search for rejection and recurrence of autoimmunity and other biomarkers) based on glucose metabolism parameters should be assessed in a prospective study.
Conclusion: In pancreas transplantation parameters derived from OGTT performed at one year yearpost transplantation may predict pancreas graft failure in the long term.

321.4

Pancreas transplantation results are not more progressing and require significant innovations

Diego Cantarovich[1], Cecile Guillen-Gueguin[1], Florent Le Borgne[1], Julien Branchereau[1], Jacques Dantal[1], Magali Giral[1], Gilles Blancho[1], Claire Garandeau[1], Aurélie Meurette[1], Maryvonne Hourmant[1], Georges Karam[1].
[1]Institut de Nephrologie, Urologie, Transplantation (ITUN), Nantes University Hospital, Nantes, France.

Background: We started our clinical pancreas transplant program in November 1987. Today (May 2015), 517 transplantations were done.
Aim: The goal of this analysis was to audit all procedures included in the database specifically created for this type of transplant and discuss possible changes in our practice to improve results.
Results: The selected period ranged from January 2000 to December 2013. During this period, 323 transplantations (Tx) were done (255 SPK and 68 PTA), with a minimum of 13 Tx in 2011 and maximum of 31 in 2004. According to each studied year, mean recipient age ranged from 37.1 to 43.6 years (20 to 65) and mean donor age from 31 to 39.8 (9 to 55), both without significant evolution over time. Mean BMI of recipients was quite similar each year, from 21.4 to 23.8 (17 to 33). Same thing for donor BMI (mean, 21.2 to 23.8; range, 16 to 33).Time on the waiting list was also relatively stable each year with a mean which never exceeded 1.4 years (maximum time observed was 6 years). In case of SPK, pre-emptive kidney Tx ranged from 9.1 to 68.4 % according to years, with a mean global value of 38%. Pancreas mean cold ischemia time (CIT) decreased from 13.2 hours in 2000 to 10.5 hours in 2013, with overall CIT of 12,7. Kidney DGF ranged from 6.2 to 29.4%, with a whole percentage of 16.6%. Percentage of patients under tacrolimus significantly increased from 43.8% in 2000 to 89.6% in 2013. All patients were under MMF in 2000. EC-MPA was initiated in 2005 and 26% of patients were under EC-MPA in 2013. Steroid-free patients represented 100% of the cohort in 2000; this percentage decreased progressively to 70% in 2013. Acute rejection (including kidney and pancreas ones) incidence, graft survival and death remain unvaried throughout this 14-year period time. Long-term pancreatic results (death-censored) were significantly impacted by donor BMI ≥25, recipient BMI ≥25 and recipient age >45 years (20% difference in survival in each 3 categories at 8 years). On the contrary, long-term kidney graft results were similar according to recipient BMI and donor BMI. We did not observe any influence of donor age or CIT on pancreas survival, although increased CIT was associated with more venous thrombosis.
Discussion: Measures to improve clinical pancreas transplantation should explore the mechanisms involved in pancreas (but not kidney) poor outcomes in relation to donor and recipient BMI. Complement and TNF-alpha blockade, hypothermic machine perfusion, medical optimized metabolic control, may be some suggestions to prevent pancreas Tx failures. Patients over 45 years may probably require a more frequent and extended evaluation before surgery. New trials should consider negative risk factors for pancreas success and test new tools to improve results. Alternatives such as kidney Tx alone, simultaneous kidney-islets or even new strategies of dialysis and medical diabetes care should also be considered in such future studies which might require multicenter collaboration.

321.5

Recipient and pancreas graft survival after kidney-pancreas transplantation in Australia and New Zealand: a cohort study 1984-2014 using ANZIPTR

Angela Webster[1,2], Alex Xi Peng[1], Henry Pleass[1], William Mulley[3], Helen Pilmore[4], Patrick J.Kelly[2].
[1]Centre for Transplant and Renal Research, Westmead hospital, Westmead, Australia; [2]Sydney School of Public Health, University of Sydney, Sydney, Australia; [3]Department of Nephrology, Monash Medical Centre, Clayton, Australia; [4]Department of Renal Medicine, Auckland City Hospital, Auckland , New Zealand.

Introduction: We evaluated survival for kidney-pancreas recipients (SPK) in Australia and New Zealand.
Methods: Data 1984-2014 from the Australia and New Zealand Islet and Pancreas Transplant Registry were used to analyse time to pancreas failure (first of; pancreatectomy, insulin-dependence, with and without death) or death (all-cause), using Kaplan-Meier survival curves, censoring at last follow-up. We used Cox models (Hazard ratios HR, with 95%CI) to identify prognostic factors.
Results: We included 627 recipients, with 5,370 years of observation, 119 (19%) deaths and 214 (34%) pancreas failures. Patient survival was 97% at 1 year, 93% 5 years, 81% 10 years, 69% 15 years and 64% 20 years (figure 1). After adjusting for other differences, risk of dying decreased by 48% for people receiving SPK in 2010-2014 compared to 1989-1994 (HR0.52; p<0.01). Recipient age increased risk of death 4% for every year older at transplantation (HR1.04; p=0.04). There was no evidence of increased risk with any other factors (p>0.05). Pancreas survival was 84% at 1 year, 76% 5 years, 64% 10 years, 56% 15 years and 50% 20 years (figure 2). Pancreas failure decreased 40% between 1989-1994 and 2010-2014 (HR0.60; p<0.02). After adjusting for other differences, risk of pancreas failure increased by 2% for every year of donor age (HR1.02; p=0.03). There was some suggestion that longer time on RRT associated with higher risk of pancreas failure (p=0.08).
Conclusion: There has been substantial improvement in patient survival and a substantial reduction in the risk of pancreas failure since SPK first began in ANZ.

Pancreas-after-islet transplantation: A path for long term insulin independence

Steven Wisel[1], James M.Gardner[1], Garrett R.Roll[2], Jack Harbell[2], Dixon Kaufman[3], Andrew Posselt[2], Peter G.Stock[2].
[1]Department of Surgery, University of California, San Francisco, San Francisco, United States; [2]Division of Transplantation, University of California, San Francisco, San Francisco, United States; [3]Division of Transplantation, University of Wisconsin, Madison, United States.

Introduction: Islet transplantation has emerged as an attractive, minimally invasive approach for treating severe Type 1 diabetes with hypoglycemic unawareness. However, islet transplantation failure rates are high, and success rates following reinfusion of islets have been compromised by allosensitization from prior islet infusions as well as lack of funding for this procedure in the US. Here we describe our series of seven consecutive patients with history of failed islet infusions and subsequent solid organ pancreas transplantation, who have achieved long-term insulin independence and preservation of renal function up to 9 years (median 6.25 years) following pancreas transplantation.
Materials and Methods: Seven consecutive patients receiving care at our institution from 2007-2016 for pancreas-after-islet (PAI) transplantation were included in this study. All patients had a prior history of preuremic type 1 diabetes and at least one lifetime episode of hypoglycemic unawareness, with 1 to 3 previously failed islet infusions prior to PAI transplant. Six patients underwent PAI at our institution; one transplant was performed at an outside institution with subsequent follow-up care at our institution. Patients received anti-thymocyte globulin and methylprednisone for induction therapy, with a standard four-drug maintenance therapy including low dose tacrolimus (trough 5-7ng/ml), mycophenolic acid (180-720 mg/d), and prednisone 5 mg/d. Low-dose mTOR inhibition was added one month following transplant, with cessation of mTOR inhibition or MMF at one year following transplant. All patients underwent routine surveillance, including protocol biopsy between 3 and 6 months post-transplant.
Results: Despite highly variable panel-reactive antibody (PRA)-positivity prior to transplant (mean 36± 39%), all seven patients achieved stable and durable insulin independence with a mean follow-up of 75.2± 31.9 months. HgbA1C values improved significantly from post-islet, pre-pancreas levels (mean 8.1± 1.5%) to post-pancreas levels (mean 5.12± 0.30%, Figure 1a). Four patients experienced acute rejection episodes successfully managed with thymoglobulin and prednisone. Renal function was preserved in this preuremic cohort (Figure 1b), with 100% allograft function as defined by insulin independence (Table 1).
Conclusion: These results suggest that pancreas-after-islet (PAI) transplantation is a viable strategy to achieve long-term insulin independence following islet graft failure. Successful outcomes are dependent on a multidrug immunosuppression regimen which minimizes toxicities of any single agent, as well as routine surveillance biopsy to addres subclinical rejection.

Table 1. Patient Demographics

Patient	Number of Prior Islet Infusions	Panel Reactive Antibody (PRA)	Date of PAI	Follow-up (months)	Insulin Independence	Last HgbA1c (%)
1	3	91%	10/4/2006	114	YES	5.0%
2	2	76%	8/27/2007	103	YES	5.2%
3	3	0%	1/2/2008	99	YES	5.2%
4	1	10%	8/26/2010	66	YES	5.3%
5	1	10%	10/4/2010	65	YES	5.6%
6	2	62%	3/26/2011	59	YES	5.0%
7	2	2%	5/10/2014	22	YES	4.6%

Clinical pancreas transplantation from deceased donor in Japan

Takashi Kenmochi[1], Toshinori Ito[2], Ichiro Nakajima[3].
[1]Department of Organ Transplant Surgery, Fujita Health University, School of Medicine, Toyoake City, Aichi, Japan; [2]Department of Surgery, Osaka University School of Medicine, Osaka, Japan; [3]Department of Kidney Surgery, Tokyo Woman's Medical University School of Medicine, Tokyo, Japan.

237 pancreas transplantations (PTx) [208 from DBD, 2 from DCD, 27 from live donors] were performed from 2000 to 2014 in Japan. We evaluated the effectiveness of PTx from deceased donors and 16 simultaneous pancreas and kidney transplantations from live donors (LDSPK) of my own experiences.
210 deceased donors PTXs in Japan: 132 donors (63%) were over 40 years, which was older as compared to the US and Europe. The Cause of death was cerebrovascular diseases in 117 donors (56%). 160 donors (76.2%) were marginal donors. Category of PTx were SPK; 167 (79.5%), PAK; 32 (15.2%) and PTA; 11 (5.2%). The duration of insulin therapy and hemodialysis of the recipients were 27.4 and 6.9 years. Induction therapy by @IL-2R or ATG was performed in 203 patients (97%) and immunosuppression was maintained by tacrolimus (98.1%) or cyclosporin (1.9%) combined with MMF and steroid. Enteric drainage was selected in 174 patients (83%) and bladder drainage in 36 patients (17%). 5-year recipient survival was 95.8%. Pancreas graft survivals were 84.3% at 1-year, 77.0% at 3-year and 70.4% at 5-year. While, kidney graft survivals were 92.5% at 1- and 3-year, and 89.2% at 5-year, respectively.
16 LDSPKs of my own experiences: I have introduced the first LDSPK in 2004 and performed 16 cases.
Recipients: Age and gender were 34.2+-5.7 years and 6 males / 10 females. All of them showed a negative serum C-peptide level (<0.03ng/ml).
Donors: Donors were 12 parents and 4 siblings. 6 donors were ABO-incompatible.
Operations and Immunosuppression: Donor operation was performed by right nephrectomy followed by distal pancreatectomy with open (8 donors) or laparoscopic procedure (8 donors). LDSPK was performed using pancreatico-cystostomy. Immunosuppression was achieved by a quadruple therapy with tacrolimus, MMF, predonisolone, and basiliximab. For ABO-incompatible cases, desensitization with rituximab, DFPP and PEX was performed.
Results: Although a pancreatic fistula was developed in one donor and a pancreatic cyst in one donor, 14 donors showed no complication including diabetes and renal dysfunction up to 11 years. One recipient developed primary nonfunction of the pancreas graft. Another patient developed venous thrombosis. Other 14 patients achieved insulin independency immediately after transplantation. These patients are maintaining insulin independency and showing the normal endocrine function. All six patients from ABO incompatible donors achieved insulin independency (100%) and withdrawal from hemodialysis (100%) without an episode of antibody mediated rejection.
Conclusion: Although majority of the deceased donors were marginal in our country, clinical outcome demonstrated that PTx was a potent and promising treatment for severe type 1 diabetic patients. Also, LDSPK can be recommended as a potent tool of treatment for type 1 diabetic patient with ESRD. Furthermore, our clinical data demonstrated that ABO-incompatible pancreatic graft survived as well as kidney graft.

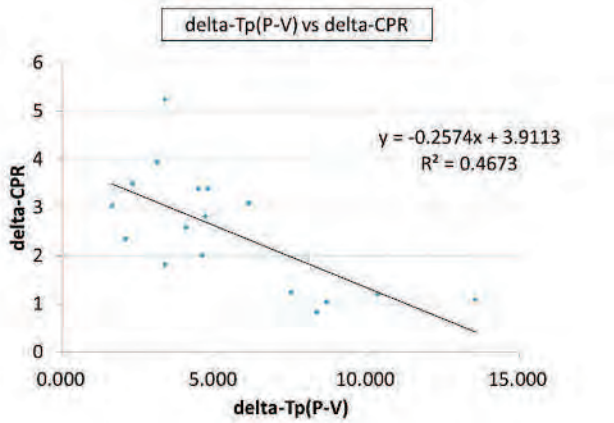
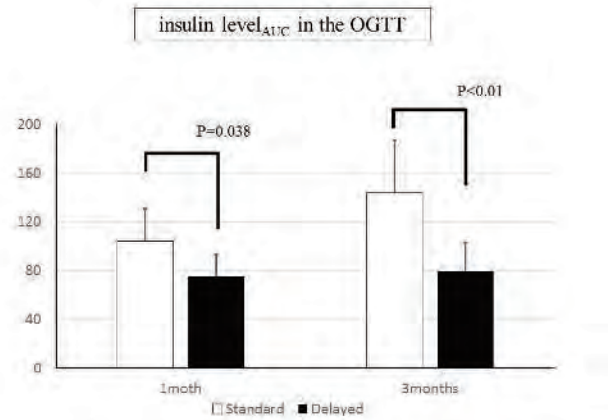
The prediction of the endocrine function of the graft using contrast-enhanced ultrasonography in clinical pancreas transplantation

Naohiro Aida[1], Takashi Kenmochi[1], Taihei Ito[1], Minoru Oshima[1], Toru Nishikawa[2], Akihiro Kawai[3], Mamoru Kusaka[3], Kiyotaka Hoshinaga[3], Hisahiro Matsubara[4].
[1]Department of Liver, Biliary Tract and Pancreas Diseases, Fujita Health University, School of Medicine, Toyoake, Japan; [2]Department of Transplantation and Regenerative Medicine, Fujita Health University, School of Medicine, Toyoake, Japan; [3]Department of Urology, Fujita Health University, School of Medicine, Toyoake, Japan; [4]Department of Frontier Surgery, Graduate School of Medicine, Chiba University, Chiba, Japan.

Introduction: In pancreas transplantation, maintaining blood circulation in the graft early after transplantation is important for organ protection. However, there is little study about the correlation between a blood flow and graft function. Contrast enhanced ultrasonography (CEUS) can be performed easily and safely, thus it is suited to the evaluation of a blood flow of the graft.
Objective: In the present study, we determined the early blood flow after transplantation by using CEUS and examined its relation with graft function.
Methods: Data from 17 cases of pancreas transplantation, performed between May 2012 and September 2015 in Fujita Health University Hospital, were retrospectively assessed. CEUS was performed within 24 hours after transplantation. The time-intensity curves of the parenchyma and vein were constructed, and each time to peak (Tp) were calculated. The time between the Tp of the parenchyma and that of the vein was measured to evaluate graft microcirculation and was defined as delta-Tp (parenchyma [P] – portal vein [V]).
Graft endocrine function was evaluated by oral glucose tolerance test [OGTT] (1month and 3 months after transplantation) and glucagon test (1 month after transplantation).
The relationship between delta-Tp(P-V) and graft endocrine function were analyzed.
Results: The delta-Tp(P-V) showed a significant negative correlation with the C-peptide increment in the glucagon test (R= -0.68).



The delta-Tp(P-V) also showed a significant negative correlation with insulin levelAUC in the OGTT at both 1 month and 3 months after transplantation (R= -0.42, R= -0.39). The patients were divided into the following two groups depending on the value of delta-Tp(P-V), ; Standard group(<7 seconds) and Delayed group (> 7 seconds). The Standard group had better insulin secretion than those in the Delayed group at both 1month and 3 months after transplantation (insulin levelAUC in the OGTT at 1month and 3 months after transplantation: 103.9 ± 26.9 vs. 75.0±18.2; P = 0.038, 143.8±43.2 vs. 79.4±23.5; P<0.01).



Conclusions: The present study demonstrated that delta-Tp (P-V) obtained in early period after transplantation was significantly correlated with the graft function at both 1 month and 3 months after transplantation. CEUS is able to evaluate a blood flow of the graft and useful for the prediction of the endocrine function of pancreas grafts.

Superior long-term outcome of pancreas transplantation alone with portal venous drainage vs. systemic venous drainage

Eric Siskind[1], Niket Todi[1], Lauren Pettinato[1], Amanda Bartosic[1], Blythe Fiscella[1], Eugene Schweitzer[1], Stephen Bartlett[1].
[1]Transplantation, University of Maryland Medical Center, Baltimore, MD, United States.

Introduction: There have been few studies analyzing portal venous drainage (PVD) versus systemic venous drainage in pancreas transplantation. The studies analyzing simultaneous kidney pancreas transplants have shown no benefit to PVD; however, these reports are confounded immunologically by systemic dr ainage of the co-transplanted kidney. Even the reports that show a benefit of PVD in pancreas transplants alone (PTA) are limited by short follow-up. We examined the difference in graft survival between portal venous drainage (PVD) and systemic venous drainage (SVD) in a long-term cohort of PTA cases.
Methods: From 1992 to present, 143 PTAs were performed at the University of Maryland. Patients were divided into two groups: PVD (n=95) or SVD (n=48).
Results: The mean graft survival of PTA is 2370 days from date of surgery calculated via a Kaplan Meier analysis. Patients with SVD had a mean graft survival of 580 days while those with PVD had a mean survival of 2680 days. (p=0.15). The five year graft survival was 28% for SVD and 60% for PVD (p=.004). There is a trend towards decreased episodes of rejection for PVD which approached significance.
Conclusion: Patients who undergo PTAs have significantly longer graft survival. We believe this is due to partial tolerance to antigen delivered into the portal system. The 60% 5-year PVD mean survival is superior to the national average of approximately 53% for PTAs[1].

En bloc dual kidney-pancreas transplantation into an adult recipient utilizing very small pediatric donor: No conflict with liver transplantation concerning anatomical division in respect to dividing arteries - all organs can be used

Johan Nordström, Carl Jorns, John Sandberg, Lars Wennberg.
Dept Transplantation Surgery, Division of Transplantation Surgery, CLINTEC, Karolinska Institute, Stockholm, Sweden.

Introduction: Simultaneous pancreas and kidney transplantation (SPK) is a treatment option for type 1 diabetes patients suffering from end-stage renal disease (ESRD). Upper age limit for donors is commonly 50-60 years but no lower age limit has been defined. Results are excellent using pediatric donors for adult recipients [2]. We present a combined pancreas and dual kidney en bloc transplantation from a 18 month-old, 12 kg donor. Surgical technique using donor aorta and cava as vascular pedicle not transecting neither pancreas nor kidneys is very feasible for SPK but raised concerns about possible problems for liver transplantation from same donor to child recipient.
Method: SPK from small pediatric donor using the en bloc technique to adult recipient. Only 1 vascular reconstruction is needed on backtable, namely an end-to-end anastomosis between the porta and upper vena cava. Several different surgical techniques has been described [5][3]. We used a previously described technique [4] with modification so that the proximal donor aorta was used for arterial anastomosis to the recipients a iliaca communis dexter. The urinary bladder was utilized aiming for bladder patch transplantation technique [1] for ureteral reconstruction but was finally not used due to excessively long ureters which raised concerns about risks for complications, i e ischemia i urethers leadine to urinary leakage and strictures as well as serving as an ileus mechanism. The 2 ureters was anastomosed separately to recipient urine bladder over 2 double-J-stents that was kept for 5 days post-op. Graft-duodenum was anastomosed to recipient jejunum approximately 40 cm distal to Ligamentum Treitz. No surgical complications was noted and organ function was immediate without need for dialysis or anti-hypertensive medicines and with excellent metabolic control. The liver was sent to another transplant center and pediatric whole liver transplantation was performed without problems. The fact that the donor had normal arterial anatomy made decisions easier, transecting liver and pancreas with sufficient vasculature for transplantation.
Result: No surgical complications. Organ function in SPK recipient was immediate. The liver was used for pediatric whole liver transplantation without problems. Our case shows that it is feasible to use very young donors for SPK en bloc without interfering with liver transplantation. Using the en bloc technique for SPK leads to short cold ischemia time (CIT). Outcome is excellent, one year follow-up: excellent metabolic control and GFR>60.
Discussion: The technique leads to short CIT which is greatly beneficial. The multiorgan procurement technique for en bloc in small pediatric donors is not complicated and does not take longer time compared to standard techniques. It can be done with no conflict with liver transplantation, at least in cases with normal arterial anatomy. The backtable is done with only one vascular reconstruction.

Long term results in pancreas re transplantation depending on the cause of primary graft failure

Lilia martinez de la Maza, Joana Ferrer, Maria Jose Ricart, Miguel Angel Lopez-Boado, Emiliano Astudillo, Ramon Rull, Santiago Sanchez-Cabus, Asma Salhi, Laureano Fernandez-Cruz, Juan Carlos Garcia-Valdecasas.
Hepato-Pacreatic-Biliary Surgery and Transplantation Department, Hospital Clinic de Barcelona, Barcelona, Spain.

Introduction: The late increase in the number of pancreas transplantations has lead to an increase in potential candidates for retrasplantation after graft failure due to technical complications or chronic immunological rejection.
Aim: To analyze the results in patients who where subject to a pancreatic retrasplantation in Hospital Clinic in Barcelona during the past 15 years weather the primary graft failure was due to immune causes or technical complications associated with surgery.
Material and Methods: We did a retrospective study to analyze the pancreas retrasplantations done from 2001 to 2015. The mean time between the first and second transplant was 57.3 ± 51.1 months. The back table end-to-end splenic with distal mesenteric artery anastomosis technique was used in 85.7% of the transplants. The donor pancreas was flushed either with UW (65.7%)) or Celsior (34.3%) solutions. The cold ischemia mean time was 11.8 ± 2.8 hours . Exocrine drainage was managed with a duodenojejunostomy in all cases. We used SPSS v20 for statistical analysis
Results: Between January 2001 and December 2015 a total of 312 pancreas transplantations were done in our institution, from which 35 were retransplantations. The group of retransplantation had mean age of 40±8 years old. Fifty one percent of these patients were men and 48.6% were women. Most of the primary graft failure was due to immune causes (57.1%), 40% was related to technical complications and in one patient the graft had to be removed because a lymphoma in the graft. In four cases (11.4%) a simultaneous pancreas-kidney retransplantation was done and in 31 patients (88.6%) a pancreas alone retransplantation was done with a functional kidney graft. The most common surgical related complication was vascular thrombosis without difference due to the primary graft failure. After a following of 82±47 months, the five-year survival was 94% in the group of immune cause of primary graft failure and 92% when primary graft failure was associated with surgical technical complications without significant difference. One year, 3 and 5 years graft survival was 79%, 73% and 61% respectively when primary graft failure was due to immune causes and 71%, 71% y 63% respectively when associated with technical complications as the cause of primary graft failure without significant difference.
Conclusions: Pancreas retransplantation can be considered as an effective and safe second option in patients with previous primary graft failure, reaching a graft survival equivalent to primary pancreas transplantation independently of the primary graft failure cause.

The optimal range of native kidney function before pancreas transplant alone minimizing the risk of end-stage renal disease

Sung Shin, Young Hoon Kim, Ji Yoon Choi, Hyun Wook Kwon, Joo Hee Jung, Duck Jong Han.
General Surgery, Asan Medical Center, Seoul, Korea.

Background: The optimal range of native kidney function minimizing the risk of end-stage renal disease (ESRD) after pancreas transplant alone (PTA) remains unclear.
Methods: A retrospective study was conducted on 84 recipients who underwent PTA at a single center from January, 1999 to August, 2015. Logistic regression was used to model the association between pre-transplant eGFR and the risk of ESRD after PTA.
Results: Nine patients (10.7%) had a pre-transplant estimated glomerular filtration rate (eGFR) <60, 10 patients (11.9%) 60 to 79.9, and 65 patients (77.4%) ≥80 ml/min/1.73m2. The cumulative probabilities of ESRD for eGFR<60, 60 to 79.9, and ≥80 ml/min/1.73m2 at 5 years were 36.5%, 0%, and 9.1% and at 8 years were 68.3, 0, and 18.2%, respectively. Pre-transplant eGFR < 60 ml/min/1.73m2 was found to be associated with a greater risk of ESRD (p = 0.04). Although there was no significant difference in the risk of ESRD between eGFR 60 to 79.9 and ≥80 ml/min/1.73m2, the post-transplant mean levels of eGFR in patients with pre-transplant eGFR 60 to 79.9 ml/min/1.73m2 were significantly lower than those with pre-transplant eGFR ≥ 80 ml/min/1.73m2 during the follow-up period (p = 0.042).
Conclusions: The ideal management of candidates for PTA with eGFR less than 80 ml/min/1.73m2 remains to be determined.

Hyperinsulinemia after pancreas transplantation: a risk for excessive weight gain, metabolic syndrome, and fatty liver disease

Richard Knight[1], Ana Islam[1], Samir Patel[2], Archana Sadhu[3], Larry Teeter[4], Edward Graviss[4], David Victor[3], Osama Gabor[1].
[1]Surgery, Houston Methodist Hospital, Houston, United States; [2]Pharmacy, Houston Methodist Hospital, Houston, United States; [3]Medicine, Houston Methodist Hospital, Houston, United States; [4]Pathology and Genomic Medicine, Houston Methodist Hospital, Houston, United States.

Aim: Recent studies have suggested that elevated insulin levels may be the cause rather that the result of obesity. We therefore hypothesized that hyperinsulinemia, due to portal-systemic drainage of the pancreas graft, may result in excessive weight gain (EWG) after transplantation, leading to metabolic syndrome and fatty liver disease. This study aimed to characterize EWG following pancreas transplantation and its association with hyperinsulinemia.
Methods: This is a single center review of 82 kidney-pancreas transplants for type 1 diabetes performed between 9/2007 and 4/2014. All transplants utilized portal-systemic venous drainage. Immunosuppression consisted of tacrolimus, mTOR inhibitor or mycophenolate mofetil, ± prednisone. EWG was defined as >18% weight increase at 1 -year post-transplant (upper limit of interquartile range of median percent weight gain at 1-year).
Results: Mean recipient age and body mass index at transplant were 41±9 years and 25±4 kg/m2, respectively. Mean weight gain at 1 year post-transplant was 11.2±13.4% of baseline. The incidence of EWG at 1 year was 29%. By multivariate analyses, independent pre-transplant risk factors for EWG included younger age (OR=0.92, p=0.01), HgbA1c >7% (OR=7.31, p=0.02), and C-peptide >0.2ng/mL (OR=3.59, p=0.05). No individual immunosuppression agent conferred a greater risk of EWG. Despite good pancreas function at 1 year in both groups (Hgb A1c 5.4±0.7% for EWG recipients vs. 5.3±0.6% for all others, p=0.40), EWG recipients had higher fasting insulin (26±15 vs. 19±11 mU/l, p=0.04), triglyceride (141±72 vs. 105±45 mg/dl, p=0.03), cholesterol (201±42 vs. 174±41 mg/dl, p=0.02), ALT (38±21 vs. 28±15 mg/dl, p=0.03), and AST (36±10 vs. 30±10 mg/dl, p=0.04) levels. Beyond 1-year the EWG group displayed continued weight gain and higher fasting insulin levels than the non-EWG cohort.
Conclusion: Almost one of 3 recipients experienced EWG within the 1st year post-transplant. Pre-transplant risk factors included younger age and poor glycemic control. Despite a well-functioning pancreas, EWG recipients had higher fasting insulin, lipids and transaminase levels. Beyond 1-year, EWG recipients continued to gain weight and remained hyperinsulinemic over time. These data suggest that hyperinsulinemia resulting from pancreas transplantation may cause EWG, potentially leading to metabolic syndrome and fatty liver disease.

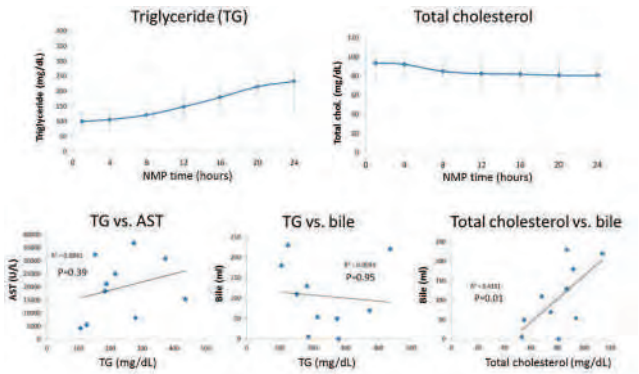
Triglyceride exportation in the preservation of discarded steatotic human livers using 24 hours ex-vivo normothermic machine perfusion

Qiang Liu, Ahmed Nassar, Giuseppe Iuppa, Basem Soliman, Laura Buccini, Matthew Blum, Toshihiro Okamoto, Teresa Diago Uso, Ana Bennett, William Baldwin, Kareem Abu-Elmagd, John Fung, Charles Miller, Cristiano Quintini.
Cleveland Clinic, Cleveland, United States.

One primary reason to discard donor livers after procurement is severe steatosis. The impact of normothermic machine perfusion (NMP) on lipid metabolism and preservation of steatotic human livers has not been studied. We perfused 10 discarded human livers with oxygenated NMP for 24 hours (after cold ischemia of 4-6 hours). The perfusate consisted of packed RBCs and fresh-frozen plasma (2.5L total volume and 20-25% hematocrit). All livers had several degrees of steatosis. Perfusate analysis showed an increase in triglyceride (TG) levels in all livers starting from the 1st hour (median 127 mg/dL; interquartile range 95-149) to 24th hour (203;171-304)(p=0.004).



Total cholesterol decreased from 101(83-109) to 85(72-94) mg/dL (p=0.11). 50% of the livers produced a significant amount of bile (≥5 ml/hr). Bile production and aspartate transaminase (AST) release in the perfusate did not correlate to TG in perfusate at 24th hour NMP, while the total cholesterol had a significant positive correlation to bile production (r=0.66; p=0.01) but a non-significant correlation to AST(r=0.54; p=0.13). The semi-quantitative scoring of steatosis did not show a significant difference from start to end of NMP. There was no significant intra-individual difference in the degree of steatosis based on quantitative image analysis. This is the first study to determine the lipid profile of the perfusate using ex-vivo human liver perfusion in 24 hours NMP preservation. Our results indicate that active TG metabolism and exportation occur ex-vivo regardless of AST release and bile production (one of the most reliable marker of ex-vivo function). The long perfusion duration (24hrs) is not sufficient to decrease the amount of steatosis as measured by histological analysis. Pharmacological intervention may be needed to decrease the amount of steatosis in ex-vivo liver perfusion.

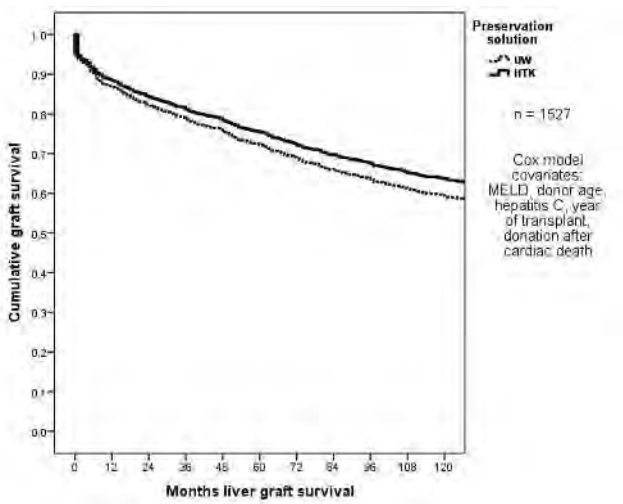
A comparison of liver transplant biliary complications for deceased donor drafts preserved with histidine-tryptophan-ketoglutarate and University of Wisconsin solutions

Richard Mangus, Jonathan A.Fridell, Chandrashekhar A.Kubal, Ray Chihara, Timothy Borup, William A.Marshall, A. J.Tector.
Surgery, Transplant, Indiana University School of Medicine, Indianapolis, IN, United States.

Introduction: Flushing of the biliary microvasculature at the time of whole organ liver graft procurement appears to be an important component in optimizing post-reperfusion blood flow to the biliary system. Two primary preservation solutions are most commonly employed in the United States, University of Wisconsin (UW) and Histidine-Tryptophan-Ketoglutarate (HTK) solutions. While HTK has a viscosity similar to that of water, UW is much more viscous. It has therefore been proposed that the less viscous HTK provides a better flush of the liver graft at the time of procurement. This then leads to the question of whether or not this improved flush results in a lower rate of biliary complications in HTK preserved livers, particularly donation after circulatory death (DCD) grafts. The present study evaluates biliary complications in 1527 consecutive liver transplant patients. The primary study variable is the choice of graft preservation solution, UW or HTK. Outcomes include post-transplant biliary complications, as well as graft and patient survival. Measured biliary complications include any need for bile duct imaging, intra- and extra-hepatic stricture formation, and bile duct leak. The secondary outcome was graft survival.
Methods: Data were extracted retrospectively from a large, single center database covering the period from 2001 to 2014. All primary imaging reports were reviewed. For this study, a patient was considered to have an anastomotic stricture if this is reported, and an intervention (balloon dilation or stent placement) is performed. Patients in whom sphincterotomy alone was performed were not considered to have a stricture. Any leakage of contrast from the biliary system was considered a biliary leak, though most were easily managed with temporary stenting of the duct.



Results: There were 1527 LTs reviewed, 1360 (89%) with duct-to-duct and 163 (11%) with Roux-Y choledochojejunostomy. Preservation included 1098 HTK (72%) and 429 UW (28%) grafts. One-year graft survival favored HTK preserved livers (88% vs 84%, p=0.02). Any biliary imaging was required for 50% of HTK and 59% of UW LTs (p=0.001). The risk of any leak was higher for UW (18%) versus HTK (7%) (p<0.001). The rate of any stricture was higher for HTK (45% vs 38%, p=0.01), but intrahepatic strictures were more common for UW

(5% vs 2%, p=0.001). Among donation after circulatory death (DCD) grafts, there was a higher risk of intrahepatic ischemic-type strictures in UW-preserved grafts (36% vs 8%, p=0.02). Multivariate Cox regression survival at 10-years favored HTK.
Conclusion: HTK liver graft preservation in deceased donors is associated with better graft survival, less imaging, less risk of biliary leak and intrahepatic strictures overall. HTK is also associated with a lower risk of intrahepatic strictures in DCD grafts.

Surgical experience of normothermic machine perfusion in human liver transplantation

David Nasralla[1], Hynek Mergental[2], Thamara Perera[2], Paulo Muiesan[2], Annemarie Weissenbacher[1], Carlo Ceresa[1], Wayel Jassem[3], Constantin Coussios[4], Peter Friend[1].
[1]Nuffield Department of Surgical Sciences, University of Oxford, Oxford Transplant Centre, Oxford, United Kingdom; [2]Liver Transplant Surgery, Queen Elizabeth Hospital, Birmingham, United Kingdom; [3]Liver Transplant Surgery, King's College Hospital, London, United Kingdom; [4]Institute of Biomedical Engineering, University of Oxford, Oxford, United Kingdom.

Introduction: Normothermic machine perfusion (NMP) offers a potential solution to the organ shortage crisis affecting liver transplantation. It involves perfusing an organ with oxygenated blood, nutrients and medications at 37°C to preserve it in a functioning, physiological state. It requires the liver backtable to be performed at the donor hospital followed by cannulation of the vessels before commencing the perfusion. NMP continues during transport and storage until transplantation. We report the logistical impact and surgical expertise that has emerged during our first 100 transplanted NMP livers using the OrganOx *metra*.
Methods: 100 livers were successfully preserved using NMP until transplantation. For all livers the following details were recorded – cold ischaemic time (CIT; cross clamp to start NMP), backtable and cannulation time (liver explant to start NMP), cannulation technique, liver anatomy, ability to commence and complete NMP.
Results: Back-table preparation and cannulation has been identified as the critical step in achieving a successful liver NMP. DBD and DCD livers (71:29) were perfused. Average CIT was 2hrs 3min with no significant difference between DBD and DCD livers (1hr 59min vs 2hr 12min; p=0.09) and similar cannulation times in both groups (1hr 30min DBD vs 1hr 36min DCD; p=0.39). This did not seem to prolong the retrieval process unless abnormal anatomy was encountered (1hr 49min abnormal vs 1hr 24min normal; p=0.00002).
IVC cannulation problems were rare. The only challenge related to PV cannulation was the risk of twisting of the vein. This was identified by absent PV flow measured by the device and corrected by untwisting the vessel.

HA cannulation has posed the greatest challenge to NMP technique due to common aberrant anatomy. One liver was not perfused due to aberrant left hepatic artery (aLHA) arising directly from the aorta (not included in analysis). Aberrant arterial anatomy was encountered in 31/100 cases (10xaRHA, 16xaLHA, 5xaLHA+aRHA) requiring either arterial reconstruction to be performed at the time of retrieval (n=10), or for the aortic tube to be excised intact with coeliac and SMA, enabling cannulation and perfusion directly through the aorta (n=3). More recently a bifurcated cannula has been used to perform dual perfusion of aberrant vessels (n=2).
In 2 cases the distance between aortic patch and the origin of LHA was too short for cannulation, requiring the use of an extension graft. Reconstruction of an aberrant artery on to GDA or splenic artery has been performed during ex-vivo NMP on 5 occasions.

All livers were successfully transplanted.
Discussion: NMP can be employed with all types of commonly encountered aberrant liver anatomy. With normal liver anatomy NMP should not significantly prolong the retrieval process but abnormal anatomy can cause a delay before commencing NMP. A reasonable level of surgical expertise and meticulous cannulation technique are required for successful perfusion.

Effect of machine perfusion and urokinase on the kidney transplants with glomerular thrombosis

Xiaopeng Yuan, Chuanbao Chen, Jian Zhou, Changxi Wang.
Third Division of Organ Transplant Center, The First Affiliated Hospital of Sun Yat-sen University, Guangzhou, People's Republic of China.
Background: Glomerular thrombosis of cadaveric kidneys usually occurred in donors with disseminated intravascular coagulation (DIC). DIC donors are frequently associated with open craniocerebral injury, massive blood transfusion and cardiopulmonary resuscitation. The transplant professionals may be unwilling to use these kidneys because of high rate of primary non-function. We studied the effect of machine perfusion with urokinase on kidneys with glomerular thrombosis.
Methods: Twelve kidneys from 6 DIC donors (5 cases of donation after brain death and 1 case of donation after cardiac death) were preserved by machine pulsatile perfusion with LifePort. Urokinase (2 × 105 units/L) was added into the KPS-1 solution. All kidneys showed extensive glomerular thrombosis on procurement biopsy. Wedge biopsies were repeated after perfusion.
Results: Causes of donor death included closed head trauma in 3, open head trauma in 2 and anoxia in 1. The terminal serum creatinine level was 409 ± 230 μmol/L (149 -816μmol/L) and the final 24-hour urine volume was 3284 ± 1460 mL(1200 - 5480mL). Twelve kidneys were transplanted and no case of hematoma occurred. The rate of glomerular thrombosis was 28.4% ± 7.1% (19.4% - 41.9%) on procurement biopsy, it was decreased to 12.8% ± 4.8% (6.1% - 20.0%) after machine perfusion and thrombolytic treatment. After a follow-up of 6 - 28 months, all renal graft survived. The estimated glomerular filtration rate (by the Modification of Diet in Renal Disease equation) of renal grafts at 3, 6 and 12 months were 33.9 ± 5.9, 37.7 ± 5.4 and 38.8 ± 6.9 ml/min/1.73m2, respectively.
Conclusions: Pre-treatment with machine perfusion and urokinase seems to be effective for kidneys with massive glomerular thrombosis. But the function of the renal grafts after thrombolytic treatment seems to be suboptimal.

A novel method of split liver ex vivo perfusion

Viola Huang[1], Negin Karimian[2], Sharon Geerts[2], Irene Beijert[3], Safak Mert[2], Korkut Uygun[2], James F.Markmann[1], Heidi Yeh[1].
[1]Transplant Surgery, Massachusetts General Hospital, Boston, United States; [2]Center of Engineering in Medicine/Surgical Services, Massachusetts General Hospital, Boston, United States; [3]Department of Hepatobiliary Surgery, University of Groningen, University Medical Center Groningen, Groningen, Netherlands.

Introduction: Each year in the United States, hundreds of procured deceased donor livers are deemed unsuitable for transplantation and discarded[1]. Ex-vivo machine perfusion (EVMP) is a promising method for improving organ preservation and viability post procurement, and is being used in clinical trials in North America and Europe[2],[3]. However, the heterogeneity of clinical deceased donor livers makes it difficult to compare the results of EVMP to standard cold storage, both in clinical and pre-clinical research using discarded human livers. We therefore developed a split liver ex-vivo machine perfusion technique to provide matched controls for each liver.
Materials and Methods: Our group established a subnormothermic (21°C) machine perfusion protocol that allows assessment of liver function, cellular injury, and recovery in real time[4]. Previously, we had only used this system on whole livers. We adapted our protocol to test whether two lobes of the same liver would be comparable to each other during perfusion, and behave similarly to whole livers. Six discarded livers were split anatomically into right and left lobes. Each lobe was perfused separately for 3 hours via its own inflow vessels, and bile output was measured. Flow, resistance, and a biochemical profile of each lobe were monitored at regular time intervals.
Results: As with whole liver perfusions, each lobe exhibited decreasing portal venous and arterial resistance, lactate production, and ALT release over time. Overall bile and ATP production was low in the split livers compared to whole liver perfusions. Within each liver, right and left lobe behavior during perfusion was comparable: portal venous and arterial resistance, ATP levels, and lactate clearance showed no significant differences. ALT release per gram of liver weight were slightly higher in left lobes compared to right lobes.

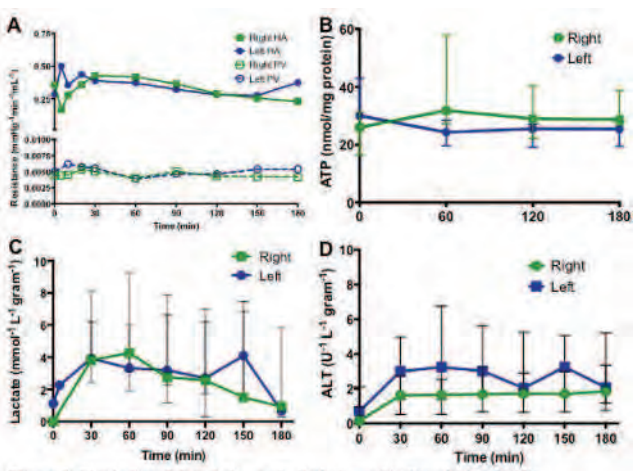

Figure 1: Single liver lobes behave similarly to each other during EVMP
Median portal venous and arterial resistance (A), cellular ATP content (B), arterial lactate (C), and ALT (D) measurements during ex-vivo machine perfusion of single liver lobes. Lactate and ALT are corrected for disparate lobe weights. Data presented as median and interquartile range.

Discussion: Single liver lobes behave similarly to whole livers during EVMP, and more importantly, right and left lobes behave similarly to each other, except for ALT production. More work needs to be done to understand why injury markers do not correspond between lobes as other physiologic and biochemical markers do.

Conclusion: Split liver perfusion is a novel approach that may allow direct comparison of different preservation techniques and treatments on the same liver, circumventing the need for extremely large numbers of experimental and control livers necessary with the wide variability of discarded human livers. Future experimental treatments could include de-fatting agents, anti-inflammatory factors, and immunosuppressants. Optimizing perfusion techniques using this system may eventually increase the supply of viable donor organs so that fewer need to be discarded.

Ex vivo perfusion of human livers induces leukocyte mobilisation

David Nasralla[1], William Critchley[2,3], Alexandra Ball[2,3], Rebecca Edge[2,3], Kavit Amin[2,3], Constantin Coussios[4], Peter Friend[1], James Fildes[2,3].
[1]Nuffield Department of Surgical Sciences, University of Oxford, Oxford, United Kingdom; [2]Manchester Collaborative Centre for Inflammation Research, University of Manchester, Manchester, United Kingdom; [3]The Transplant Centre, University Hospital of South Manchester, Manchester, United Kingdom; [4]Institute of Biomedical Engineering, University of Oxford, Oxford, United Kingdom.

Introduction: Use of extended criteria donors has become widespread due to a lack of organs deemed acceptable for liver transplantation. However, the use of such organs is associated with graft dysfunction post-transplant. Ex vivo normothermic machine perfusion (NMP) is a preservation technique with the potential to enable evaluation and reconditioning of such marginal organs. We have previously demonstrated that ex vivo organ perfusion diminishes passenger leukocyte content; however, the effect on donor livers has not previously been assessed. We aimed to quantify major leukocyte populations within the perfusate at serial time points to determine whether ex-vivo NMP induces immune cell migration out of the organ. Leukocyte diapedesis was then correlated with clinical variables pre- and post-transplantation.
Methods: For each NMP, donor type (DBD/DCD), level of steatosis (n=14 none/mild vs n=7 moderate/severe), warm and cold ischaemic times (WIT/CIT), donor BMI and donor age were recorded. Peak AST values within 7 days post-transplant were also recorded. NMP was performed using the OrganOx metra device for up to 14 hours. Perfusate samples from n=21 procedures were obtained prior to organ attachment and at 30, 60 and 240 minutes. Leukocyte populations were phenotyped and quantified using flow cytometry.
Results: NMP induces the significant migration of leukocytes into the circuit within 30 minutes (B cells, T cells, NK cells, classical monocytes and non-classical monocytes, all $p<0.01$). Leukocyte number in the circuit is then diminished to marginally above baseline at 1 and 4 hours. Donor leukocyte diapedesis is not altered by donor type ($p=0.982$), WIT ($p=0.465$), CIT ($p=0.262$), donor BMI ($p=0.316$) or donor age ($p=0.285$) but is increased in association with steatosis severity ($p=0.016$). Additionally, post-transplant peak AST values are not affected by the extent of leukocyte migration ($p=0.726$). One liver experienced a second period of warm ischaemia during NMP, which induced a subsequent peak in immune migration into the circuit at the end of perfusion.
Discussion: Ex vivo NMP of the donor liver induces early diapedesis of passenger leukocytes into the circuit, an effect that is elevated in severely steatotic organs. The reduced immune cell count at 1 and 4 hours suggests that these leukocytes either adhere to the circuit or repopulate the organ. The additional immune migration in response to the second warm ischaemic injury suggests that immune return to the organ may occur. Our findings provide insight into the immunological processes that occur following liver transplantation, and specifically the relationship between steatosis severity and ischaemia reperfusion injury. Incorporating a leukocyte filter into the circuit may maximise the removal of passenger leukocytes and their transfer into the recipient, thereby modulating direct allorecognition.

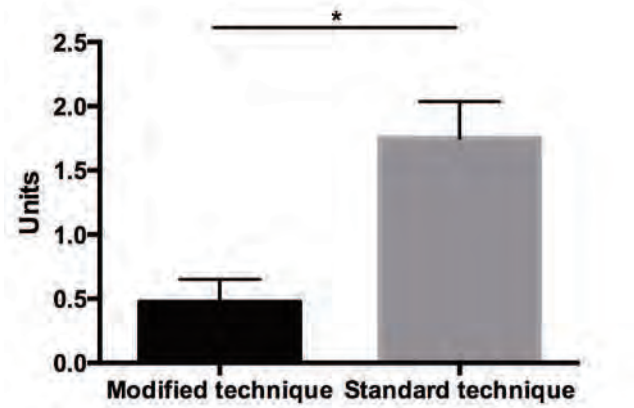
Harmonic scalpel in the rapid procurement of the pancreas for transplantation: Recipient outcomes

Ahmer Hameed[1,4], Teresa Yu[4], Lawrence Yuen[1,2], Vincent Lam[1,2], Brendan Ryan[1], Wayne Hawthorne[1,2], Richard Allen[1,2,3], Jerome Laurence[2,3], Henry Pleass[1,2,3].
[1]Department of Surgery, Westmead Hospital, Sydney, Australia; [2]Discipline of Surgery, University of Sydney, Sydney, Australia; [3]Department of Surgery, Royal Prince Alfred Hospital, Sydney, Australia; [4]Sydney Medical School, University of Sydney, Sydney, Australia.

Introduction: Dissection of the superior and inferior margins of the pancreas during the en bloc recovery of the pancreas is time consuming and is often associated with significant blood loss in recipients[1]. We have learnt from other surgical procedures that newer energy devices can be used to minimize dissection time and blood loss.
Methods: Here we describe a novel, two-phase technique for the procurement of the pancreas using ultrasonic shears (Harmonic Scalpel), both in situ and on the back-table, at a major tertiary centre. The Harmonic Scalpel is especially useful in fashioning a narrow SMA/SMV pedicle, overall allowing rapid skeletonization of the pancreas. It can further be employed on the back-table to divide the spleen and remove any excess/fatty tissue.

Recipient outcomes utilizing these donors were analyzed from 2011-2015, and included blood loss, packed red blood cell (PRBC) requirement, and primary graft thrombosis/loss rates. These were subsequently compared to a subset of pancreas recipients in whom this modified technique was not utilized (standard technique). Statistical analyses employed the Mann-Whitney and Fisher's exact tests for continuous and categorical variables, respectively (GraphPad Prism



Results: The mean PRBC requirement for all modified technique pancreas recipients (n = 21) was 0.5 units (95% CI 0.1-0.9), compared to 1.8 units (95% CI 1.2-2.3) in the standard technique group (n = 36; p < 0.01).
Mean blood loss in standard group was 928 ml (95% CI 533-1322), compared to 488 ml (95% CI 324-652 ml) in the modified technique patients (p = 0.14). During the whole study period, one of 20 (5%) simultaneous pancreas-kidney transplant patients in the modified technique group underwent graft pancreatectomy (day 9) due to primary graft vessel thrombosis compared to 6/102 (5.8%) in the standard technique group (p = 0.68). The mean time to graft loss in the standard group was 2.5 days.
Conclusions: Use of the Harmonic Scalpel in pancreas procurement simultaneously reduces blood product requirement in the recipient whilst allowing rapid organ procurement, without any increase in other adverse outcomes, including graft loss rates due to thrombosis.

Hypothermic machine perfusion of en bloc kidneys from infant and neonatal donors

Abul Siddiky, Imeshi Wijetunga, Vivek Upasani, Muhammed Jameel, Lutz Hostert, Niaz Ahmad.
Department of Transplantation, St. James's University Hospital, Leeds, United Kingdom.

Introduction: Renal transplantation from donors less than two years of age have been rare in the United Kingdom (UK) at a rate of one transplant per year over the last two decades. Renal transplantation from a donor less than two-months of age was first performed in the UK in 2013. Until recently (2015), UK legislation did not permit the diagnosis of brain-stem death in infants under two-months of age and only donations after cardiac death (DCD) have been possible. In our experience, in situ hypothermic flush of the kidneys is often inadequate in these donors and the kidneys cannot be effectively flushed on the back-table after procurement. In this abstract we describe our experience with hypothermic machine perfusion (HMP) of infant and neonatal kidneys.
Methods: All renal transplants from donors less than two-months of age from the period March 2013 to January 2016 were included in this review. All kidneys were retrieved and transplanted en bloc with the abdominal aorta and inferior vena cava. Hypothermic machine perfusion was initially used for inadequate in situ flush and subsequently for all kidneys from such donors. The LifePort Kidney Transporter (Organ Recovery SystemTM) machine was used with Kidney Perfusion Solution (KPS-1) as the perfusion solution. Perfusion was started at a pressure of 30 mmHg which was gradually reduced to 20 mmHg over a period of 5 minutes, and maintained at this pressure up until transplantation.
Results: In the review period, nine transplants were performed from donors less than two-months of age; eight from DCD and one from donation after brain death (DBD). Two kidneys had static cold storage (SCS) and seven underwent HMP. All the kidneys in the HMP group had blood removed from the kidney once on the machine and had visibly improved flush. There was one primary non-function (SCS) and one delayed graft function (HMP). Seven kidneys had primary function (1 SCS, 6 HMP). A very high resistance and low flow rate were observed in the machine perfused kidneys with a mean resistance of 1.15 ± 0.48 and flow rate of 19.00 ml/min ± 7.05 (see Table 1).

Table 1. Summary of demographic data and machine parameters at time of transplantation

En bloc	Age (days)	Weight (Kg)	Flow (ml/min)	Resistance
1	23	3.2	21	1.02
2	30	4.2	10	1.98
3	6	3.4	10	1.64
4	58	4.2	22	0.95
5	0.5	1.3	20	0.90
6	238	7.2	20	0.95
7	2	3.0	30	0.60
Mean (SD)	51.07 (84.87)	3.79 (1.79)	19 (7.05)	1.15 (0.48)
Range	0.5-238	1.3-7.2	10-30	0.60-1.98

Discussion: This is the first reported series of hypothermic machine perfusion of kidneys from infant and neonatal donors. The current machines are not calibrated for paediatric, particularly infant and neonatal, kidneys. A high resistance and low flow rate has been observed in these kidneys and our evidence suggests that this is not an indicator for function or quality but normal for en bloc kidneys. Delayed graft function may have to be redefined in cases of infant and neonatal donor kidneys.

[1]General, Visceral and Transplantation Surgery, University Hospital Essen, Essen, Germany; [2]Institute of Physiological Chemistry, University Hospital Essen, Essen, Germany.

Introduction: Controlled oxygenated rewarming (COR) of cold stored livers by machine perfusion demonstrated convincing results in the first clinical pilot series[1] and was, hence, now applied in steatotic liver allografts. This study analyzes short-term available perfusion characteristics.
Methods: Between 03/2015 and 06/2015 eight distally procured livers from DBD-donors, which had been rejected by other transplant centers and had a histologically proven steatosis of ≥30% were subjected to the COR protocol before transplantation: Immediately after arrival in our transplant center hepatic artery and portal vein were cannulated. Gentle rewarming of the graft was effectuated thereafter by pressure controlled oxygenated machine perfusion (Organ Assist, Groningen, NL) while gradually increasing perfusate temperature up to 20°C. Real-time biochemical analysis of perfusate parameters was carried out in constant time intervals during the controlled rewarming.
Results: Median donor age was 60 (50-71) years, ischemic times were 7.6 (6.7-13.5) hours and the DRI was 2.1 (1.6-2.5). 2 out of 8 organs were not transplanted due to the macroscopic appearance and the overall risk profile. During the rewarming the median arterial flow increased constantly from 105 to 159.5 ml/min and the median portal flow from 165 ml/min to 255 ml/min. Weighing of the allografts showed similar values before and after perfusion (median weight ratio after/before perfusion= 1.01). Histological analysis did not reveal any negative perfusion associated effects, especially no injury to the endothelium or edema. Oxygen consumption increased steadily during the rewarming period, while acid base homeostasis and lactate levels remained stable. Perfusate analysis demonstrated rising glucose concentrations from median 133.5 to 256 mg/dl, triglyceride values from median 16.5 up to 33.5 mg/dl and potassium levels from 21.9 to 30 mmol/l. Enzyme leakage peaked after reaching the subnormothermic temperature range (Median LDH, AST and ALT: 7686 U/l, 3263 U/l and 2395 U/l, respectively). Mitochondrial release of GLDH showed increasing values from median 80.5 to 137.1 U/l during the rewarming period. The two discarded livers demonstrated a continuous release of aminotransferases, with significantly higher highest peak values in the perfusate (8542 U/l & 5186 U/l) compared to transplanted organs.
A significant correlation ($r2=0.8$; $p<0.05$) was observed for the AST release into the perfusate with the postoperative aminotransferase peak. After minimum follow-up of 6 months after transplantation, all recipients are alive with excellent graft function.
Conclusions: Short-term available perfusion parameters during rewarming to subnormothermic temperatures help to characterize steatotic allografts. Further validation of correlations with the outcome in clinical trials represents a possible new tool to assess eligibility for transplantation and might therefore reduce the rate of discarded organs.

Peri-operative organ perfusion with ATG-fresenius results in improved graft function in clinical liver and kidney transplantation

Paul Ritschl[1], Julia Günther[2], Manuel Maglione[2], Lena Hofhansel[2], Susanne Ebner[2], Sascha Weiss[1], Nicole Bergmann[2], Annemarie Weissenbacher[2], Christian Margreiter[2], Benno Cardini[2], Matthias Biebl[1], Robert Sucher[1], Christian Denecke[1], Felix Aigner[1], Robert Öllinger[1], Stefan Schneeberger[2], Johann Pratschke[1], Katja Kotsch[1].
[1]Department of General, Visceral and Transplantation Surgery, Charité – Universitaetsmedizin Berlin, Berlin, Germany; [2]Center for Operative Medicine, Department of Visceral, Transplant and Thoracic Surgery, Medical University of Innsbruck, Innsbruck, Austria.

The gap between the number of patients awaiting an organ and the number of available organs is steadily increasing. Therefore the use of marginal donor organs with the consequences of higher risk of unfavorable transplantation (Tx) outcome has become reality. The most prominent characteristics impacting organ quality organs include age, cold ischemia, or donation after cardiac death (DCD). Consequently these organs are prone to a higher grade of ischemia-reperfusion injury (I/RI). In order to improve marginal allograft outcome, machine perfusion of solid organs has regained the highest attention. However, further research is necessary before it will become an established technique for the daily transplant routine. As antithymocyte globulin (ATG) is an established clinical therapeutic agent and has been further demonstrated to reduce I/RI in both clinical and experimental Tx, we hypothesized that pre-operative perfusion with ATG may be beneficial in reducing I/RI-related inflammation leading to improved graft function post Tx. We therefore performed a randomized controlled clinical trial involving 30 liver (LTx) and 50 kidney recipients (NTx) at the Department of Surgery, Innsbruck Medical University. Primary endpoints were defined as graft and patient survival after 7 days and one year; secondary endpoints were defined as initial graft function, presence of acute rejection, and clinical parameters. Prior to implantation organs were perfused and incubated for 5 min. with ATG-Fresenius (n=24 for kidney with 12,5mg ATG dissolved in 0.5l 0.9% NaCl; n=16 for liver with 25mg ATG dissolved 1l 0.9% NaCl) and subsequently flushed with NaCl. Control organs were perfused with saline only (n=26 kidney; n=14 liver). No significant differences were observed regarding donor and recipient age, gender, cold ischemia time, HLA mismatch, body mass index or hospital stay between ATG perfused (AP) and control perfused (CP) organ recipients. Mean age of all NTx recipients was 55.04 ± 13.64 yrs and of liver recipients 57.23 ± 9.65 years. During the early hospitalization phase, 16 out of 26 CP-NTx patients required dialysis during the first 7 days post Tx, whereas only 10 out of 24 AP-NTx patients received dialysis (p=n.s.). AP-NTx recipients illustrated clearly better graft function until day 15 post Tx reflected by lower creatinine and urea levels. This result was more evident in younger AP-NTx recipients (<55 yrs) compared with aged AP-NTx (≥55 years) patients (p=0.049 at day 7 post Tx) – an effect which was not observed for CP-NTx patients. This result was further confirmed for young AP-LTx compared to CP-LTx patients reflected by reduced gamma-GT levels at day 10 post Tx (p=0.034). Moreover, AP-perfused liver biopsies illustrate lower levels of CRP compared with CP livers post reperfusion (p=0.02). We present here the first clinical study on peri-operative organ perfusion with ATG suggesting an age-dependent effect independent from the organ transplanted.

What should be moved, graft or machine? Travel strategy in an expanded criteria donor program. organ procurement and transplant organizations (OPO) perspective

Francisco Javier Burgos[1], Victoria Gomez-Dos Santos[1], Victor Diez-Nicolas[1], Sara Alvarez[1], Vital Hevia[1], Adolfo Martinez[2], Laura Martinez[1], Ana Fernandez[3].
[1]Urology, Hospital Ramón y Cajal, Madrid, Spain; [2]Transplant Coordination , Hospital Ramón y Cajal, Madrid, Spain; [3]Nephrology, Hospital Ramón y Cajal, Madrid, Spain.

Introduction: The growing demand for organs has led to the expansion of donor source to include expanded criteria donors (ECD) and donors after cardiac death (DCD). The Machine Preservation Trial has showed that HMP decreases the incidence of PNF and DGF, and increases 1-year graft survival compared to standard static cold storage.
A critical issue for OPOs is to determine if HMP is necessary all along the cold isquemia time before transplantation or if only a period of "in-house" HMP after cold storage (hypothermic reconditioning) could be enough to improve kidney graft function. Several groups have proposed reconditioning of cold-stored kidneys even if clinical logistics only permit one hour of therapy. The aim of the study is to assess the impact of MP in local and extrahospitalary donors in terms of DGF. The study protocol was approved by the Hospital Ethics Committee in Clinical Research.
Material and Methods: Study data were prospectively collected in a cohort of consecutive ECD between February 2012 and September 2015. Ethical approval was obtained from Ethics Review Board. Pulsatile HMP was provided by LifePort® Kidney Transporter machine. Local kidneys were placed on LifePort in the donor operating room and delivered to the recipient on the pump. Kidneys imported from other organ procurement hospital were initially placed on ice until reaching our transplant center. No graft was discarded attending to perfusion parameters. DGF was defined as no fall in serum creatinine concentration of 10% or more within 48 hours.
Results: 112 ECD donors and 148 recipients were included in the analysis. 68.2% donors were of extrahospitalary origin. Local and extrahospitalary donors were different for brain death etiology, donor age, HTA and DM rates (Fig 1) with worse risk factors for local donors.

LOCAL AND EXTRAHOSPITALARY DONORS CHARACTERISTICS			
Sex (Male / Female)	Local Donor	59.6% / 40.4%	0.455
	Extrahospitalary	53.0% / 47.0%	
Brain Death Etiology (CVA / Trauma)	Local Donor	91.5% / 0%	**0,031**
	Extrahospitalary	72.3% / 13.9%	
Donor age (Me CI 95%)	Local Donor	65.5 (60.5; 70.4)	**0.000**
	Extrahospitalary	74.0 (71.8; 76.3)	
HTA	Local Donor	89.4%	**0,003**
	Extrahospitalary	66.0%	
DM	Local Donor	51.1%	**0,000**
	Extrahospitalary	18.6%	

As we expect total cold isquemia time and relative machine perfusion time were significantly different (Fig 2).

Preservation Characteristics and DGF rate			
Glomerulosclerosis (%) (Me; CI 95%)	Local Donor	8.1 (6.1-10.0)	0.553
	Extrahospitalary Donor	9.1 (7.6-10.7)	
Cold isquemia time (h)	Local Donor	16.2 (15.1 – 17.3)	**0,002**
	Extrahospitalary Donor	18.4 (17.4 – 19.3)	
Relative Machine Time	Local Donor	0.92 (0.89 – 0.95)	**0,000**
	Extrahospitalary Donor	0.44 (0.40 – 0.48)	
DGF	Local Donor	13.0% (6/46)	**0.032**
	Extrahospitalary Donor	29.5% (28/95)	

DGF rate were also significantly different for local and extrahospitalary donors respectively (13.0% vs 29.5%; p= 0.032). DGF rate was higher in the extrahospitalary donor group that are iniatilly preserved on ice and only connected to the pump when they reached our hospital. So pump lenght of time was lower. In multivariable risk analysis machine preservation time was a protective factor. Each hour in the pump diminishes DGF risk in a 20%.
Conclusions: Despite positive results of short periods of HMP reconditioning in the experimental setting, better results in terms of immediate graft function in grafts have been obtained from local donors placed on LifePort for the complete period of cold isquemia time. This conclusion could be translated in a machine travel policy recommendation for OPOs.

Hyperbranched polyglycerol-based organ preservation solution: Advantages for cold kidney perfusion

Caigan Du[1], Shadan Li[1], Iren Constantinescu[2], Qiunong Guan[1], Manu T.Kalathottukaren[2], Donald E.Brooks[2,3], Christopher Y.C.Nguan[1], Jayachandran N.Kizhakkedathu[2,3].
[1]Department of Urologic Sciences, University of British Columbia, Vancouver, BC, Canada; [2]Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, Canada; [3]Department of Chemistry, University of British Columbia, Vancouver, BC, Canada.

Background: Both efficient and effective perfusion as well as effective cold storage of donor organs with a preservation solution are critical for the prevention of donor organ injury during procurement; however current preservation solutions including University of Wisconsin (UW) solution do not always yield the expected outcomes. Our preliminary study has demonstrated that hyperbranched polyglycerol (HPG)-based solution is a novel alternative to current solutions in cold storage of donor organs[1]. The current research was designed to evaluate the advantages of HPG-based solution for cold kidney perfusion.
Methods: Perfusion efficiency of preservation solutions (HPG versus UW) was tested in mouse kidneys, and their effectiveness of blood washout was evaluated using a semi-quantitative scoring system. Tissue damage was examined by histology. The interactions of preservation solutions with human red blood cells (RBCs) were examined using both sedimentation and aggregation tests.
Results: here, we showed that the lower viscosity of HPG-based solution was correlated with faster and more efficient perfusion through donor kidneys compared to UW solution. HPG-based solution was also more effective in removing RBCs from the kidney compared to UW solution, and was associated with less tissue damage in donor kidneys. The in vitro examination of the preservation solution – RBC interactions showed that unlike UW solution that significantly accelerated RBC sedimentation and induced RBC hyperaggregation, HPG solution had minimum impact on the RBC sedimentation and prevented RBC aggregation.
Conclusion: Our data suggest that HPG solution is more efficient and effective than UW solution in the removal of the blood from donor kidneys and caused less tissue damage, suggesting that HPG solution is a promising candidate to supplant standard UW solution for donor kidney perfusion in transplantation.

Ex vivo normothermic perfusion reduces kidney immunogenicity prior to transplantation via removal of passenger leukocytes

John Stone[1,2], Alexandra L.Ball[1,2], William R.Critchley[1,2], Triin Major[1,2], Rebecca J.Edge[1,2], Kavit Amin[1,2], Marc Clancy[3], James E.Fildes[1,2].
[1]Manchester Collaborative Centre for Inflammation Research (MCCIR), University of Manchester, Manchester, United Kingdom; [2]The Transplant Centre, University Hospital of South Manchester, Manchester, United Kingdom; [3]The Transplant Unit, Western Infirmary Hospital, Glasgow, United Kingdom.

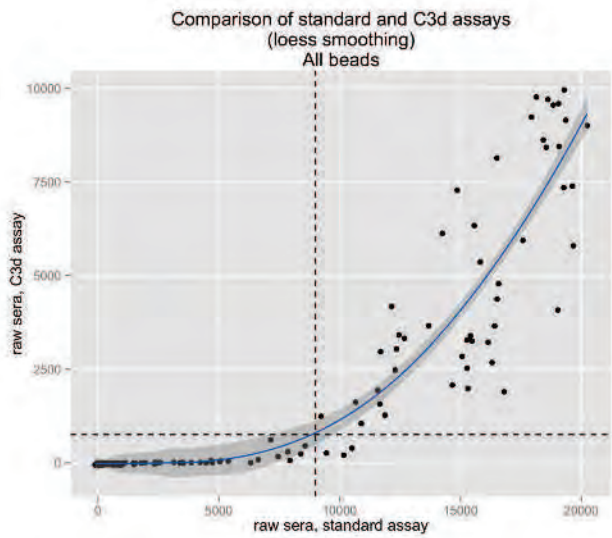
Introduction: Ex vivo normothermic perfusion (EVNP) can improve access to kidney transplantation by enabling the safe preservation and evaluation of extended criteria donor organs, following both circulatory and brain stem death. Aside from evaluation, EVNP can be used to characterise the inflammatory and immunological contribution of the donor kidney in isolation. Here we demonstrate that the kidney possesses a clinically relevant immune repertoire that can orchestrate allorecognition and drive pro-inflammatory responses. Furthermore, EVNP can be used as an immunomodulatory strategy to manipulate the donor kidney prior to transplantation.
Methods: Explanted porcine kidneys (n=5) underwent 2 hours of static cold storage followed by 6 hours of EVNP. Perfusate samples were collected at baseline and hourly intervals. Immune cells were characterised via flow cytometry and an inflammatory profile was generated via cytokine quantification. Cell free mitochondrial and genomic DNA was also determined as markers of cell death.
Results: All kidneys functioned within normal parameters and met the criteria for transplantation at the end of perfusion. Throughout perfusion there were continuous increases in pro-inflammatory cytokines including IFN-γ ($p=0.021$), IL-1α ($p=0.025$), IL-1β ($p=0.010$), IL-1RA ($p=0.025$), IL-2 ($p=0.017$), IL-6 ($p=0.007$), IL-8 ($p=0.007$), IL-12 ($p=0.007$) and IL-18 ($p=0.009$). IL-10 also increased ($p=0.007$), however GM-CSF, IL-4 and TNF-α did not change from baseline, suggesting EVNP drives a non-specific pro-inflammatory response. Increasing concentrations in cell free mitochondrial and genomic DNA were also observed ($p=0.008$ and $p<0.001$ respectively), suggestive of cell death. During perfusion, there was also a marked cellular diapedesis of T cells ($p=0.052$), B cells ($p=0.026$), NK cells ($p=0.015$) and monocytes ($p=0.040$) from the kidney into the circuit. Minor populations of neutrophils, eosinophils and macrophages were also detected.
Discussion: EVNP initiates a non-specific pro-inflammatory cytokine storm and a release of mitochondrial and genomic DNA. This is likely to be responsible for immune cell activation and mobilisation into the circuit prior to transplantation. Interestingly however, the pro-inflammatory EVNP environment did not impact upon renal function. This data therefore suggests that EVNP can be used to immunodeplete and saturate the pro-inflammatory capacity of the donor kidney prior to transplantation. In addition it could provide a platform for the development of novel immunomodulatory therapies.

323.1

Correlation Between C3d-fixing Donor Specific HLA Antibody and Luminex MFI

Paolo Malvezzi[1], Morgane Villemaire[1], Thomas Jouve[1], Anne Legall[2], Dominique Masson[2], Lionel Rostaing[1].
[1]Clinique de Néphrologie, CHU Grenoble, Grenoble, France; [2]Laboratoire de Histocompatibilité, EFS , Grenoble, France.

Introduction: Chronic antibody–mediated rejection is the main cause of late kidney graft loss. Finding in the serum donor-specific antibodies (DSA) is the main criteria for this diagnosis. Single-antigen (SA) Luminex assays provide DSA identification and a semi-quantitative estimate of the amount of antibody by mean fluorescence intensity measurement (MFI). Recent data have shown that patients whose DSA fix C3d have a worse clinical outcome, implying that C3d specific Luminex assays might provide useful prognostic data. In this work, we compared C3dDSA to standard MFI in a cohort of patients having developed de novo class 2 DSA and analyzed graft survival at one year following detection.
Methods: We included kidney graft recipients transplanted between 2005 and 2015 in our center, who developed de novo class 2 DSA. Serum was tested by standard SA Luminex technique and by C3d – fixing antibody detection system (IMMUCOR®) according to the manufacturer's instructions. Clinical data was analyzed regarding graft function and survival at DSA detection and one year later.
Results: 41/924 patients (4.4%) developed class 2 DSA. 65 serum samples were analyzed. Among them, 43 serum samples were negative for C3dDSA (66%). As shown in figure 1, an MFI threshold of 9000 in SA Luminex assay permitted to differentiate between the negative and the positive C3dDSA. This also holds true when all single bead results are taken into account.
From a clinical standpoint: 23% of patients doubled their creatinine level or lost their graft at one year. C3d positivity was not significantly associated to worse survival.
Conclusion: We show that C3d fixing antibody detection is highly correlated to SA Luminex MFI: in our cohort an MFI threshold of 9000 in SA Luminex predicts C3d positivity. Furthermore we do not find any short-term correlation between C3d positivity and graft survival. We conclude that when chronic antibody mediated rejection occurs the concentration of antibodies probably determine complement activation.



323.2

Pretransplant AT1Rabs are associated with acute rejection in 2-haplotypes kidney transplant recipients

Jose Manuel Arreola[1,2], Josefina Alberu[2], Mario Vilatoba[2], Alan Contreras[2], Julio Granados[2], Luis Morales-Buenrostro[3].
[1]Transplantation Department, Centenario Hospital Miguel Hidalgo, Aguascalientes, Mexico; [2]Transplantation Department, National Institute of Medical Sciences and Nutrition "Salvador Zubirán", Mexico DF, Mexico; [3]Nephrology and Mineral Metabolism, National Institute of Medical Sciences and Nutrition "Salvador Zubirán", Mexico DF, Mexico.

Kidney transplant recipients (KTR) who share 2-haplotypes (2-H) with their donors are privileged patients with a mean reported graft survival of 20 years. Nevertheless these patients are not free of acute rejection (AR) episodes and a high proportion of them reject the graft with discontinuation of immunosuppression. This immunological events are not explained by HLA antigens, then other non-HLA antigens could play a role in this AR episodes. Angiotensin II type 1 receptor antibodies (AT1Rabs) are non-HLA abs that has been associated with acute allograft rejection and graft loss even in 2-haplotypes KTR.
Methodology: This is a retrospective cohort study of 2-H living donor KTR between March/2009 and Sept/2013. All the patients have pre KT AT1Rabs measured by ELISA (CellTrend GMBH, One Lambda Canoga Park, CA, USA) and at least one protocol biopsy at 12 months of follow-up; all other biopsies were performed for graft dysfunction. Biopsy findings were classified according to BANFF 2013 criteria.
Results: Twenty-two KTR were included, with a mean age of 31.5 yr (min-max 18 – 51); M:F 12/10. The mean posttransplant follow-up was 2.8 yrs (min- max 0.9 – 5.8 yrs). During this period, 6/22 (27.2 %) had AR episodes (Cellular AR= 4, antibody mediated AR = 1, and mixed AR=1). Three of them had the AR episode during the first year of follow-up and the other three patients had the episode after that time. The median pre KT level of AT1Rabs was 11.7 U (IQR 7.19 – 18.93). Patients with AR had higher AT1Rabs level (19.7 IQR 14.1 – 89) than patients without AR (9.76, IQR 6.51 – 13.18) (p=0.055). AT1Rabs with cutoff value of 14 U was the best predictor of AR (Figure 1).

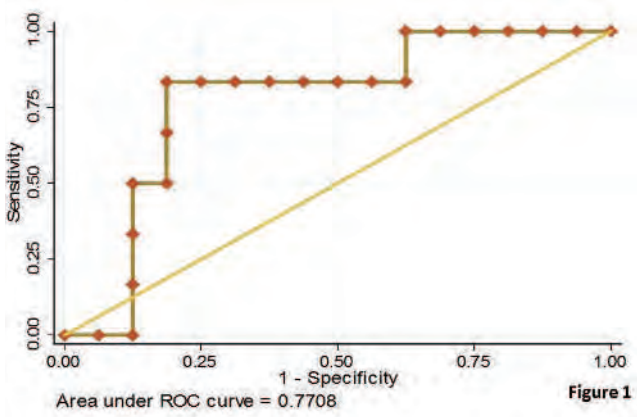


Figure 1

In the univariate analysis only AT1Rab > 14 U significantly predicted AR. (OR 21.6, 95% CI 1.81 – 260, p=0.015). Also, after the first 6 months of follow-up there was a significant difference in eGFR between KTR with and w/o AT1R>14 U (Figure 2).
Conclusions: AT1Rabs are related with AR episodes and worse graft function in 2-H KTR population. These observations add information to the role of non-HLA antigens in KTR.

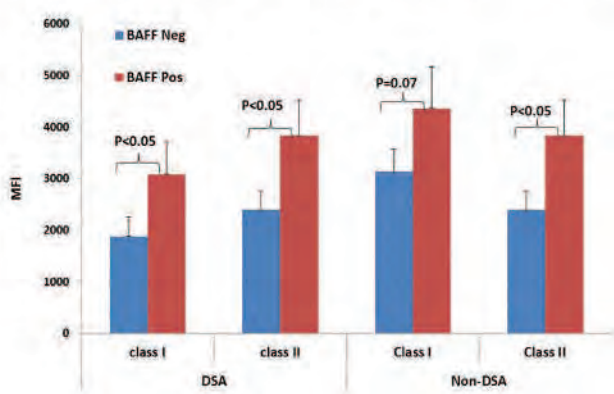
The levels of de novo HLA antibodies are determined by soluble B cell-activating factor belonging to the TNF family (BAFF) post transplantation

Junchao Cai[1], W. Huang[1], L.M. Rebellato[2], C.E. Haisch[3], KP Briley[2], P. Bolin[4], S.A. Kendrick[5], C. Morgan[2], P.I. Terasaki[1], M.J. Everly[1].
[1]Terasaki Foundation Laboratory, Los Angeles, CA, United States; [2]Department of Pathology, East Carolina University, Greenville, NC, United States; [3]Department of Surgery, East Carolina University, Greenville, NC, United States; [4]Department of Medicine, East Carolina University, Greenville, NC, United States; [5]Eastern Nephrology and Associates, Greenville, NC, United States.

It has been shown that excessive level of BAFF causes abnormally high antibody production which results in autoimmune diseases. Here we investigate the effect of BAFF on the production of HLA antibody after renal transplantation. A total of 171 transplant recipients who received renal transplants during 2004-2009 were enrolled into this study. The sera before transplantation and 3 to 6 month post-transplantation were tested for BAFF using Luminex technology. Sera from 20 normal healthy males were used as negative controls. The cutoff value to determine the positivity of soluble BAFF was set at 3500 MFI based on the average level of normal controls plus 3 standard deviations. . HLA class I and class II antibodies were detected using single antigen bead assay (One Lambda Inc, Canoga Park, CA). The level of BAFF post-transplant was significantly lower than that of pre-transplant sera (3100+/-1534 vs 3475+/-1289, p=0.0032). 63% of patients had a decreased level of BAFF while 37% of patients had an increased level of BAFF post-transplant. Interestingly, the peak levels of de novo HLA

Figure 1. The soluble BAFF is associated with high levels of both DSA and NDSA



In conclusion, the level of BAFF in peripheral blood was significantly reduced post-transplantation for the majority of renal transplant recipients, possibly due to immunosuppression. However, patients with higher levels of BAFF post-transplant developed de novo HLA antibodies. These data suggest that strategies to interfere with the production of BAFF may help inhibit the production of HLA antibodies.

Preformed C1q-binding DSA are more clearly associated with adverse outcomes after HLA-incompatible kidney transplantation than DSA strength

Jorge Malheiro[1], Ana Castro[1], Sandra Tafulo[2], Leonidio Dias[1], La Salete Martins[1], Idalina Beirão[1], António Castro-Henriques[1].
[1]Nephrology & Kidney Transplantation, Centro Hospitalar do Porto, Porto, Portugal; [2]Histocompatibility Lab, Centro do Sangue e Transplantação do Porto, Porto, Portugal.

Introduction: Transplantation in the presence of donor-specific antibodies (DSA) is challenging given the high risk of acute and/or chronic active antibody mediated rejection (AMR). We aimed to study the impact of preformed DSA characteristics (strength and C1q-binding ability) on posttransplant outcomes.
Materials and Methods: We retrospectively studied 60 kidney-transplanted patients with negative cytotoxic crossmatch but with preformed DSA detected by single antigen beads (SAB) assays (IgG and C1q kits).
Results: Cohort median DSA MFI was 6500. Thirteen patients had C1q-binding DSA. Eighteen patients experienced AMR.

Comparison of clinical and immunological characteristics according to C1q DSA status

	C1q- DSA N=47	C1q+ DSA N=13	P
At transplant			
Recipient age, mean	48	48	0.920
Male recipient, %	32	46	0.349
Retransplant, %	34	77	0.006
Cytotoxic PRA (%), median	4	35	0.036
HLA mismatch, mean	3.68	4.00	0.327
DSA MFI, median	5300	20000	0.00002
DSA number, median	2	4	0.001
ATG induction, %	57	92	0.023
Desensitization with Ivig+PP+Rtx, %	9	31	0.059
After transplant			
Delayed graft function, %	34	39	0.755
AMR, %	17	77	0.00003
eGFR at 1-year, mean	57	43	0.029
Proteinuria > 0.5g/g at 1-year, %	12	55	0.006
DSA detectable at 1-year, %	36	82	0.010

ROC curve analysis showed that the optimal DSA MFI cut-off for prediction of AMR was 10000.

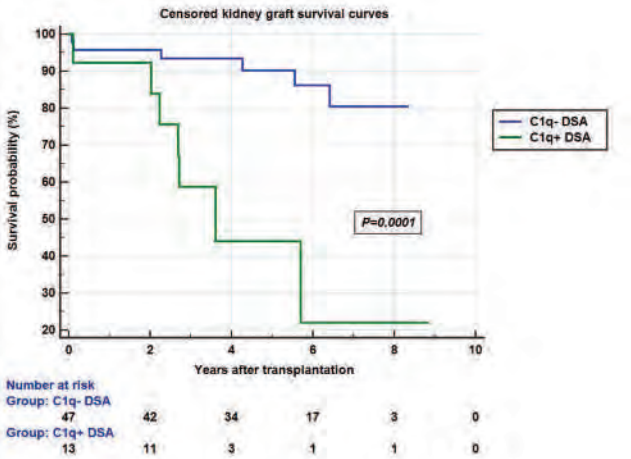
Analysis of DSA characteristics as predictors of AMR

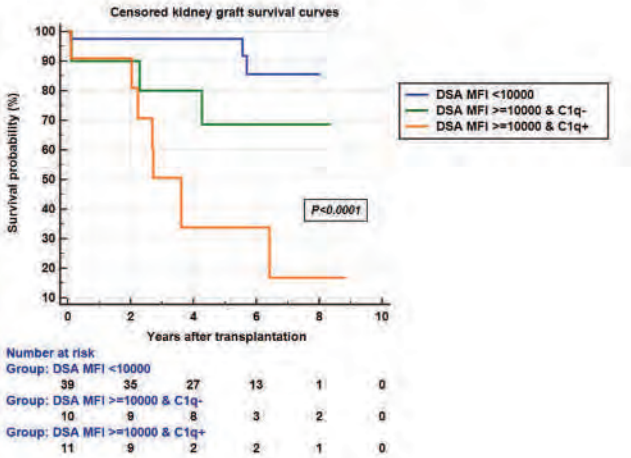
	Sensitivity (%)	Specificity (%)	Positive predictive value (PPV, %)	Negative predictive value (NPV, %)	Diagnostic odds ratio (DOR)
DSA MFI ≥10000 (n=21)	72	81	62	87	11.1
C1q+ DSA (n=13)	56	93	77	83	16.2

Comparison of clinical and immunological characteristics according to C1q DSA status in patients with a DSA MFI ≥10000

	C1q- DSA N=10	C1q+ DSA N=11	P
At transplant			
Retransplant, %	40	91	0.013
Cytotoxic PRA (%), median	50	52	0.832
HLA mismatch, mean	3.80	4.09	0.510
DSA MFI, median	18000	21000	0.313
ATG induction, %	70	100	0.050
Desensitization with Ivig+PP+Rtx, %	20	27	0.606
After transplant			
AMR, %	40	82	0.049
eGFR at 1-year, mean	47	39	0.314
Proteinuria > 0.5g/g at 1-year, %	22	56	0.147
DSA detectable at 1-year, %	56	100	0.023

Censored kidney graft survival at 6-years was 81.3% in patients with C1q- DSA and 44.1% in those with C1q+ DSA.





Censored kidney graft survival at 6-years was 85.6% in patients with DSA MFI <10000, 68.6% in those with C1q-/MFI ≥10000 DSA and 33.7% in those with C1q+/MFI ≥10000 DSA.

Conclusions: C1q-binding DSA was highly correlated with DSA strength. Nevertheless, AMR was better predicted by the presence of C1q+ DSA (higher DOR and PPV) than by using the optimal DSA MFI cut-off. Moreover, C1q+ DSA was associated with lower graft function, increased proteinuria and higher persistence of DSA at 1-year. C1q+ DSA patients had poorer graft survival than C1q- DSA ones, even within those with strong (MFI ≥10000) DSA.

323.5

ABO incompatibility might protect against chronic antibody mediated rejection caused by de novo DSA after renal transplantation

Manabu Okada[1,2], Kenta Futamura[1], Takayuki Yamamoto[1], Takahisa Hiramitsu[1], Makoto Tsujita[1], Norihiko Goto[1], Shunji Narumi[1], Yoshihiko Watarai[1], Kenta Iwasaki[2], Takaaki Kobayashi[2].
[1]Transplant and Endocrine Surgery, Japanese Red Cross Nagoya Daini Hospital, Nagoya, Japan; [2]Transplant Surgery, Aichi Medical University, Nagakute, Japan.

Introduction: There seems to be a quite difference in graft outcome between ABO-incompatible and HLA-incompatible renal transplantation (ABO-I and HLA-I), although anti-donor (anti-A/B and anti-HLA) antibodies could similarly be attached to the graft. Chronic antibody mediated rejection (AMR) which remains a major obstacle to long-term graft survival could be influenced by anti- HLA antibody, but not by anti-A/B antibodies. We have demonstrated that anti-A/B antibody binding to endothelial cells might induce "graft accommodation" (no injury even in the presence of anti-donor antibody) through up-regulation of CD55 and CD59, and down-regulation of HLA class I and II expression by in vitro experiments, unlike anti-HLA antibody. The aim of this study was to elucidate the potential benefit of ABO-incompatibility, regarding chronic AMR.
Methods: 521 living donor renal transplantation were performed at Nagoya Daini Red Cross Hospital between 2005 and 2011. Pretransplant DSA-positive recipients (n=34) were excluded. Patients (n=25) who could not be followed up from 2011 due to graft loss, death or changing hospital, were also excluded. Thus, a total of 448 (129 ABO-I and 319 ABO-Id/C) were included in this study. Annual HLA antibody screening and HLA specificity tests have detected de novo DSA, which encouraged patients to undergo indication biopsy even without renal dysfunction.
Results: 5-year graft survival rates of ABO-I, ABO-Id/C and HLA-I were 93%, 97% and 75%, respectively. Main cause of graft failure in ABO-I was death with functioning grafts such as infection, CVD and malignancy, which was considered to be related to desensitization.
Between 2011 and 2015, de novo DSA was detected in 11/129 (8.5%) of ABO-I, and in 46/319 (14.4%) of ABO-Id/C. Indication biopsy was conducted in 40 patients who had de novo DSA. Biopsy-proven CAMR were diagnosed in 18 patients. 22 patients had no CAMR pathologically. Biopsy-proven subclinical CAMR was detected in 2/8 (25%) of ABO-I, whereas it was observed in 16/32 (50%) of ABO-Id/C.
Conclusion: The possibility has been suggested that anti-A/B antibody binding might have a protective effect on chronic AMR caused by de novo DSA. Promising results might be expected in ABO-I, if the adverse effect of desensitization therapy could be minimized.

De novo donor specific antibodies in kidney transplantation - a systematic review and meta-analysis

Ankit Sharma[1,2], Joshua R.Lewis[1,2,3], Wai H.Lim[3,4], Suetonia Palmer[5], Giovanni Strippoli[1,2], Jeremy R.Chapman[6], Jonathan C.Craig[1,2], Germaine Wong[1,2].
[1]Centre for Kidney Research, Children's Hospital at Westmead, Westmead, Australia; [2]School of Public Health, The University of Sydney, Sydney, Australia; [3]School of Medicine and Pharmacology, University of Western Australia , Perth, Australia; [4]Department of Renal Medicine, Sir Charles Gairdner Hospital, Perth, Australia; [5]Department of Medicine, University of Otago, Christchurch, New Zealand; [6]Centre for Transplant and Renal Research, Westmead Hospital, Westmead, Australia.

Pre-transplant donor specific anti-human leukocyte antigen antibodies (DSA) are associated with poorer graft outcomes after kidney transplantation. De novo DSA (dnDSA) are common but the implications of these antibodies for patient-relevant outcomes are uncertain. We undertook a systematic review and meta-analysis of prospective and retrospective cohort studies of adult and paediatric kidney or adult simultaneous kidney-pancreas transplant recipients to determine the association between dnDSA and transplant and patient outcomes. We searched MEDLINE and Embase for studies published by November, 2015. Thirty-seven studies were eligible, involving 9844 transplant recipients. Associations between dnDSA and outcomes were estimated by random effects meta-analysis with univariate meta-regression used to explore sources of between-study heterogeneity. Pre-specified outcomes were graft loss (23 studies, 636/5177), any acute rejection (13 studies, 352/2103), antibody mediated rejection (14 studies, 149/2395) and death (6 studies, 64/1517). The prevalence of recipients with dnDSA was 16.3%. Transplant recipients with dnDSA experienced an increased relative risk (RR) for any acute rejection (RR 3.12; 95% CI 2.04-4.79, antibody−mediated rejection (RR 12.98; 7.09-23.76), graft loss (RR 4.17; 3.31-5.24) and death from any cause (RR 2.32, 1.00-5.37). There was moderate to substantial heterogeneity in estimates between studies (I2 41-80%). Study-level factors explaining some heterogeneity included proportion of living donors, recipient age, and diagnostic assay for dnDSA. These findings suggest the presence of dnDSA is associated with an increased risk of acute rejection, particularly antibody mediated rejection and subsequent graft loss. Therefore studies evaluating the effects of interventions to lower dnDSA with graft and patient outcomes are needed.

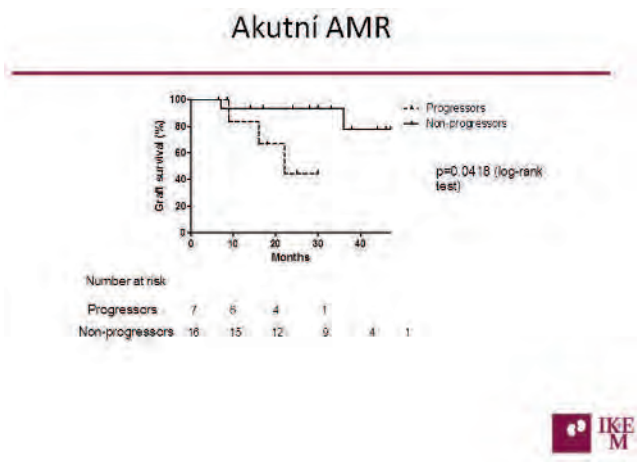
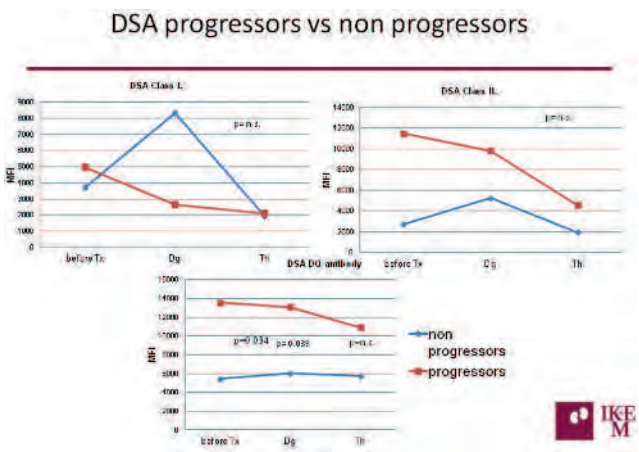
Do we know how to treat resistant antibody-mediated rejection effectively? A single centre experience

Janka Slatinska[1], Eva Honsova[2], Vladimir Hanzal[1], Petra Bohacova[3], Tomas Marada[4], Petra Hruba[5], Micheala Zelinova[1], Ondrej Viklicky[1,5].
[1]Department of Nephrology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [2]Department of Pathology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [3]Department of Immunology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [4]Department of Transplant Surgery, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [5]Transplant Laboratory, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Introduction and Aims: Acute antibody-mediated rejection (AMR) remains one of the major barriers to successful long-term outcomes. Previously reported therapeutic superiority of combination of plasmapheresis (PP) and intravenous immunoglobulin (IVIG) may however fail in some resistant cases. Thus, the aim of this work was to analyze the efficacy and safety of administration of bortezomib (B) and rituximab (RTX)-based treatment of resistant AMR.
Methods: We retrospectively analyzed documentation of 772 patients who underwent renal transplantation between 1/2012-6/2015. Novel therapeutic approach to resistant acute AMR in kidney transplant recipients was applied in 23 patients (3%) based on administration of B [1 cycle of 4 doses of B (1.3 mg/m2)], small doses of i.v. corticosteroids, PP and a dose of RTX (375mg/m2). This protocol was administrated after conventional treatment had failed. Resistant AMR was defined as a persisting deterioration or non-function of renal allograft in patients with histological verification of AMR, positive C4d staining and detection of donor specific antibodies (DSA) receiving standard antirejection treatment with PP + IVIG. Patients (pts) were followed for 6-48 months.
Results: Therapy of resistant acute AMR was administered to 23 pts after kidney transplantation with median peak PRA 52%, actual PRA 36%, mean HLA mismatch in HLA-A 1.2 ± 0.4, HLA-B 1.7 ± 0.5, HLA-DR 1.3 ± 0, with median of 5.8 years on dialysis. 3 pts underwent 1st kidney transplantation, while 20 patients retransplantation (2nd Tx n=10, 3rd Tx n=6, 4th Tx n=4). Immunosuppressive protocol consisted of induction with antithymocyte globulin (n=22) or basiliximab (n=1). Diagnosis of resistant acute AMR was made on 14.th POD.Based on therapeutic effect, 15 pts received 1, 7 pts 2 cycles and 1 patient was treated with 3 cycles of B. We observed DGF in 26.1%.Using B regimen in treating resistant acute AMR led to decrease in DSA quantity in HLA especially in class I (p=0.005), class II (p = 0.015), but not in DQ (p= 0.2). No significant improvement of renal function was observed during the follow-up.The pts with the levels of serum creatinine increased more than 25% of baseline level in 6 months after administration of protocol with B, are progressors (n=7). The progressors graft survival was 57% in 20 months. The quantity of MFI DQ antibodies was significantly higher than in pts with stable renal function (non progressors). The side-effects observed were UTI (35%), colitis (13%), polyneuropathy (26%), hepatotopathy (13%), fluid retention (22%), thrombocytopenia (78%), leucopenia (56.5%), sepsis (30.4%).
Conclusions: Traditional AMR therapeutic strategies have focused on antibody removal and B-cell depletion while not directly focusing on plasma cell depletion. Bortezomib was effective against HLA I and II class antibodies, the problem with DQ antibodies is still unsolved. Bortezomib-related toxicities were all transient.





323.8

Early acute humoral rejection in the absence of anti-HLA antibodies: clinico-pathological description from a French nation-wide study

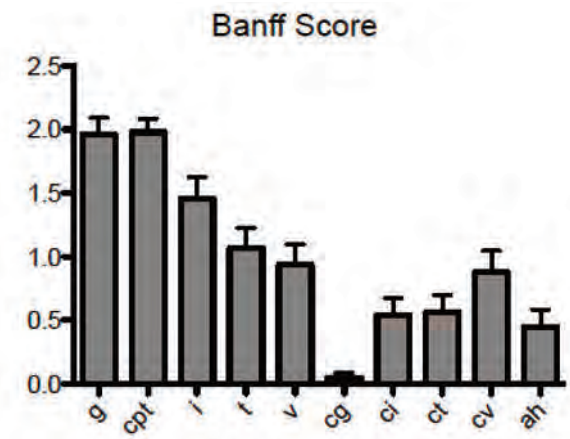
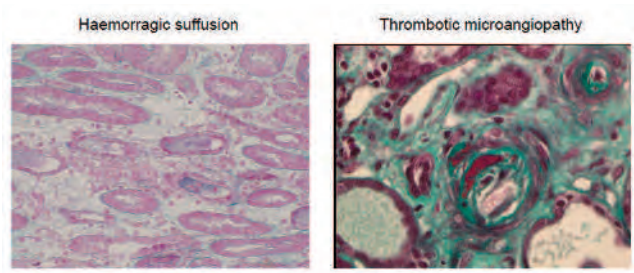
Background: Antibody mediated rejection (ABMR) is associated with poor transplant outcome. Pathogenic alloantibodies are usually directed against HLA antigens. However evidence of ABMR in the absence of anti-HLA antibodies strongly suggests the implication of non-HLA antibodies, usually identified under the generic term of anti-endothelial cell antibodies (AECA). Despite the severity of non-HLA ABMR, the available data remain elusive.
Materials and Methods: We implemented a retrospective nation-wide study to improve undertanding of non-HLA ABMR. Inclusion criteria were: first or re-transplantion, deceased or living-donor; acute allograft dysfunction during the first three months; allograft biopsy showing a total score of glomerulitis and peritubular capillaritis g+ptc≥3 according to the Banff classification; absence of identified anti-HLA DSAs using Luminex® .
Results: Demographical and clinical parameters were collected for 47 cases. Recipient age was 46±2 yrs. Male/female ratio was 3/1. Mean time of dialysis was 3.7±0.6 yrs. Donor age was 51±2 yrs. Cold ischemia time was 15.8±1.5 hrs. All patients but one received induction therapy (85% basiliximab, 13% thymoglobuline), a CNI (72% tacrolimus, 28% cyclosporine), MPA and steroids.
Rejection was diagnosed at day 15±4 in the absence of graft function recovery in 47% of patients. The remaining 25 patients defined a poor serum creatinine nadir of 228±28 µmol/L. Acute graft dysfunction (318±42 µmol/L) led to the diagnosis of acute rejection at day 25±6. No anti-HLA DSA were observed. Mean g+ptc score was 3,9 [3; 6]. In addition, intimal arteritis and interstitial inflammation (i≥1) were observed in 48% and 72% of cases, respectively.



Additional lesions included haemorragic suffusion and thrombotic microangiopathy in 21% and 23% of cases, respectively.



Therapeutic strategies included steroids pulses (89%), thymoglobulines (23%), rituximab (30%), IVIG (45%) and plasmapheresis (60%). Primary non function was observed in 2 cases and one patient was back to dialysis at 2 years. At last follow up (3±1 yrs) serum creatinine was 182±15 µmol/l.
Conclusion: This study provides a close clinico-pathological description of non-HLA ABMR. Non-HLA ABMR is a severe condition associated with graft lost. Additional histological and mechannistic analyses are upcoming. Therapeutic issue is challenging and will need further studies.

Post-transplant monitoring of donor-specific anti-HLA antibodies and their characteristics improves risk stratification of kidney allograft loss

Denis Viglietti[1], Alexandre Loupy[2], Carol Bentlejewski[3], Christophe Legendre[2], Denis Glotz[1], Adriana Zeevi[3], Carmen Lefaucheur[1].
[1]Saint-Louis Hospital, Paris, France; [2]Necker Hospital, Paris, France; [3]University of Pittsburgh Medical Center, Pittsburgh, PA, United States.

Circulating donor-specific anti-HLA antibodies (DSA) are associated with allograft failure in solid-organ transplantation. We investigated the pathogenic characteristics of DSA that may improve risk prediction of allograft loss in a population-based study.
We enrolled consecutive patients who received kidney allografts at two Paris centers between 2008 and 2011. Patients were screened for the presence of circulating DSA at the time of transplantation (day-0), at one year and two years after transplantation or during an episode of acute rejection in the first two years after transplantation. We assessed DSA characteristics, including specificity, HLA class, mean fluorescence intensity, C1q-binding capacity, and IgG subclasses at day-0 and at the time of first post-transplant detection.
Of the 858 patients included in the study 88 (10.3%) patients had day-0 DSA and 184 (21.6%) patients were identified with post-transplant DSA. When we considered all immunologic parameters at the time of transplantation, the detection of day-0 DSA was the strongest independent immunologic risk factor of allograft loss (HR=2.7, 95% CI: 1.6-4.6; p<0.001). The post-transplant independent immunologic determinants of allograft loss were the detection of C1q-binding DSA (HR=4.4, 95% CI: 2.2-8.8, p<0.001) and the detection of IgG3-positive DSA (HR=3.5, 95% CI: 1.6-7.4, p=0.001).We built a multivariate model for allograft loss at the time of transplantation integrating donor age, donor type, cold ischemia time and day-0 DSA. This baseline model showed a moderate discrimination capacity (C-statistic of 0.66). The addition of post-transplant DSA increased significantly the performance of the baseline model (C-statistic of 0.71). The detection of C1q-binding DSA and IgG3-positive DSA further improved the risk prediction of allograft loss: C-statistic, 0.75 (1000 bootstrap mean difference: 0.029, 95% CI: 0.028-0.030) and 0.74 (1000 bootstrap mean difference: 0.022, 95% CI: 0.021-0.023), respectively, and integrated discrimination improvement, 0.07 (p<0.001) and 0.06 (p<0.001), respectively.
Post-transplant serial monitoring of DSA improves risk stratification of kidney allograft loss. The characterization of DSA by complement-binding capacity and IgG3 subclass further improves the performance to predict allograft loss beyond their simple detection.

323.10

Complement-binding donor-specific anti-HLA antibodies are associated with severe kidney allograft arteriosclerosis

Alexandre Loupy[1], Denis Viglietti[2], Jean-Paul Duong Van Huyen[1], Denis Glotz[2], Christophe Legendre[1], Adriana Zeevi[3], Carmen Lefaucheur[2].
[1]Necker Hospital, Paris, France; [2]Saint-Louis Hospital, Paris, France; [3]University of Pittsburgh Medical Center, Pittsburgh, PA, United States.

The role of circulating donor-specific anti-HLA antibodies (DSA) in the development of accelerated arteriosclerosis have been recently reported in kidney transplant recipients. This study investigated the characteristics of DSA that are associated with the severity of allograft arteriosclerosis.
We enrolled 744 consecutive kidney transplantation performed between January 1, 2004 and January 1, 2010 at Necker Hospital (Paris, France), with systematic assessment of injury phenotype and arteriosclerotic lesions using the vascular fibrous intimal thickening (cv) Banff score on allograft biopsies performed at one year after transplantation. We assessed circulating DSA and their characteristics (specificity, HLA class, mean fluorescence intensity [MFI] and C1q-binding) at six months after transplantation.
We identified 281 patients with cv0 score, 213 patients with cv1 score, 189 patients with cv2 score and 61 patients with cv3 score. The distribution of DSA according to cv score was the following: 47/281 (17%) in cv0 patients, 39/213 (18%) in cv1 patients, 63/189 (33%) in cv2 patients and 28/61 (46%) in cv3 patients. Immunodominant DSA (iDSA) MFI level was positively correlated with the severity of arteriosclerosis (Spearman's rho=0.23, p=0.002), with a mean MFI of 3204.0±3725.2 in cv0 patients, 3760±3598 in cv1 patients, 4892±4676 in cv2 patients and 5541±3892 in cv3 patients. C1q-binding DSA prevalence increased with the severity of allograft arteriosclerosis: 8/281 (3%) in cv0 patients, 6/213 (3%) in cv1 patients, 25/189 (13%) in cv2 patients and 9/61 (15%) in cv3 patients (p<0.001). Patients with C1q-binding iDSA had a higher cv score compared with patients with non-C1q-binding DSA (1.7±1.0 versus 1.3±1.1, respectively, p=0.01). The C1q-binding capacity of DSA was associated with increased microvascular inflammation (p<0.001) and C4d deposition in peritubular capillaries or arteries (p<0.001).
This study shows a biological gradient between DSA MFI level and the severity of allograft arteriosclerosis. The complement-binding capacity of DSA is associated with an increased severity of arteriosclerosis and complement deposition in allograft.

323.11

The natural history of donor specific antibodies in kidney transplant recipients and associated clinical outcomes

Susan Wan[1,2], Kate Wyburn[1,2], Jian Lin Yin[1,2], Narelle Watson[3], John Saunders[1], Josette Eris[1,2].
[1]Department of Renal Medicine, Royal Prince Alfred Hospital, Sydney, Australia; [2]Sydney Medical School, University of Sydney, Sydney, Australia; [3]NSW Transplantation and Immunogenetics Laboratory, Clinical Services and Research Division, Australian Red Cross Blood Service, Sydney, Australia.

Introduction: Kidney transplantation is the treatment of choice for end stage kidney disease. While there have been significant advances in early post-transplant graft survival, there has been little change in long-term outcomes. The causes of graft loss are multifactorial, and the previously under-recognised role of donor specific antibody (DSA) is now considered to contribute significantly. DSA have been implicated in the development of rejection and graft dysfunction. However, the natural history of DSA remains poorly characterized.
Aim: To characterize the development of DSA and the associations with clinical outcomes in kidney transplant recipients (KTx).
Materials and Methods: Serum samples from adult KTx performed at a single unit between July 2010 and May 2015 were prospectively collected pre-transplant and at Days 7, 28 and Months 3, 6, 9, 12 post-transplant and tested for Class I and II DSA and C1q binding on a luminex platform. Clinical outcomes including acute rejection (AR) and graft function were recorded and all episodes of AR were biopsy proven.
Results: 166 recipients had pre- and post-transplant DSA testing. Mean follow-up was 35 ± 17 months. Ninety-two (55%) patients had DSA; 62 (37%) had pre-existing DSA only, 14 (8%) had denovo (dn)DSA only, and 16 (10%) had pre-existing and dnDSA. Of patients with dnDSA; 9 (30%) had Class I antibodies only, 16 (53%) had Class II antibodies only and 5 (17%) had Class I & II antibodies. In 3 patients (11%) the dnDSA was C1q-binding. Twenty-five (32%) patients with pre-existing DSA and 17 (57%) patients with dnDSA had AR. Patients with dnDSA vs those without were more likely to develop AR (OR 3.63; 95%CI 1.61-8.22; P=0.002), however there was no increased risk in patients with pre-existing DSA only (OR 0.71; 95%CI 0.36-1.42; P=0.337). Median time to rejection was 1.9 months (IQR 0.2-4.9). Mean creatinine at 3, 6 and 12 months post-transplant was higher in patients with dnDSA compared to those without dnDSA (Mean 12-month creatinine: 172 ± 67 vs 128 ± 38 μmol/L; t62=-3.22; P=0.002).
Conclusion: While there was no association between the presence of pre-existing DSA and rejection, the development of dnDSA, which occurred in 18% of patients, was associated with a higher risk of AR and worse graft function. Monitoring the emergence of dnDSA may assist with determining and mitigating the risk of rejection.

323.12

Non-validation of pre-transplant sensitization against angiotensin II type1 receptor as risk factor of graft and patients outcomes in kidney transplantation

Clément Deltombe[1], Florence Florence[2,3], Dany Anglicheau[3,4,6], Emmanuel Morelon[4,7], Katy Trébern-Launay[1,4], Florent Le Borgne[2], Marie Rimbert[8], Pierrick Guérif[1], Stéphanie Malard-Castagnet[3,5], Yohann Foucher[2], Magali Giral[1,2,3,4].
[1]Institute for Transplantation, Urology and Nephrology (ITUN), Nantes University Hospital, Nantes, France; [2]SPHERE-EA4275, Nantes University, Nantes, France; [3]LabEx Transplantex, Founds, Nantes, France; [4]Thematic Research and Care Network RTRS, Centaure, Nantes, France; [5]HLA Laboratory, Etablissement Français du Sang, Nantes, France; [6]Department of Kidney Transplantation, Necker University Hospital, AP-HP, Paris, France; [7]Department of Transplantation and Clinical Immunology, Hospices Civils de Lyon, Hopital Edouard Herriot, Lyon, France; [8]CIMNA platform, Nantes University Hospital, Nantes, France.

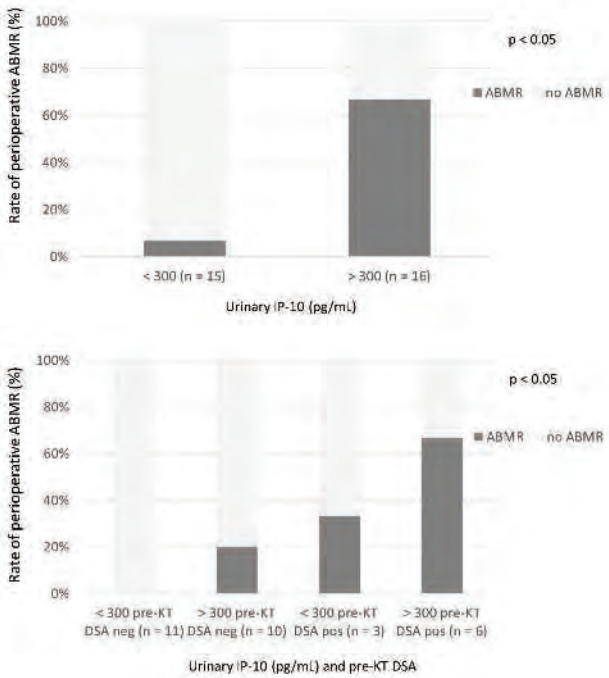
Context: Several studies have suggested that anti-angiotensin II type 1 receptor antibodies before transplantation constitute a risk factor of acute rejection episode and graft failure. We aimed to propose an external validation of such an etiologic role.
Methods: We studied 940 kidney transplant recipients from 3 French centers of the DIVAT cohort. Multivariable Cox models were performed to estimate the association between pre-transplant anti-angiotensin II type 1 receptor antibodies and time to acute rejection episode or time to graft failure.
Results: There were 387 patients (41.2%) with a pre-transplant anti-angiotensin II type 1 receptor antibodies higher than 10U/mL, i.e. the level above which we previously reported higher risks of acute episode rejection and graft failure. However, the results of the present study indicated that a pre-transplant anti-angiotensin II type 1 receptor antibodies higher than 10U/mL was not significantly associated with higher risks of acute rejection episode (HR=1.04, 95%CI from 0.80 to 1.35), nor with risk of return to dialysis (HR=0.86, 95%CI from 0.56 to 1.33).
Conclusion: Our study did not confirm the association between the pre-transplant anti-angiotensin II type 1 receptor antibodies and the kidney transplant outcomes.

323.13

Urine IP-10 as the biomarker for ABMR in Kidney transplant recipient with DGF

Natavudh Townamchai[1], Asada Leelahavanichkul[2], Jade Supapol[3], Yingyos Avihingsanon[1], Kearkiat Praditpornsilpa[1].
[1]Department of Medicine, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand; [2]Department of Microbiology, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand; [3]Department of Surgery, Chulalongkorn University and King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, Thailand.

Background: In the setting of DGF in kidney transplantation (KT), early acute ABMR, which needs early treatment, has to be differentiated from simple ischemic acute tubular necrosis (ATN). Concerning the higher risk of bleeding complication during this period, the clinician is reluctant to perform kidney biopsy. The biomarkers are needed for acute ABMR prediction during this vulnerable period.
Methods: There were 115 incident recipients during September 2012 to December 2014, which all of them were negative for CDC-AHG crossmatch. The total number of recipients with DGF were enrolled (n=31). None of them underwent desensitization prior transplantation. The urine IP-10 (also called CXCL-10) at day 7 were measured by ELISA method in all DGF recipients. The allograft biopsy was performed at day 7 for detection of ABMR. Recipients were stratified in to four groups according to pre-KT DSA status and urine IP-10 level.
Results: None of our patients was anuria at day 7 after transplantation. Seven of 31 DGF recipients had ABMR (22.6%). The median urine IP-10 level of 31 recipients was 326.6 pg/mL (range from 0 to 6999 pg/mL). Based on ROC analysis, the most optimal cut point for low vs high IP-10 level was at 300 pg/mL with 85.7% sensitivity and 58.3% specificity. The recipients with high IP-10 level had higher rate of ABMR compared to low IP-10 recipients, 37.5% vs 6.7%, p<0.05 (figure 1).



The rates of ABMR among negative pre-KT DSA/low IP-10, negative DSA/high IP-10, positive DSA/low IP-10, and positive DSA / high IP-10 recipients were 0, 20.0, 33.5 and 66.7%, respectively (p<0.05, figure1).

Conclusions: In DGF, the perioperative ABMR can be predicted by urine IP-10 at day 7. Together with pre-KT DSA, urine IP-10 provides additional predictive value for ABMR prediction.

Combined en-bloc heart-liver transplantation for patients with congenital heart disease complicated by cirrhosis

C. Andrew Bonham[1], Jackie Lee[1], Thomas Pham[1], Waldo Concepcion[1], Sarah Conlon[1], Katsuhide Maeda[1], Seth Hollander[2], Carlos Esquivel[1].
[1]Surgery, Stanford University Medical School, Palo Alto, CA, United States; [2]Pediatrics, Stanford University Medical School, Palo Alto, CA, United States.

There are over 1 million adolescent and young adults with congenital heart disease (CHD), with estimates the number will increase by 5% per year. Hepatic complications correlate with elevated hepatic venous pressures and low cardiac index, and are related to duration of follow-up, with odds ratios of 4.4 and 9 at 11-15 and 16-20 years post-Fontan[1]. Hepatic complications including variceal bleeding, protein losing enteropathy, hepatopulmonary syndrome, ascites, hepatic encephalopathy and hepatocellular carcinoma contribute to significant morbidity and mortality. Cardiac transplantation for congestive heart failure in the setting of cirrhosis carries a high risk of liver failure. Combined heart-liver transplantation (CHLT) corrects both defects. Guidelines as to which patients would benefit from this procedure remain poorly defined. Historically, the most common indication for CHLT was amyloidosis. CHD patients with cirrhosis are considerably more challenging, with multiple sternotomies, portal hypertension and coagulopathy. We report our experience of CHLT using a novel en-bloc technique with excellent results.
Ten patients received CHLT between August 2006 and May 2015. Indications for CHLT included end stage heart disease complicated by cirrhosis identified on imaging or biopsy with evidence of portal hypertension (varices, splenomegaly, ascites). Seven patients had CHD, with failed Fontan the most common diagnosis. All patients had complications secondary to cirrhosis. Two patients were sensitized. Prospective crossmatch at time of organ offer was negative in all patients. Immunosuppression included anti-thymocyte globulin induction, tacrolimus, mycophenolate, and steroids.
There were no deaths, with mean follow up of 53.3 months. Over 100 endomyocardial biopsies were performed after transplant, with no evidence of rejection in any patient. The en bloc procedure shortens ischemic time and provides excellent results in these challenging patients. Inclusion of the liver appears to be immunoprotective for the heart.

Effects of acute and chronic amiodarone use in patients before heart transplantation on post-transplant outcomes

Rasmus Rivinius[1], Matthias Helmschrott[1], Arjang Ruhparwar[2], Bastian Schmack[2], Christian Erbel[1], Christian A.Gleissner[1], Mohammadreza Akhavanpoor[1], Lutz Frankenstein[1], Fabrice F.Darche[1], Patrick A.Schweizer[1], Dierk Thomas[1], Philipp Ehlermann[1], Tom Bruckner[3], Hugo A.Katus[1], Andreas O.Doesch[1].
[1]Department of Cardiology, Angiology and Pneumology, Heidelberg University Hospital, Heidelberg, Germany; [2]Department of Cardiac Surgery, Heidelberg University Hospital, Heidelberg, Germany; [3]Institute for Medical Biometry and Informatics, University of Heidelberg, Heidelberg, Germany.

Introduction: Major concerns about the safety of pre-transplant amiodarone use in patients with end-stage heart failure have been recently raised. Due to its long half-life, the newly transplanted heart is exposed to amiodarone posing potential risks such as increased mortality after heart transplantation (HTX). The aim of this study was to compare the effects of acute and chronic amiodarone use in patients before HTX on post-transplant outcomes.
Methods: This retrospective single-center study included 530 adult patients who received HTX between 06/1989 and 12/2012. Patients were stratified by their amiodarone therapy before HTX: No continuous amiodarone use (≤ 90 days before HTX), acute continuous amiodarone use (≤ 90 days before HTX), and chronic continuous amiodarone use (> 90 days before HTX). Analysis comprised recipient data, donor data, principal diagnosis for HTX, transplant sex mismatch, perioperative data, and initial post-transplant medication. The occurrence of early post-transplant atrial fibrillation (AF) ≤ 30 days after HTX and mortality after HTX were chosen as primary outcomes. Kaplan–Meier estimator using log-rank tests was applied for freedom from early post-transplant AF and survival after HTX.
Results: 412 patients (77.7%) were appointed to the "no use of amiodarone before HTX" group, 23 patients (4.4%) to the "acute use of amiodarone before HTX" group, and 95 patients (17.9%) to the "chronic use of amiodarone before HTX" group.
Indications for acute amiodarone use were AF in 1 patient (4.3%), ventricular tachycardia in 20 patients (87.0%), and ventricular fibrillation in 2 patients (8.7%). Indications for chronic amiodarone use included AF in 13 patients (13.7%), Wolff–Parkinson–White syndrome in 1 patient (1.1%), ventricular tachycardia in 73 patients (76.8%), and ventricular fibrillation in 8 patients (8.4%).
We found no statistically significant difference between the three groups in 30-day (P = 0.8656), 1-year (P = 1.0000), 2-year (P = 0.8763), 5-year (P = 0.5174), or overall follow-up mortality after HTX (P = 0.1936). Moreover, Kaplan–Meier survival analysis showed no statistically significant difference in 30-day (P = 0.8610) or overall survival (P = 0.2924).
Patients with chronic amiodarone use before HTX had the lowest rate of early post-transplant AF (no amiodarone before HTX [13.6%], acute use of amiodarone before HTX [13.0%], and chronic use of amiodarone before HTX [2.1%], P = 0.0065). Additionally, this group had a significantly lower rate of AF in the Kaplan–Meier analysis of freedom from early post-transplant (P = 0.0081).
Conclusion: In contrast to former publications, we found the administration of acute or chronic amiodarone in patients with end-stage heart failure and arrhythmias before heart transplantation not to be associated with an increased mortality after HTX. Importantly, chronic amiodarone use reduces the occurrence of early post-transplant AF whereas acute amiodarone therapy shows no such effect.

324.3

Terlipressin increases blood pressure and facilitates weaning from cardiopulmonary bypass in heart transplant recipients with refractory hypotension

Nukhet Akovali[1], Aynur Camkiran Firat[1], Duygu Taskin[1], Pinar Zeyneloglu[1], Bahadir Gultekin[2], Atilla Sezgin[2], Arash Pirat[1].
[1]Anesthesiology, Baskent University Hospital, Ankara, Turkey; [2]Cardivascular Surgery, Baskent University Hospital, Ankara, Turkey.

Introduction: Refractory hypotension may occur during the weaning period from cardiopulmonary bypass (CPB) in orthotopic heart transplantation (OHT) and can be multifactorial. Vasopressin plays major role in circulatory homeostasis, but vasopressin is currently not available in our country. So, we usually use terlipressin that is a synthetic analog of vasopressin and a prodrug.
Materials and Methods: We retrospectively collected data from the records of consecutive heart transplantations from June 2013 to December 2015. Eighteen patients underwent orthotopic heart transplantation (OHT) for end-stage heart disease at our institution and five patients were used terlipressin. All of them were retrospectively evaluated from anesthetic and surgical charts. Patients' characteristics potential to have impact on anesthestic management as well as postoperative outcome were recorded. Anesthesic technique included induction with midazolam and fentanyl followed by maintenance with desflurane, air/O2 and fentanyl infusion. Beside standard invasive monitoring, pulse contour cardiac output measurement device was used and pulmonary artery monitorization was performed in all of the patients.
Predefined strict hemodynamic criteria were used to assess the success of weaning at our instutions. If weaning was not successful, CPB was reinstituted and terlipressin bolus (0.01-0.02 mg/kg) was used. If the second weaning attempt failed, terlipressin infusion (3 mg/24 hours) was started. The data collected for each case were demographic features, duration of mechanical ventilation, early (<30 days) and late postoperative mortality.
Results: Of the 5 patients considered, one patient was younger than 16 years. Average age was 27.6±18.6 years and average body weight was 54.3±25.5 kg. The cross clamp time was 128.4±14.4 minutes, cardiopulmonary bypass time was 237±66.8 minutes, and total ischemia time was 240.0±44.3 minutes. Ultrafiltration was performed in 4 patients with an average amount of 1037±415 mL. Postoperative length of mechanical ventilation was 44.6±53.9 hours, lactate levels at the end of surgery was 8.9±4.0 mmol/L, 2 (40%) patients required renal replacement therapy and 1 (%20) patient had revisions due to bleeding. In-hospital mortality rate after the OHT was 20% (one patient), and there were no operative mortality.
Discussion: In this report we describe five patients undergoing OHT. Despite inotropic therapy (dopamine, dobutamine and adrenaline) the hemodynamic situation deteriorated, necessitating the administration terlipressin.
Conclusion: The case series have demonstrated an important beneficial effect of terlipressin when the weaning from CPB attempt failed, especially as a rescue treatment in patients with long total ischemia time or impaired donor left ventricular function undergoing heart transplantation. It may be beneficial for its postoperative hemodynamic profile, may reduce the doses of requirements of catecholamines and contribute to prevention of the postcardiotomy vasoplegic shock.

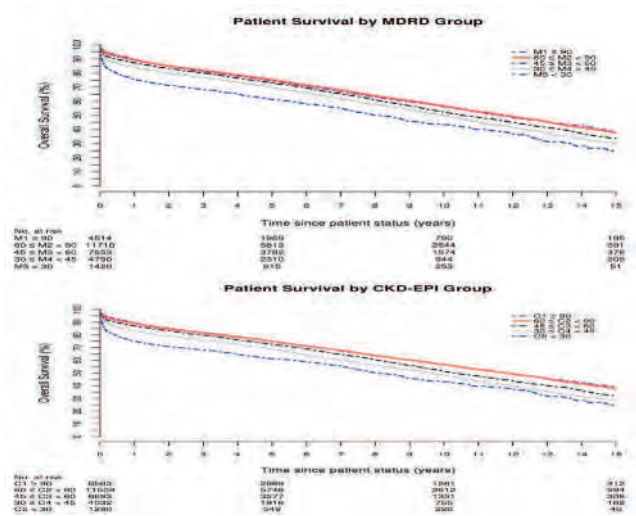
Pre-orthotopic heart transplant (OHT) estimated glomerular filtration rate (eGFR) predicts post-OHT mortality and renal outcomes

Hani M. Wadei[1], David Hodges[2], Parag C.Patel[1], Philip J.Habib[1].
[1]Transplant, Mayo Clinic, Jacksonville, FL, United States; [2]Health Sciences Research, Mayo Clinic, Jacksonville, FL, United States.

Background: There are limited information on the relationship between pre-OHT estimated glomerular filtration rate (eGFR) and adjusted short and long term survival and renal outcomes post-OHT.
Methods: Using the United Network of Organ Sharing (UNOS) database we estimated pre-OHT eGFR using the Modification of Diet in Renal Disease (MDRD) and the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations in patients aged ≥18 years who received OHT between 1988 and 2013 in the US. Cox proportional hazards models were used to investigate the relationship between eGFR and post-OHT mortality. The following variables were adjusted for: age, sex, ethnicity, BMI, cold ischemia time, diabetes, inotrope use, era of transplant, listing status and ventricular assist device (VAD).The primary outcome was to determine if pre-OHT eGFR independently predicted post-OHT mortality.
Results: 30,090 patients were included, of these 46.1% and 39.9% had an eGFR <60 mL/min/1.73 m2 by MDRD and CKD-EPI, respectively. The 1, 3, 5 and 10-year patient mortality was progressively lower with each drop in GFR category using either equation.



Compared with eGFR ≥90 mL/min/1.73 m2, the adjusted hazard ratio of mortality was 1.09 (95% CI: 1.02-1.26) for eGFR 45-59 mL/min/1.73 m2, 1.22 (95% CI-1.23-1.31) for eGFR 30-44 mL/min/1.73 m2 and 1.55 (95% CI 1.41-1.70) for eGFR <30 mL/min/1.73 m2 by MDRD. Using CKD-EPI, 4,955 (16.5%) patients were reclassified upward, 40 (0.1%) downward and the remaining 25,092 (83.4%) remained in agreement with the MDRD category.There was no advantage of CKD-EPI over MDRD in determining post-OHT mortality. Pre-OHT eGFR by either equation was predictive of post-OHT end stage renal disease (ESRD) and the need for kidney transplantation with the highest risk in those with pre-OHT eGFR <30 mL/min/1.73 m2 by either equation.
Conclusions: Pre-OHT eGFR was independently associated with mortality, ESRD and kidney transplantation following OHT. There was no advantage of CKD-EPI over MDRD in determining post-OHT mortality or renal outcomes.
Grant support for biostatistics was awarded through the Mayo Clinic

Relationship between brachial artery flow-mediated dilation and clinical characteristics in heart transplant recipients

Takuya Watanabe[1,2], Norihide Fukushima[1], Yoshihiro Miyamoto[2], Osamu Seguchi[1], Masanobu Yanase[1], Tomoyuki Fujita[1,3], Kunihiro Nishimura[2], Takuma Sato[1], Haruki Sunami[1], Seiko Nakajima[1], Eriko Hisamatsu[1], Kensuke Kuroda[1], Norihiro Okada[1], Hiroki Hata[1,3], Junjiro Kobayashi[3], Takeshi Nakatani[1].
[1]Transplantation, National Cerebral and Cardiovascular Center, Osaka, Japan; [2]Preventive Cardiology, National Cerebral and Cardiovascular Center, Osaka, Japan; [3]Cardiovascular Surgery, National Cerebral and Cardiovascular Center, Osaka, Japan.

Introduction: Peripheral endothelial (PE) dysfunction assessed by brachial artery flow-mediated dilation (BA-FMD) has a potential prognostic value in patients with various cardiovascular diseases. However, clinical implication of BA-FMD in heart transplant (HTx) recipients remains unclear and associated factors with them are not fully elucidated.
We sought to clarify the relationship between BA-FMD and clinical characteristics in HTx recipients.
Materials and Methods: We measured BA-FMD in HTx recipients who survived at least 1 year post-HTx. Forty-three HTx recipients underwent BA-FMD measurement at a mean 5.3 years after HTx. BA-FMD was first treated as a continuous variable. Subsequently, BA-FMD value was treated categorical variables by defining the first quartile value as the cut-off point in PE dysfunction. A cut-off point of 5.2% in BA-FMD was chosen.
Results: The indication for HTx was non-ischemic heart disease in 41 recipients (95.3%). Mean BA-FMD was 8.0±3.4% (range 2.1-14.4%). PE dysfunction was observed in 11 recipients (25.6%). Recipients with past smoking history exhibited lower BA-FMD (6.0±2.6% vs 9.0±3.3%, p=0.005) and higher prevalence of PE dysfunction (50.0% vs 13.8%, p=0.011) compared with never smokers. Follow-up duration from HTx to BA-FMD measurement was negatively associated with prevalence of PE dysfunction in logistic regression analysis with adjustment of recipient sex and age (Odds ratio [OR]=0.75, 95% confidence interval [CI]=0.56-0.99, p=0.043). Ten recipients who survived more than 10 years post-HTx did not exhibit a PE dysfunction. In multivariable logistic model including recipient sex, age, smoking history, follow-up duration from HTx, previous hypertension, diabetes mellitus and hyperlipidemia, smoking history was independently associated with the high prevalence of PE dysfunction (OR=9.33, 95%CI=1.31-66.48, p=0.026).
Discussions: BA-FMD in our recipients may be higher than that in previous studies, which suggests the association of atherosclerotic conditions prior to HTx with BA-FMD value after HTx, because majority of our recipients were diagnosed with non-ischemic cardiomyopathy. Regarding the association between PE function and follow-up duration from HTx, the present study may add a concept that BA-FMD may be improved even after 1 year post-HTx as time passed after HTx. Since presence of ischemic heart disease prior to HTx and smoking history have been reported to be associated with poor prognosis after HTx, this independent association between impaired BA-FMD and these factors may confirm the potential relationship between PE dysfunction and clinical prognosis in HTx recipients.
Conclusion: These results suggest that BA-FMD in maintenance periods of HTx was associated with potential risk factors for poor outcome in HTx recipients, therefore, BA-FMD measurement after HTx may be useful for predicting clinical outcome in HTx recipients.

324.6

Effects of exercise training on cardiac reserve and autonomic activity in post heart transplant patients and patients receiving left ventricular assist devices support by assessment of heart rate profile

Katherine Fan[1], Jenny Ng[3], Cyril Ko[1], Kandra Chan[1], Kathy Cheng[1], Cally Ho[2], Timmy Au[2].
[1]Cardiac Medical Unit, Grantham Hospital, Aberdeen, Hong Kong; [2]Department of Cardiothoracic Surgery, Queen Mary Hospital, Pok Fu Lam, Hong Kong; [3]Physiotherapy Department, Grantham Hospital, Aberdeen, Hong Kong.

Purpose: Despite improved survival after heart transplant (HT) and left ventricular assist devices (LVAD) implantation, some patients (pts) continue to experience exercise intolerance and functional limitations which might have been due to extended hospital stay and significant frailty. Chronotropic incompetance and abnormal heart rate recovery (HRR) immediately after exercise reflecting profound abnormalities of autonomic nervous system control during exercise have been reported in pts with chronic heart failure. These abnormalities are valid prognostic markers and strongly associated with increased mortality. We studied the effects of exercise training in pats with LVAD and post HT by assessing the heart rate profile [peak heart rate, chronotropic reserve (CR) and heart rate recovery (HRR)]**.**
Methods: A total of 42 pts: 26 pts with HT (58% men; mean age 49 yrs) and 16 pts with LVAD (81% men; mean age 50 yrs) underwent a 12 weeks' supervised exercise program starting 3 months after surgery. Symptom-limited cardiopulmonary exercise test were performed at baseline and at 3 months during the end of the program. Chronotropic response to exercise was evaluated by the percentage of CR= (peak HR – resting HR/220− age− resting HR) x 100%]. HRR was calculated as the difference between peak HR and HR 1 minute later (HRR1, bpm) during recovery.
Results: The results are shown in Table 1. Exercise training resulted in significant improvement in exercise capacity in both groups of pts at the end of program (METS and CR). There were significantly improved HRR1 in LVAD pts. but remained unchanged in post HT group however.
Heart rate profile at baseline and 3 months post training:

	Heart Transplant group			LVAD group		
	Baseline	3 months	P value	Baseline	3 months	P value
METS level	5.3± 1.5	8.0±2.3	0.0001	2.1±0.4	3.7±1.3	0.00013
Resting HR (bpm)	92.3±4.7	97.6±13.6	0.03	86±11.4	83±16	0.5
Peak HR (bpm)	114.3±16.7	126.3±16.8	0.0003	102.3±12.8	107.8±20	0.2
HRR1	2.5±4	2.6±4.6	0.9	6.3±6.7	10.1±8	0.0015
CR (%)	40±18	57.7±23	0.00015	26.7±8.5	40±22	0.03

Conclusions: Despite different pathophysiologic processes from different treatment strategies for end-stage heart failure in HT and LVAD pts, exercise capacity and CR were improved in both groups, suggesting an accentuated improvement in fitness due to the intervention. Exercise training also improved autonomic activities with in LVAD pts but not post HT pts, consistent with physiology of denervated heart.
Heart rate profile can potentially represent a simple, non-invasive tool to assess outcomes and possibility of becoming a therapeutic target during cardiac exercise rehabilitation.

324.7

Physical function and self-reported health status in pre-transplant patients with left ventricular assisted device - local experience of out-patient cardiac rehabilitation program in Hong Kong

Jenny Ng[1], Katherine Fan[2], Jacky Li[1], Karanda Chan[2], Ka Yan Cheng[2], Mun Yee Cheung[2], Derek Chan[1], Siu Lai Lam[3], Rita Li[3], Cally Ho[3], Timmy Au[3].
[1]Physiotherapy Department, Grantham Hospital, Aberdeen, Hong Kong; [2]Cardiac Medical Unit , Grantham Hospital, Aberdeen, Hong Kong; [3]Cardiothoracic Surgical Department , Queen Mary Hospital, Pokfulam, Hong Kong.

Introduction: Left ventricular assisted device (LVAD) has been accepted as durable mechanical circulatory support for patient with advanced systolic heart failure (HF) as bridge-to-transplant in Hong Kong. Many remained frail and severely deconditioned even after LVAD implantation while waiting for heart transplantation. Cardiac rehabilitation (CR) and exercise training has been shown to be safe and has an impact on physical capacity and quality of life.
Objective: To evaluate the effects of exercise training on physical function and quality-of-life in patients with advanced HF after LVAD implantation while waiting for heart transplantation in an out-patient CR program in Hong Kong.
Method: A total of 16 patients (13 men, 81%, mean age 50±11, BMI 25±5) joined the program at mean 4.7 months after LVAD implantation (15 HeartMate II & 1 HeartWare) and completed a 12 months' program of CR. Progressive low intensity aerobic treadmill walking exercise and light resistance training for the large muscle groups of lower limbs (<7 lb.) were chosen as predominant exercise. Exercise intensity is titrated to rating of perceived exertion (RPE 0-10) ≤3 and to an asymptomatic level. Data of Six-Minute Walk Test (6MWT), Hand Grips (HG) strength, and Short-Form 36 (SF-36) were obtained and compared with baseline, 6 months and 12 months (end of CR program). Changes from baseline to follow-up were analyzed with a paired t-test.
Results and Discussion: The functional class improved significantly in NYHA. Mean exercise training session was 17±8 visits per patient. Treadmill time and intensity improved significantly from mean duration 13±5 mins to mean 20±5 mins ($p<0.001$) and from mean 2±0.4 METs to mean 3.7±1.3 METs ($p<0.001$) at the end of program. There were statistically significant improvements in both 6MWT and HG strength. Physical domains of SF-36 showed significant improvement in both Physical Functioning and Role-Physical (role limitation due to physical problems). Social Functioning domain showed insignificant improvement at mid-term but gradually increased significantly at the end of the program. However, Mental Health domain decreased significantly at end of CR (See Table 1). There was no adverse event in >250 training sessions. Three of them were successfully bridged to heart transplantation.
Conclusion: Indicators of physical function and self-reported health status improved after patients with LVAD who attended CR. Cultural difference may affect LVAD patients' own perception of well being. There is a need for continuous psychological and emotional support in LVAD patients waiting for their heart transplant surgery, therefore a comprehensive CR is recommended. Whether such improvements translate into improved clinical outcomes remain to be determined.

Is perfect long-term result of continuous-flow LVAD for bridge to transplantation possible?

Minoru Ono[1], Kan Nawata[1], Haruo Yamauchi[1], Osamu Kinoshita[1], Mitsutoshi Kimura[1], Daisuke Nitta[2], Teruhiko Imamura[2], Eisuke Amiya[2], Masaru Hatano[2].
[1]Department of Cardiac Surgery, The University of Tokyo, Tokyo, Japan; [2]Department of Cardiovascular Medicine, The University of Tokyo, Tokyo, Japan.

Introduction: There are many recent reports stating improved long-term results of continuous-flow LVAD for bridge to transplantation (BTT) and destination therapy. However, significant adverse events were not infrequent, some of which may lead to death even in the era of improved device mechanism and patient management. We analyzed LVAD implants for BTT indication at our institute, and compared long-term results between early and recent cases.
Material and Methods: Since November 2007, 100 continuous-flow LVAD implantations for BTT indication were performed. There were 26 females with an average age of 39.5 years (11 – 64). Primary heart diseases were non-ischemic dilated cardiomyopathy in 71, ischemic cardiomyopathy in 9, dilated-phase hypertrophic cardiomyopathy in 8 and others in 12. We examined outcomes after LVAD implantation focusing on survival and transplant (Tx) eligibility, and compared long-term results between early implant group (n = 46: November 2007 to September 2013) and recent implant group (n = 54: October 2013 to the present time).
Results: Five devices were used such as 34 HeartMate II, 24 EVAHEART, 22 Jarvik 2000, 19 DuraHeart and 1 HVAD. Average support duration is 555 days (9 – 1405). Twenty-eight patients underwent heart Tx after 833-day support, 3 were weaned from LVAD due to functional recovery after 260-day support, 5 experienced device change without 1 death due to device infection after 728-day support, 7 died after 302-day support and 57 in ongoing support. All Tx patients were alive but 1 who died from pneumonia 25 months after Tx. There was no patient who is ineligible for heart Tx among those of ongoing support at the time of evaluation. Actuarial survivals of patients in early and recent implant groups were 89.1%, 87.0% and 81.9% at 1, 2 and 3 years, respectively, and 100% and 100% at 1 and 2 years, respectively ($p < 0.03$ by log-rank test).
Discussion: Long-term results of LVAD implantation for BTT indication in recent years were satisfactory in many centers and perfect in our institute. We have revised and refined implant techniques and patient management aiming at prevention of surgical bleeding and less transfusion, migration of pump and cannulae and prevention of driveline infection. These refined strategies seemed to have a strong and favorable impact on recent improvement of long-term results.
Conclusions: Long-term results of continuous-flow LVAD for BTT indication greatly progressed thanks to refined implant techniques and patient management. This management strategies may have positive impact on better heart Tx results.

Medical utilization and costs of herpes zoster hospitalizations following heart transplantation in Taiwan

Kwai-Fong Lee[1,2], Yi-Chang Lin[3], Yi-Ting Tsai[3], Chih-Yuan Lin [3], Chung-Yi Lee[3], Hung-Yen Ke [3], Feng-Yen Lin[7], Wei-Hwa Lee[4,5], Chien-Sung Tsai[2,3,6].
[1]Biobank Management Center, Tri-Service General Hospital, Taipei, Taiwan; [2]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan; [3]Division of Cardiovascular Surgery, Tri-Service General Hospital, Taipei, Taiwan; [4]Pathology, Taipei Medical University Shuang Ho Hospital, Taipei, Taiwan; [5]Graduate Institute of Injury Prevention and Control, Taipei Medical University, Taipei, Taiwan; [6]Division of Cardiovascular Surgery, Taoyuan Armed Forces General Hospital, Taoyuan, Taiwan; [7]Internal Medicine, Taipei Medical University, Taipei, Taiwan.

Background: Herpes zoster is a significant complication in solid organ transplant recipients. The data of incidence, medical utilization and costs of herpes zoster hospitalizations following heart transplantation in Taiwan is limited.
Methods: Heart transplantation patients with more than 90-day follow up between 2001 and 2012 were identified by Taiwan National Health Insurance research database. We used Student's t test to exam the difference and Kaplan Meier method to calculate the probability of developing herpes zoster hospitalizations following heart transplant.
Results: After exclusion of prior heart transplant and follow up less than 90 days, a total of 702 heart recipients were included with a median follow up of 42 months. 38 patients (5.4%) developed herpes zoster hospitalizations; the median time to onset was 14.2 months and overall incidence was 13.4 cases per 1000 person-years. There was no gender difference of incidence but older recipients (age ≥ 55 years old while heart transplantation) had high occurrence of herpes zoster hospitalizations ($p<0.01$). Of these 38 recipients with 50 herpes zoster hospitalizations, the average of total medical cost was $118,994 NTD (3,606 USD) and mean length of stay was 13.4 day. Fees of drug and room accounted for 54 % of total medical cost (34.3% and 20.0%, respectively). Twenty-seven of the herpes zoster hospitalization episodes (54.0%) were treated with acyclovir. Older recipients (age ≥ 55 years old while heart transplantation) had longer stay in hospital ($p=0.03$) but not total medical cost.
Conclusion: Older recipients have higher incidence and need more medical utilization for herpes zoster hospitalizations. Further strategies against herpes zoster infection after heart transplantations are crucial.

324.10

Metabolic profile of donation after circulatory death hearts during reconditioning

Hong Chee Chew[1], Ling Gao[1], Jeanette Villaneuva[1], Mark Hicks[1], Kumud Dhital[1,2], Peter MacDonald[1,2].
[1]Transplant Laboratory, Victor Chang Cardiac Research Institute, Sydney, Australia; [2]Heart Lung Clinic, St Vincent's Hospital, Sydney, Australia.

Aim: Donation after Circulatory Death (DCD) hearts have been shown to be viable after appropriate period of resuscitation on ex-vivo reperfusion circuits. These hearts were subsequently transplanted, and short term outcomes appear to be equivalent to brain dead (BD) heart transplants. Ischaemic events in the peri-mortem period cause considerable metabolic derangements which possibly impact cardiac reconditioning. Hence we aim to understand cardiac metabolic demands during early ex-vivo perfusion in order to limit ischaemic reperfusion injury (IRI) and improve functional recovery in DCD hearts.
Method: Landrace pigs (n=12) were anaesthetised and asphyxiated until circulatory arrest, followed by a stand-off period of 5mins. Blood collection and preservation flush occurred prior to explantation and installation on the ex-vivo device. Blood samples at baseline, following circuit priming, and every hour thereafter were taken. Arterial pH, haematocrit (Hct) and electrolyte profile (K+, Ca2+, and HCO3-) were measured using an I-Stat analyser.
Results: All results are presented in table below.

	Baseline	Blood + Priming Solution	Installation of Heart	180 mins post reconditioning
pH	7.36 ± 0.08	7.53± 0.06	7.27 ± 0.05	7.31 ± 0.06
Hct	23 ± 5.5%	15 ± 6.0%	13 ± 3.1%	
Ca^{2+} (mM)	1.3 ± 0.15	0.64 ± 0.32	0.53 ± 0.36	
K^{+} (mM)	3.89 ± 0.19	5.59 ± 1.78	4.66 ± 1.98	
HCO_3^- (mM)	33.78 ± 2.93	23.92 ± 3.15	20.42 ± 2.67	
Lactate	2.14 ± 2.33		2.64 ± 0.56	1.75 ± 0.63

Warm ischaemic time (WIT) and back-table time (BTT) was 21 +/- 5 and 29 +/- 6 min for the heart. The average blood volume collected was 1.6L: 1:1 dilution with Krebs resulted in significant hemodilution (from 23 +/- 5% to 15 +/- 6%) and hypocalcemia (1.30 +/- 0.15 to 0.64 +/- 0.32mM). This resulted in sub-optimal cardiac contractile recovery despite a favourable lactate profile. Changes in [Ca], [HCO} worsens overtime due to consumption, unless externally replaced. In contrast, a rise in [K] with circuit priming is partially corrected following heart installation. There is considerable alkalosis when introducing blood to the priming solution (500mls Krebs solution + Gelofusine) but this is overcompensated with acidosis when the heart is initially installed on the ex-vivo circuit. However, this acidosis is corrected overtime.
Conclusion: In porcine model, significant biochemical derangement occurs from the time of withdrawal. In addition to the dilutional effect of the priming solution, there is consumptive trend overtime unless externally replaced. Correction by the organ is limited and requires stringent replacement to ensure adequate recovery.

Low molecular weight heparine as alternative anticoagulation therapy in patients with left ventricular assist devices

Ozgur Ersoy[1], Bahadır Gültekin[1], Arbër Kutllovci[2], Ilknur Akkaya[1], H. Tankut Akay[1], Atilla Sezgin[1].
[1]Department of Cardiovascular Surgery, Baskent University, Ankara, Turkey; [2]Department of Cardiac Surgery, University of Prishtina Hasan Prishtina Faculty of Medicine, University Clinic Centre of Kosova, Prishtina, Kosovo.

Introduction: Anti-coagulation therapy is necessary in patients with left ventricular assist devices (LVAD). Low molecular weight heparine (LMWH) in the early post-operative period and oral anticoagulation (Warfarin sodium) in the late post-operative period are preferred for most of the patients with LVAD implantations. The aim of this study was to discuss the use of LMWH in patients with LVAD implantations who can not use oral Warfarin sodium.
Material and Methods: Thirty seven patients with LVAD implantations from January 2012 to February 2016 have been evaluated. Average age of patients is 36,0±24,62 years. We have to use LMWH for six of the patients. We used LMWH from the early post operative period for two of them, we started to use LMWH for four of them after discontinuing Warfarin sodium because of cerebrovascular accidents or while waiting for emergency heart transplantion list. LMWH acitvity was monitored by measuring of anti-factor Xa levels in plasma per week.
Results: Mean effective anti-Xa activity was 0,73±0.19 IU/mL which was within the defined range of efficacy 0,6 to 1 IU/mL. Mean period of anti-coagulation time with LMWH was 124 days±63 days (maximum 184 days, minimum days. There was no observed pump thrombus and thromboembolic complications. There was only one patient with gastrointestinal bleeding required an intervention.
Conclusion: Our results show that use of LMWH has constant biological efficacy and can be an alternative of anticoagulation therapy for long time¸ but more studies are needed to be assure.

Hospital readmissions after left ventricular assist device implantation

Christian Heim, Nattipong Mekkhala, Markus Kondruweit, Michael Weyand, Rene Tandler.
Cardiac Surgery, University of Erlangen, Erlangen, Germany.

Objectives: The number of patients provided with a continuous flow left ventricular assist device (LVAD) is steadily increasing. So far, little is known about health care resource utilization in the long term. Therefore the aim of this study was to analyse unplanned hospital readmissions of patients after LVAD implantation.
Methods: We analysed the clinical course of 62 patients who underwent continuous flow LVAD implantation (HeartWare HVAD or BerlinHeart Incor) between January 2010 and December 2014 and were followed up in our outpatient care unit. The cause of readmission, timing after LVAD implantation, and length of hospital stay were evaluated.
Results: 41 of 62 patients were readmitted 78 times (1.9 times/patient) until the end of follow up (cut off 08/31/2015). The median follow up after LVAD implantation was 17.5 months. The main causes of unplanned readmissions included neurological events (10% stroke and 8% ICB), assist device associated infections (12%), haemorrhage and gastrointestinal bleeding (13%) and device thrombosis (6%). Other causes included non-device related infections (11%). Analysis of device specific cause of hospital readmission revealed a trend of gastrointestinal bleeding and device thrombosis in HeartWare patients and stroke and haemorrhage in BerlinHeart Incor patients. Interestingly, readmissions did not significantly influence long-term survival in a negative manner (6.8% mortality [pts. without readmission] vs. 13.2% mortality [pts. with readmission]; p=.65).
Conclusion: Main causes of readmission after LVAD implantation included neurological events and bleeding. Interestingly, readmissions did not significantly influence long-term survival in a negative manner. Multiple readmissions of a single patient with the same clinical pattern might bias the analysis. Further investigations appear attractive to analyse health care resource utilization after LVAD implantation.

324.13

Prior clotting events as predictor of post LVAD morbidity and mortality

Justin Johannesen[2], Jabar Whittier[1], Matthew Carazo[1], Scott Feitell[1], Theresa Rowe[1], Wade Fischer[3], Shelley Hankins[1], Howard J.Eisen[1].
[1]Cardiology, Drexel University College of Medicine, Philadelphia, PA, United States; [2]Internal Medicine, Drexel University College of Medicine, Philadelphia, PA, United States; [3]Cardiothoracic Surgery, Drexel University College of Medicine, Philadelphia, PA, United States.

Introduction: Bleeding, pump thrombosis, and other thromboembolic events remain among the most feared post implantation complications for patients receiving LVADs. Despite these concerns, a patient's coagulopathy history is rarely discussed when patients are presented as potential candidates for device implantation. This project aims to determine if patients with previous histories of clotting are more prone to these post LVAD complications.
Methods: A retrospective chart review of 46 patients who received Heartmate II LVADs from 2008-2013 in a single university transplant center was performed. These patients were sorted into those who had no history of clotting events and those who did. Clotting events included PE, DVT, LV/LA thrombus, thrombophlebitis and CVA. The two groups were then examined to determine which group suffered more post LVAD complications including hemorrhage, pump thrombosis, death within 6 months, stroke and MI.
Results: Of a total of 46 patients, 12 had a history of previous clot while 34 did not. Seventeen patients had an adverse event post LVAD implantation. Of those 17 patients, nine had a history of prior clot. In our analysis we found a significant relationship between history of clot and adverse LVAD outcome ($p = .004$, OR 9.75, 95% CI 2.11-44.9).
Conclusion: Despite a limited number of patients, our results showed a statistically significant difference in post LVAD complications between those patients with prior clotting events and those without. While future larger studies are warranted, these results would argue for different coagulation parameters in patients with histories of clotting.

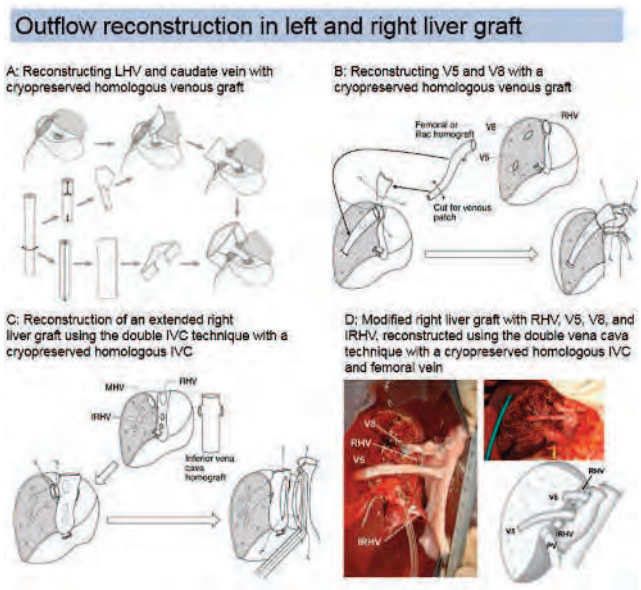
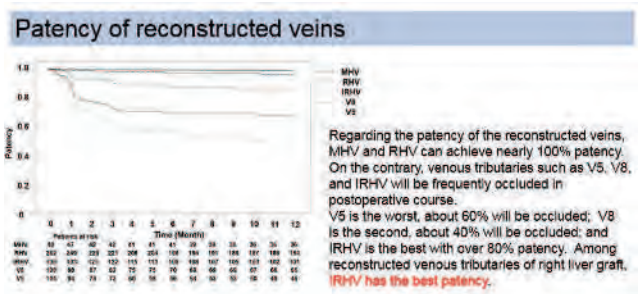
Outflow reconstruction using the homologous venous grafts in living donor liver transplantation: Experience at the University of Tokyo Hospital

Nobuhisa Akamatsu[1,2], Sumihito Tamura[1,2], Yoshihiro Sakamoto[2], Kiyoshi Hasegawa[2], Norihiro Kokudo[2].
[1]Tissue Bank, The University of Tokyo Hospital, Tokyo, Japan; [2]Artificial Organ and Transplantation Surgery Division, Department of Surgery, University of Tokyo, Tokyo, Japan.

Back ground: It is well accepted that not only the actual graft volume but also the uncongested volume of it is a key issue for the successful LDLT. Therefore, congested area should be minimized to the possible extent. Reconstructing the MHV tributaries, IRHV or caudate vein are important with this aspect, however, direct anastomosis between these vessels to IVC requires the technical difficulty and prolongs warm ischemic time. To overcome these problems, we have reported several innovations in the reconstruction of these veins at the bench surgery, utilizing the cryopreserved homologous veins (Figure 1).



Method: We have performed 462 adult LDLT. Of these 55% of the donors underwent right liver resection, 39% with left liver resection, and 7% with posterior liver resection. We routinely use the cryopreserved vein grafts for the outflow reconstruction, and herein present our way of venous reconstruction in LDLT.
Results: Left liver graft and right liver graft is equal in terms of short- and long-term outcome, provided the proper graft selection algorithm. 90 days mortality rate was 5%. The incidence of severe complications (Clavien Grade IIIb and more) was 38%. The incidence of outflow obstruction requiring interventional or surgical treatment was 1% in the left (2/179) and 2% in the right liver (6/257), respectively. Regarding the patency of the reconstructed veins, LHV MHV and RHV can achieve nearly 100% patency. On the contrary, venous tributaries such as V5, V8, and IRHV will be frequently occluded in postoperative course. V5 is the worst, about 60% will be occluded; V8 is the second, about 40% will be occluded; and IRHV is the best with over 80% patency. Among reconstructed venous tributaries of right liver graft, IRHV has the best patency (Figure 2).



Conclusion: In conclusions, outflow reconstruction is a key for the successful results. Cryopreserved vein graft is useful for the reconstruction.

Outcome of living donor liver transplantation using right liver allografts with multiple arterial supply

Kyo Won Lee[1], Min Jung Kim[2], Sanghoon Lee[1], Nuri Lee[1], Chan Woo Cho[1], Kyeong Sik Kim[1], Seounghyun Kim[1], Ji Soo Lee[1], Jong Man Kim[1], Gyuseong Choi[1], Jae-Won Joh[1].
[1]Department of Surgery, Samsung Medical Center , Seoul, Korea; [2]Department of Surgery , Jeju National University Hospital , Jeju, Korea.

Introduction: Partial liver graft with multiple hepatic arterial (HA) stumps can be faced in 10% of living donor liver transplantation (LDLT). In these cases, a smaller HA may elicit hepatic artery thrombosis. Therefore, whether to reconstruct all HA stumps on a graft is an ongoing debate. This study was designed to validate the safety of partial reconstruction of multiple HAs in LDLT using right lobe graft.
Method: From January 2000 to June 2014, 1149 patients underwent LDLT procedures at the Samsung Medical Center. Among them, 30 cases of LDLT using right lobe graft with multiple HA stumps and 149 cases of LDLT using right lobe graft with single HA sampled from database were enrolled. These cases were divided into three groups: single HA group (Group 1, n = 149), multiple HAs with total reconstruction (Group 2, n = 19), and multiple HAs with partial reconstruction (Group 3, n = 11). Biliary complication rate, HA complication rate, patient survival, and graft survival were compared among groups. Partial reconstruction was performed only when there was pulsatile back-bleeding after larger HA reconstruction and sufficient intrahepatic arterial flow was confirmed by Doppler ultrasound (DUS).
Result: In Group 2, the median size of donor HAs was smaller ($P < 0.001$) and the duration of HA reconstruction was longer ($P < 0.001$). However, there was no significant difference in biliary complication rate, artery complication rate, patient survival, and graft survival. Risk factor analysis revealed that multiple HAs itself and partial reconstruction of HAs were not related to biliary anastomosis stenosis, biliary leakage, hepatic artery stenosis, graft survival and patient survival.
Conclusion: In conclusion, partial reconstruction of HAs in LDLT using right lobe graft is feasible when intrahepatic arterial communication is confirmed by pulsatile back-bleeding from the smaller artery and DUS.

The effect of anhepatic phase extended by temporary portocaval shunt on anesthetic sensitivity to desflurane administered at a constant age-adjusted minimum alveolar concentration and postoperative cognitive function in patients undergoing living donor liver transplantation

Jong Hae Kim[1], Jin Yong Jung[1], Dong Lak Choi[2], Taeha Ryu[1], Sung Hye Byun[1], Joo Dong Kim[2].
[1]Department of Anesthesiology and Pain Medicine, School of Medicine, Catholic University of Daegu, Daegu, Korea; [2]Division of Hepatobiliary Pancreas Surgery and Abdominal Organ Transplantation,Department of Surgery, School of Medicine, Catholic University of Daegu, Daegu, Korea.

Introduction: Anesthetic requirements have been found to be lowest during anhepatic phase among the three phases of living donor liver transplantation (LDLT). However, the effect of duration of the anhepatic phase on anesthetic sensitivity and postoperative cognitive function has not been investigated when a constant minimum alveolar concentration (MAC) of inhalational anesthetic agent is administered. We assessed the anesthetic sensitivity to desflurane administered at a constant MAC and perioperative cognitive function in patients undergoing LDLT where the duration of the anhepatic phase was extended by temporary portocaval shunt (TPCS) to test the hypothesis that a prolonged anhepatic phase increases the anesthetic sensitivity, in turn resulting in postoperative cognitive decline.
Materials and Methods: This study was conducted in 67 consecutive patients undergoing LDLT from February 2014 to January 2016. Anesthesia was maintained at an end-tidal desflurane concentration, which corresponds to 0.6 age-adjusted MAC, between the peritoneal incision and closure. A TPCS was created in select cases, such as severe adhesions or massive bleeding. Throughout the surgery, bispectral index (BIS) was maintained below 60 and was averaged at 1-minute intervals. Mini-mental state examination in the Korean version of the consortium to establish a registry for Alzheimer's disease assessment packet (MMSE-KC) was performed 1 day before and 7 days after the LDLT. The averaged BIS values of each phase and preoperative and postoperative MMSE-KC scores were compared between the patients receiving TPCS (TPCS group) and those who did not (non-TPCS group).
Results: TPCS was performed in 16 patients (24%). The TPCS prolonged the duration of the anhepatic phase (125.9 ± 29.4 versus 54.9 ± 20.5 minutes [mean ± standard deviation], $P < 0.0001$) shortening that of the preanhepatic phase (80.1 ± 38.4 versus 137.2 ± 27.9 minutes, $P < 0.0001$). The averaged BIS values during the three phases were comparable between the two groups. No significant interval changes in the averaged BIS value were observed during the three consecutive phases. Likewise, there were no significant differences in MMSE-KC score assessed 1 day before and 7 days after the LDLT between the two groups. The preoperative MMSE-KC scores were unchanged postoperatively in the two groups.
Discussion: The extension of the anhepatic phase does not seem to affect the anesthetic sensitivity to desflurane and postoperative cognitive function according to the insignificant differences in BIS values during the three phases and perioperative MMSE-KC scores between the two groups as well as the insignificant interval changes in BIS values throughout the surgery and cognitive function between 1 day before and 7 days after the surgery.
Conclusion: The prolonged duration of anhepatic phase caused by TPCS does not influence anesthetic sensitivity to desflurane and postoperative cognitive function.

Domino liver transplantation: Technique and outcome

Neslihan Celik, Frederick Vyas, Armando Ganoza, Geoffrey J.Bond, Kyle A.Soltys, Rakesh Sindhi, George V.Mazariegos.
Hillman Center for Pediatric Transplantation, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA, United States.

Aim: Domino liver transplantation (DomLT) using allografts with metabolic disorders enhances organ utilization but is not well described in children. Since the documentation of short and long term course of these patients are critical to decision making about the safety of this procedure, we reviewed the outcomes of DomLT at a single center.
Methods: All patients receiving DomLT were analyzed retrospectively with minimum one year follow-up period for patient and donor characteristics, early and late postoperative complications and patient and graft survivals. We also reviewed the MSUD (Maple Syrup Urine Disease) donors of these patients who received deceased donor liver transplantation at the same time in terms of age, weight, cold ischemia time, postoperative leucine levels and peak ALT (Alanine Aminotransferase) levels during postoperative 48 hours.
Results: Between 2007 and 2014, 10 patients underwent liver transplantation with domino live-donor allografts from MSUD patients. The indications were progressive familial intrahepatic cholestasis, cystic fibrosis, congenital hepatic fibrosis, embryonal sarcoma, primary sclerosing cholangitis, alpha-1-antitrypsin deficiency and chronic rejection after liver transplantation. All patients and grafts survived. Median recipient and donor ages were 19.4 and 16.6 respectively. There was no vascular complication at early postoperative period, one patient had portal vein thrombosis 3 years after transplantation and meso-Rex bypass was performed. Small for size syndrome occurred in reduced left lobe DomLT recipient and managed successfully. Biliary stricture developed in 2 patients and solved by stenting.
The data and comparison were listed in the Table below

Recipient Demographics and Functional Metrics	DomLT Recipient	MSUD Recipient	p-value
Mean age at transplantation (years)	22.4	15.9	0.28
Mean weight (kg)	56.1	55.1	0.93
Posttransplant mean leucine level (umol/dL)	12.3	18.1	0.000
Posttransplant mean cold ischemia time (minute)	302.4	349.0	0.26
Posttransplant peak ALT in 48 hours (IU/L)	288.1	984.8	0.007

Conclusion: Patient and graft survival in DomLT from MSUD donors has been excellent at long term follow-up. Metabolic function has been normal in all recipients on normal unrestricted protein intake. Ischemia preservation injury based on peak ALT has been significantly decreased in DomLT recipients. Domino transplant from pediatric and adult recipients with selected metabolic disease should be increasingly considered.

Outcome of partial reconstruction of multiple hepatic arteries in pediatric living donor liver transplantation using left lateral section grafts

Kyo Won Lee[1], Min Jung Kim[2], Jong Man Kim[1], Gyuseoung Choi[1], Jae-Won Joh[1], Nuri Lee[1], Kyeong sik Kim[1], Ji Soo Lee[1], Seounghyun Kim[1], Jonghwan Lee[1].
[1]Department of Surgery , Samsung Medical Center , Seoul, Korea; [2]Department of Surgery, Jeju National University Hospital , Jeju, Korea.

Introduction: In pediatric end-stage liver disease patients, the use of partial liver grafts from adult living donors has been increasing for liver transplantation due to a shortage of size-matched liver allografts. Partial liver grafts commonly involve multiple hepatic artery (HA) stumps. In these cases, a smaller HA may elicit hepatic artery thrombosis (HAT). Whether to reconstruct all HA stumps on a graft is an ongoing debate.
Methods: This study was designed to validate the safety of partial reconstruction of multiple HAs in pediatric living donor liver transplantation (LDLT) cases. From January 2000 to June 2014, 159 pediatric patients underwent LDLT. Among these, ABOi cases, re-transplantation cases, and right lobe cases were excluded. The remaining 136 patients were categorized into three groups: single HA group (group 1, n = 74), multiple HAs with total anastomosis group (group 2, n = 23), and multiple HAs with partial reconstruction group (group 3, n = 39). Biliary complication rate, HA complication rate, patient survival, and graft survival were compared between groups. Partial reconstruction was performed only when there was pulsatile back-bleeding after larger HA reconstruction and sufficient intrahepatic arterial flow was confirmed by Doppler ultrasound (DUS).
Results: In group 2, the median size of donor HAs was smaller ($P < 0.001$) and the duration of HA reconstruction was longer ($P < 0.001$). However, there was no significant difference in biliary complication rate, artery complication rate, patient survival, and graft survival. Risk factor analysis revealed that male recipients, bile duct diameter < 5mm, and total duration of operation were risk factors for biliary anastomosis stricture (BAS). Multiple HAs itself and partial reconstruction of multiple HAs were not risk factors of BAS.
Conclusion: In pediatric LDLT, partial reconstruction of HAs in a left liver graft with multiple HA stumps does not increase the risk of BAS or affect graft survival when intrahepatic arterial communication is confirmed by pulsatile back-bleeding from the smaller artery and DUS.

The novel use biodegradable SX-ELLA biliary stent placed by percutaneous transhepatic aproach for the treatment of biliary stenosis after liver transplantation

Cristina Dopazo[1], Anna Curell[1], Iratxe Diez[3], Carla Gonzalez-Junyent[3], Mireia Caralt[1], David Hernandez[3], Jose Luis Lazaro[1], Javier Juamperez[4], Lluis Castells[2], Jesus Quintero[4], Mercedes Perez[3], Itxarone Bilbao[1], Ramon Charco[1].
[1]Department of HPB Surgery and Transplants, Hospital Universitario Vall D'Hebron, Barcelona, Spain; [2]Department of Internal Medicine, Liver Unit, Hospital Universitario Vall D'Hebron, Barcelona, Spain; [3]Department of Interventional Radiology, Hospital Universitario Vall D'Hebron, Barcelona, Spain; [4]Pediatric Liver Transplant Unit, Hospital Universitario Vall D'Hebron, Barcelona, Spain.

Introduction: The uncovered self-expandable metal stents placed by percutaenous transhepatic approach (PTA) was used routinely in our center for the treatment of biliary stenosis after liver transplantation (LT) when balloon dilatation was failed. However the rate of complications thereafter achieved more than 60%. Biodegradable SX-ELLA biliary stents are available in our center since August 2014 and no results in LT were published previously in the literature.
Objectives: To evaluate feasibility, safety and outcome of patients treated with biodegradable SX-ELLA biliary stents placed by percutaneous transhepatic approach for the treatment of biliary stenosis after LT in adult and pediatric setting.
Methods: Observational retrospective single-centre study including adult and pediatric patients underwent a first LT who developed biliary stenosis (anastomotic or non anastomotic stenosis) treated with Biodegradable SX-ELLA biliary stents. Once biliary stenosis is diagnosed by Magnetic Resonance Cholangio-pancreatography the percutaneous transhepatic balloon dilatation of biliary stenosis is the first approach in our center, and stenting when the stenosis is not resolved after two or more procedures. The stent size depends on balloon size and length of stenosis. The median patient follow-up period after stent was placed was 14 months (6-19 months).
Results: Between August 2014 and August 2015 ten patients required a biodegradable SX-ELLA biliary stent by PTA. Six patients were adults with a median age of 60 (49-68) years-old, the main indication for LT was HCC (67%) and all of them have received whole graft from brain-dead donors and the biliary reconstruction was end-to-end in all cases. Four patients were children with a median age of 1 (1-9) years-old, the cause of transplant was Wilson disease, hepatoblastoma, biliary atresia and cholestatic familiar disease and two patients received whole graft from brain-dead donors and two cases partial graft (split liver and living donor) being the hepatoyeyunostomy performed in 3 of them. The biliary complications after LT appeared in a median time of 15 (1-194) months.
After a median of unsuccessful balloon dilatation of 1.5 (1-4), biodegradable SX-ELLA biliary stents were placed due to anastomosis stenosis in 9 cases (with patent artery in 6 patients) and one case was due to non-anastomotic stenosis. Stents implantations were always feasible and no immediate major complications occurred in any case. Three adult patients with arterial thrombosis (30%) presented the following complications after procedure related to progression of ischemic cholangiopathy: one cholangitis at 30th day and two stent obstructions at 63rd and 85th day respectively. None of them required further surgical treatment.
Conclusions: Biodegradable biliary stents represents a new feasible option for treatment of biliary stenosis after LT either in adult or children LT patients with a low early morbidity.

V5/V8 hepatic vein thrombus after left lobe donation surgery

Kaori Kuramitsu, Takumi Fukumoto, Hisoka Kinoshita, Motofumi Tanaka, Masahiro Kido, Sachio Terai, Taku Matsumoto, Tadahiro Goto, Sadaki Asari, Hirochika Toyama, Tetsuo Ajiki, Yonson Ku.
Surgery, Division of Hepato-Biliary and Pancreatic Surgery, Kobe University, Kobe, Japan.

Background: Left lobe liver graft has been widely accepted as a favorable grafts for living donors. However up to date, detailed analysis is not well performed for potential risks for left lobe donors. We analyzed the effect of V5/V8 hepatic vein thrombus on left lobe donors after left lobe donation surgery.
Methods: From February 2004 to November 205, 40 cases of left lobe donation surgery were performed at Kobe University Hospital. Among them 35 cases (87.5%) were eligible for the study with CT images. Preoperative factors (donor age, liver/spleen ratio, % of remnant liver volume/whole liver volume, middle hepatic vein (MHV) dominancy), intraoperative factors (bleeding volume, operation time, intraoperative transfusion), and postoperative factors (AST/ALT/T-bil levels at peak and day 7, length of hospital stay, remnant liver regeneration at 1 week and 1 month) were analyzed as a potential risk factor for the formation of V5/V8 thrombus.
Results: V5/V8 thrombus was detected in 21 cases (60%). Among preoperative factors, MHV dominancy (p=0.01) was identified as a risk factor for the formation of V5/V8 thrombus. Among intraoperative factors, bleeding volume (p=0.02), operation time (p=0.03), and intraoperative transfusion (p=0.01) were identified as risk factors. Among postoperative factors, level of day7 ALT was identified as a risk factor. Postoperative remnant liver regeneration at 1 week and 1 month did not differ with the existence of V5/V8 thrombus with statistical difference.
Conclusion: V5/V8 thrombus was identified in 60% of cases after left lobe donation surgery. Although the existence did not affect postoperative donor courses, it is now proved that the formation of V5/V8 thrombus associated with surgical difficulties. To maintain zero donor mortalities, cautions should be taken for the selection of left lobe grafts especially for MHV dominant cases.

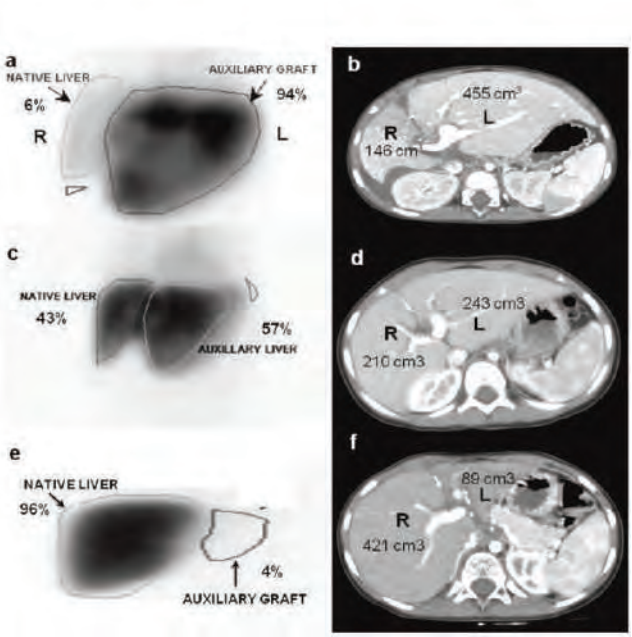
Auxiliary partial orthotopic liver transplantation (APOLT): A safe & effective alternative to orthotopic liver transplantation for patients with acute liver failure and non-cirrhotic metabolic liver disease

Mettu Reddy, Naresh Shanmugham, Joy Varghese, Ilankumaran Kaliamoorthy, Rajesh Rajalingam, Venugopal Kota, Gomathy Narasimhan, Mohamed Rela.
Institute of Liver Disease & Transplantation, Global Health City, Chennai, India.

Background: In Auxiliary Partial Orthotopic Liver Transplantation (APOLT), a part of the recipient's native liver is resected and a healthy partial graft is implanted orthotopically in its place. It has been used in selected cases of acute liver failure (ALF) and non-cirrhotic metabolic liver disease (MLD). In ALF, it acts as a bridge to native liver regeneration, while in MLD it supplements the native liver with the missing functional protein thus correcting the symptoms. It is not universally accepted because of concerns of technical complications. We present our series of APOLT procedures and discuss the indications, safety, and outcomes.
Methods: Data of all APOLT procedures performed in our institute between Sep 2009 and Feb 2016 was retrieved. Indications for APOLT, operative details, complications, short term and long term outcomes are reported.
Results: 14 APOLT procedures were performed during the study period, forming 2% of our overall transplant numbers. Follow-up ranged from 2 weeks to 75 months.
6 APOLT procedures were performed for ALF. There were 3 children & 3 adults (Age range 9 months to 31 years). All underwent LDLT-APOLT (Graft type: left lateral: 2, left lobe:1, right lobe:3) after native hepatectomy (left hepatectomy:3, right hepatectomy: 3). There were no early or late technical complications. One patient transplanted for yellow phosphorus poisoning died 4 weeks after transplant with multiple organ failure. Of the 5 survivors, two children had good native liver regeneration and were completely weaned off immunosuppression while 3 others were stable on immunosuppression.
8 APOLT procedures were performed for MLD (6 children, 2 adult). Indications were Criggler Najar syndrome type 1 (n=3), propionic acidemia (n=4) and citrullinemia (n=1). 5 patients underwent LDLT-APOLT while 2 underwent DDLTsplit- APOLT. All patients underwent left hepatectomy and received left lateral grafts (n=6) or left lobe grafts (n=2). All patients needed intra-operative portal flow modulation by graded portal banding to prevent portal steal. One child with propionic acidemia developed early HAT, which was managed successfully with surgical revascularisation. Another child with propionic acidemia developed recurrence of symptoms secondary to portal steal after 12 months. This was effectively managed by segmental native portal vein embolization. At followup all 8 patients were in good health with complete resolution of their original symptoms.
Discussion: Our data shows that APOLT is a safe alternative to orthotopic liver transplantation for selected patients with ALF. In our ALF cohort, two patients (33%) had become completely immunosuppression free. APOLT in MLD ensures adequate backup native liver function in case of graft related complications thus improving recipient safety. It also improves living donor safety as a smaller sized graft, (such as left lateral graft) is sufficient to treat the metabolic defect even in adult recipients. To our knowledge, this is the largest reported Asian series outside Japan.
Conclusion: APOLT is a viable alternative to OLT for selected patients with ALF and noncirrhotic MLD.



Serial HIDA and CT scans in a 2 year old child who underwent left sided APOLT for fulminant liver failure due to Hepatitis A infection. Figures a,b at 1 month, c,d at 24 months and e,f at 30 months. Serial scans show a gradual increase in size of native liver remnant (right lobe), while the left graft shrinks. This child was completely taken off immunosuppression 24 months after transplant.

325.9

Reducing non-anastomotic biliary strictures after donation after circulatory death liver transplantation, a matter of time?

Nicholas Gilbo, Ina Jochmans, Mauricio Sainz, Jacques Pirenne, Diethard Monbaliu.
Abdominal Transplantation Surgery and Coordination, University Hospitals of Leuven, Leuven, Belgium.

Liver Transplantation (LT) from donation after circulatory death (DCD) is associated with increased non-anastomotic biliary strictures (NAS) and graft loss. Donor and recipient demographics, transplant and outcome data were compared between recipients with NAS (NAS+) and those without (NAS-) in a cohort of 61 consecutive DCD-LT (01/2003-12/2013). Risk factors for NAS occurring <1y after DCD-LT were identified in multivariate regression. Median (IQR) is given.
13/61 developed NAS. Incidence of NAS decreased over time (30% in 2003-2010, 15% in 2011-2013) in parallel with a decrease in cold ischemia time (CIT) [6.8h (5.5-8) in 2003-2010, 5.4h (4.75-6.4) in 2011-2013, p=0.002]. Donor and recipient age and gender, warm ischemia time [NAS+ 20min (15-29) vs NAS- 22min (16-28), p=ns], donor peak AST/ALT did not differ. NAS+ had a higher DRI [3.01 (2.86-3.49) vs 2.67 (2.37-3.05), p=0.031], longer CIT [7.3h (5.95-8.52) vs 5.6h (4.97-6.75), p=0.004] and anastomotic time [55min (46.5-60.5) vs 46min (42-52.5), p=0.038]. NAS occurred more frequently in grafts exposed to CIT>5h vs CIT<5h (26.5% vs 0%, p=0.054). Peak ALT post-LT was higher in NAS+ vs NAS- [1114IU/L (745-1566) vs 645IU/L (318-1087), p=0.019]. No difference in early allograft dysfunction (NAS+ 23.1% vs NAS- 20.8%, p=ns) or acute kidney injury was observed. The need for re-LT and endoscopic biliary intervention was higher in NAS+ vs NAS- (7.7% vs 0% and 84.6% vs 10.4% respectively, p<0.0001). One year censored graft and patient survival were similar between NAS+ and NAS- (84.6% vs 89.6%, 92.3% vs 91.7% respectively, p=ns). NAS did not influence the risk of death (HR:1, 95%CI:0.28-3.6) or graft loss (HR:1.62, 95%CI:0.57-4.6). CIT was the only independent risk factor of NAS (HR:1.42, 95%CI:1.06-1.92). Even with overall short CIT (5.78h, 5.13-7.13), the risk for NAS development in the 1st year post-transplant increases 1,42 times by every additional hour of CIT. In the absence of interventions that might directly prevent NAS, active efforts to maximally reduce CIT in DCD-LT are essential.

325.10

Liver stiffness measurement using acoustic radiation force impulse (ARFI) in living and deceased donor orthotopic liver transplantation patients

Murat Haberal[1], Hale Turnaoglu[1], Adnan Ozdemir[1], Nihal Uslu[1], Nihan Haberal Reyhan[2], Gokhan Moray[3], Mehmet Haberal[3].
[1]Radiology, Baskent University, Ankara, Turkey; [2]Pathology, Baskent University, Ankara, Turkey; [3]General Surgery, Baskent University, Ankara, Turkey.

Background: Acoustic Radiation Force Impulse (ARFI) elastography is a new technology that provides numerical measurements (wave-velocity values) of tissue stiffness. It has been shown that ARFI is a reliable technique for diagnosing and excluding liver cirrhosis. However, the value of the ARFI technique is not yet well established in the clinical management of liver transplantation patients. The aim of this study was to evaluate the diagnostic efficiency of the ARFI technology of the assessment of fibrosis in orthotopic liver transplantation patients.
Materials and Methods: We enrolled 28 orthotopic liver transplantation patients (living and deceased donor), whose biopsy decision has been given clinically due to posttransplantation dysfunction, prospectively. ARFI elastographic measurements were applied before the biopsy or within three days after the biopsy, by two radiologists. Ten measurements in segment III-IV on the left lobe graft and segment VII-VIII on the right lobe graft could be obtained, avoiding large vessels or bile ducts. The measurements were performed about 3 cm in depth from the surface of the liver.
After the core needle liver biopsy, specimens of the patients were analyzed by an experienced pathologist, according to the modified Ishak scoring system. The measurements of ARFI sonoelastography and the results of pathology specimens were compared with the nonparametric Kruskal Wallis test (with Conover-Dunn multiple comparison test). The statistical significance was set at $p<0.05$.
Results: Orthotopic liver transplantation were deceased-donor in 5 patients (17.9%), and from living donor in 23 patients (82.1%). A total of 28 biopsies, 4 of fibrosis score were evaluated as F0 (14.3%), 16 of fibrosis score were evaluated as F1 (57.1%), 4 of fibrosis score were evaluated as F2 (14.3%) and 4 of fibrosis score were evaluated as F3 (14.3%). There were no specimens which fibrosis score evaluated as F4, F5 or F6. The ARFI measurements mean was calculated 1.4±0.07 in F0, 1.74±0.57 in F1, 2.19±0.7 in F2 and 2.18±0.35 in F3. There were no significant correlation of mean ARFI values between the F0 vs F1 and F0 vs F2 stages ($p= 0.956$, $p=0.234$, respectively). A statistically significant correlation of mean ARFI values was found between the F0 and F3 fibrosis stages ($p=0.046$).

Conclusions: ARFI imaging is a promising screening test for detecting significant liver fibrosis (≥F3 in modified Ishak scoring) in living or deceased donor orthotopic liver transplantation patients.

325.11

Efficacy of acoustic radiation force impulse (ARFI) elastography for predicting post-transplant clinical outcomes in living donor liver transplantation

Koji Natsuda, Akihiko Soyama, Mitsuhisa Takatsuki, Masaaki Hidaka, Takanobu Hara, Tota Kugiyama, Hajime Imamura, Zhassulan Baimakhanov, Satomi Okada, Shinichiro Ono, Amane Kitasato, Tamotsu Kuroki, Susumu Eguchi.
Department of Surgery, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan.

Introduction: Although time-zero biopsy has been reported to predict adverse clinical outcomes after liver transplantation, the results will be known after transplantation. Recently, acoustic radiation force impulse (ARFI) elastography is widely used for evaluating liver fibrosis. The aim of this study was to evaluate the efficacy of preoperative ARFI elastography for evaluating a quality of the graft and clinical outcomes in living donor liver transplantation (LDLT).
Patients and Methods: Seventy-four LDLT donor candidates s in Nagasaki University Hospital between August 2010 and August 2015 who preoperatively underwent ARFI elastography were enrolled in this study. Velocity of shear wave (Vs) value of the right lobe was measured by ARFI elastography, and we conducted following analyses: 1, correlation between Vs and the age of donors, 2, correlation between Vs and fibrosis staging of time-zero biopsy, 3, correlation between Vs and the regeneration rate of remnant liver (liver volume 1 month after LDLT/ expected remnant liver volume), 4, correlation between Vs and 1-year survival rate.
Results: The median of Vs was 1.05, and range was 0.73-1.93. 1. There was no significant correlation between Vs and the age of donors. 2. The number of F0/F1/F2 in time-zero biopsy were 59/14/1, respectively. The Vs of F0 and F1/2 were 1.05 and 1.08 (N.S.). 3. We used two Vs cut-off values those were previously reported (Sporea et al. Eur J Radiol. 2012): 1.19 (equal to F1) and 1.33 (equal to F2). And all patients were separated by graft types, right lobe graft (RLG, n=29) and extended left lobe graft (ELLG, n=45). In RLG, the median Vs lower or higher than 1.19 (n=25, 4) and 1.33 (n=27, 2) were 2.27 and 1.60 ($P <0.01$), 2.22 and 1.77 ($P =0.13$), respectively. And in ELLG, the median Vs lower or higher than 1.19 (n=34, 11) and 1.33 (n=40, 5) were 1.30 and 1.27 ($P =0.35$), 1.31 and 1.18 ($P <0.05$), respectively. 4. One year survival rate of the recipients in the same category in section 3 were compared by log-rank test. One year survival rate lower or higher than 1.19 and 1.33 were 84.2% and 65.2% ($P =0.09$), 82.7% and 57.1% ($P <0.05$), respectively.
Discussion: Despite significant correlation between Vs and clinical outcomes, Vs was not correlated with donor age and the zero-biopsy. Hence, Vs was considered an independent predictor of post-transplant clinical outcomes.
Conclusion: The grafts with preoperative high Vs value resulted in poorer graft regeneration and worse short-term survival of recipient despite no differences in time-zero biopsy. Preoperative ARFI elastography might be an useful tool for predicting post-transplant clinical outcomes. ARFI elastography was considered an effective examination for preoperative evaluation in LDLT.

Early enteral feeding after living donor liver transplantation prevents infectious complications: A prospective pilot study

Jong Man Kim[1], Kyung-Sik Kim[1], Nuri Lee[1], Chan-Woo Cho[1], Hyun Jung Kim[1], Sung-Hye Kim[2], Miyong Rha[2], Gyu-Seong Choi[1], Choon Hyuck D.Kwon[1], Jae-Won Joh[1], Suk-Koo Lee[1].
[1]Department of Surgery, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul, Korea; [2]Department of Dietetics, Samsung Medical Center, Seoul, Korea.

Background: Infectious complications, including bacteria, virus, and fungus, often occur after liver transplantation and are the most frequent cause of in-hospital mortality. The present study prospectively analyze the effect of early enteral feeding in patients after living donor liver transplantation (LDLT)**.**
Methods: Between January 2013 and August 2013, 36 patients underwent LDLT. These patients were randomly assigned to receive enteral formula via nasointestinal feeding tubes (EN group, n=17) or maintenance on intravenous fluid until oral diets were initiated (control group, n=19). All patients completed the study.
Results: The pretransplant and perioperative characteristics of patients did not differ between the two groups. The incidence of bacterial infection was significantly lower in the EN group (29.4%) than in the control group (63.2%) (P=0.043). Additionally, the incidence of bile duct complications in the EN group was lower than in the control group (5.9% vs. 31.6%, P=0.041). Multivariate analysis showed that early enteral feeding was closely associated with bacterial infections (odds ratio, 0.178; P=0.041). There was no statistically significant difference in nutritional status between the two groups. There were no cases of in-hospital mortality.
Conclusion: Early enteral feeding after LDLT prevents post-transplant bacterial infection, suggesting the possibility of a reduction of in-hospital mortality as a result of decreased infectious complications.

Auxiliary partial orthotopic liver transplantation versus heterotopic auxiliary partial liver transplantation – single center experience

Kohei Miura, Takashi Kobayashi, Zhengkun Zhang, Daiki Soma, Yuki Hirose, Hirosuke Ishikawa, Tomohiro Katada, Taku Ohashi, Kazuyasu Takizawa, Kabuto Takano, Jun Sakata, Toshifumi Wakai.
Division of Digestive and General Surgery, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan.

Introduction: Small-for-size is a major obstacle in adult living donor liver transplantation (LDLT). Renal dysfunction is also a direct complication which affect to prognosis after LDLT. We have successfully performed auxiliary partial living donor liver transplantation for recipients with end stage liver disease. The aim of this study was to evaluate this procedure by comparing auxiliary partial orthotopic liver transplantation (APOLT) with heterotopic auxiliary partial liver transplantation (HAPLT).
Methods: The clinical records of eight patients who underwent auxiliary partial living donor liver transplantation from March 2000 to May 2009 were analyzed. In these patients, four underwent APOLT and the other four underwent HAPLT. We compared the clinical outcomes including characteristics of recipients and donors, intraoperative findings, and postoperative findings of these two different procedures.
Results: The primary disease of the patients were fulminant hepatitis 3, alcoholic liver cirrhosis 1 in APOLT, and fulminant hepatitis 3, primary biliary cirrhosis 1 in HAPLT. Mean age and MELD score of the patients were 35 years vs 57 years, and 27 vs 27 respectively (APOLT vs HAPLT). Child-Pugh grade was C in all 8 cases. Blood type was identical 3, compatible 1 in APOLT and identical 2, compatible 2 in HAPLT. Partial liver graft was right lobe 2, left lobe 2 in APOLT, and left lobe in all cases in HAPLT. Mean graft-to-recipient weight ratio (GRWR), operation time, and blood loss were 0.79% vs 0.73%, 917 min vs 825 min, and 39764 ml vs 18943 ml respectively. In APOLT, 2 of 4 (50%) patients were alive (96, 144 months) and 1 case achieved free of immunosuppression after sufficient recovery of the native liver. One was lost at 6 years after operation because of intraabdominal infection, and the other was lost at 10 months after surgery because of sepsis. In HAPLT, only 1 of 4 (25%) patient was alive (168 months). One was lost at post-operative day (POD) 3 because of cytomegalovirus pneumonia and the other 2 were lost because of hypoxic encephalopathy at POD 28, aspiration pneumoniae at 15 months after operation.
Conclusions: In APOLT, the age of recipient tended to be younger and the amount of bleeding tended to be larger than in HAPLT. Although auxiliary partial living donor liver transplantation might be a choice as an aid for severe liver failure cases such as small-for-size or renal dysfunction, further study was required to find appropriate indication for treating them.

What keeps TTS members up at night? Preliminary results of an international ethics survey

Dominique Martin[1], Kristof Van Assche[2], Katrina Bramstedt[3], Rudolf Garcia-Gallont[4], Jacob Lavee[5], Riadh Fadhil[6], Richard Trompeter[7], Beatriz Dominguez-Gil[8].
[1]Deakin University, Geelong, Australia; [2]University of Antwerp, Antwerp, Belgium; [3]Bond University, Robina, Australia; [4]Hospital General San Juan de Dios, Guatemala City, Guatemala; [5]Tel Aviv University, Tel Aviv, Israel; [6]Hamad Medical Corporation, Doha, Qatar; [7]UCL Centre for Nephrology, London, United Kingdom; [8]Organización Nacional de Trasplantes, Madrid, Spain.

Introduction: Professionals working in the field of transplantation may confront a number of ethical issues in their daily practice. Previous studies have explored professional attitudes concerning specific issues, but not the prevalence of such issues. We report here selected findings from a cohort of Transplantation Society members who were early participants in an international survey of transplant professionals investigating their experiences of ethical issues.
Methods: An invitation to participate in an online survey (hosted by SurveyMonkey) was emailed to all members of The Transplantation Society (TTS). Available in English and Spanish, the questionnaire included items assessing members' experience of ethical concerns or dilemmas in seven categories (living donation; deceased donation; organ allocation and transplantation; organ trading and transplant tourism; healthcare funding; research and publications; professional interactions).
Results: During the first five days of data collection, 163 participants representing 40 countries were recruited who identified as a member or possible member of TTS. The majority were physicians (41%) or surgeons (35%), male (70%), and from North America (38%; 22% Europe; 16% Latin America; 9% Oceania; 7% Asia; 4% Middle East; 4% Africa). 78% of participants reported experience of ethical dilemmas in the field of living organ donation (LD); of those reporting concerns about specific categories of LD (n=123), 68% were concerned about young adults, 42% about non-residents who travelled to donate, and 40% about donors who lack insurance or have limited access to healthcare. 61% of participants reported experience of dilemmas in deceased donation; of whom 46% identified extended criteria donors and those with potentially transmissible diseases as raising ethical concerns. Participants reported experience with ethical issues concerning waiting lists, selection and organ allocation(93%); organ trading, transplant tourism or financial incentives for donation(37%); healthcare funding (44%); research or publications(33%); and interactions with colleagues (56%). 47% reported experiencing an ethical dilemma in the last year (46% had not; 7% preferred not to answer). See **Table 1** for a list of issues commonly experienced within each category. Respondents identified follow up care of living donors(39%), equity in access to transplantation in developing countries(36%), and financial incentives for living donation(35%) as the most important issues for TTS to address. Priority activities were development of guidelines for management of specific ethical issues(63%); educational and training resources in clinical ethics(60%); position statements on key ethical issues in transplantation(56%).
Conclusions: These preliminary findings suggest that TTS members commonly experience a range of ethical concerns in their professional practice, and identify potential areas of need for professional guidance in transplant ethics.

Table 1: Three most commonly selected practices raising ethical concerns for professionals in specific areas of practice

Categories of practice/areas of practice	Three most commonly selected practices raising ethical concerns	Proportion of question respondents selecting these items (n)
Living donation – 78% (127) had experienced ethical issues		
Donor recruitment	Encouraging potential related donors without undue pressure	55% (64)
	Public solicitation of donors	52% (60)
	Managing those wishing to donate for money	47% (55)
Donor evaluation	Medical evaluation	61%(72)
	Psychosocial evaluation	59%(70
	Donor-recipient relationship evaluation AND detecting coercion of potential donors by family members	(equal third) 57% (68)
Other areas of concern	Follow-up care of living donors	79% (81)
	Financial costs for living donors	50%(51)
	Financial incentives for living donors	43% (44)
Deceased donation – 62% (101) had experienced ethical issues		
Process	Referral of potential donors prior to death determination (DDt)	49% (31)
	Evaluating medical suitability prior to DDt	49% (31)
	protocols for ante-mortem interventions in donation after circulatory determination of death	44% (28)
Consent/authorization	Cultural or religious objections to deceased donation	51% (39)
	Managing family disagreement	54% (41)
	Family disagreement in the context of registered donors	47% (36)
Waitlisting, candidate selection, or allocation – 93% (151) had experienced ethical issues		
Waitlisting/ candidate selection	Medical criteria governing eligibility for waiting list	62% (61)
	Listing for combined organ transplants	34% (34)
	Non medical criteria governing waiting list eligibility AND listing of foreign patients who travel for transplantation	(equal third) 32% (32)
Allocation of deceased donor organs	Organ allocation policies	56%(43)
	Inequities in organ sharing at the regional level	39%(30)
	Allocation to patients with acute illness due to self-harm or drug or alcohol abuse	26%(20)
Aspects of allocation policies	Conflicts between equality of opportunity and maximising utility	79%(73)
	Age matching	38% (35)
	Prioritization of pediatric candidates	25% (23)
Organ trading, transplant tourism or incentives for donation – 38% (61) had experienced ethical issues		
Trading, tourism or incentives	Managing patients who return after suspected transplant tourism	75% (45)
	Managing patients considering transplant tourism	67% (40)
	Managing living donor-recipient pairs where commercial relationship is suspected	50% (30)
Healthcare funding – 44% (71) had experienced ethical issues		
Funding	Patients unable to afford immunosuppression	63%(44)
	Patients unable to afford transplantation	60%(42)
	Patients unable to afford living donation AND living donors unable to health insurance or follow up care	(Equal third) 43%(30)
Research and Publications – 33% (53) had experienced ethical issues		
Research	Obtaining funding for research	50%(22)
	Excessive regulation of research	41%(18)
	Researcher conflicts of interest	34%(15)
Publication	Including colleagues as authors who don't meet journal criteria	
	Pressure not to publish problematic findings AND determining authorship AND reviewing journal articles	(Equal second) 33% (12)
Interactions with professional colleagues - 56% (91) had experienced ethical issues		
Professional interactions	Disagreement regarding suitability of transplant candidates	67%(61)
	Disagreement regarding suitability of potential living donors	53%(48)
	Disagreement regarding suitability of potential deceased donors	52%(47)

GPS-Enabled smartphone integration into digitalDonor electronic donor record produces double-digit increase in donation by ensuring rapid response to assist donor families and physicians

Thomas Mone[1], Prasad Garimella[2], Tom Seto[3].
[1]Administration, OneLegacy, Los Angeles, CA, United States; [2]Operations, OneLegacy, Los Angeles, CA, United States; [3]Information Technology, OneLegacy, Los Angeles, CA, United States.

Organ donation authorization and organ transplantation are most successful in regions and programs with dedicated, trained, specialized, professional organ recovery staff who are available to collaborate with hospital staff and MDs and meet with families when they are the critical decisions of continued care are being made. However the very low frequency of brain dead donation opportunities prevents scheduling these staff at each potential donor hospital 24 hours per day. Thus, most donation programs dispatch staff in combinations of scheduled rounds and individual case referral response. In a well-staffed and well-scheduled recovery program this methodology ensures timely availability 80-90% of the time. However, families in crisis are often unbound by clocks and workday schedules and can appear at the hospital at any time. Further, the combination of the increase in DCD donor candidates and economic and resource contention that prompts hospitals and MDs to discontinue "terminal" care has resulted in doctor-family end of life conversations earlier than in years past.

Thus, OPOs must adapt their potential donor referral response practices to ensure early detection, collaboration with hospital staff, and availabilty to families. At OneLegacy in Los Angeles, California, whcih serves a populaiotn of 19.5 million, 210 donor hopsials, and 11 local transplant centers, this challenge has been addressed with a combination of human and technological innovations in referral repsonse that has increased donation from 418 donors per year to 460, independent of increases inautorizaiton rates.

The first of these innovations was recruiting and training dedicated Referral Response Coordinators, who routinely are Emergency Medical Technicians who are trained to be "first responders" to potential donor referrals.

The second innovation was to re-train hospitals to refer cases, not at a specific Glasgow Coma Scale number, but rather any time a patient has a sever neurological injury and is on a ventilator.

The third innovation is the creation of "geo-fences" around each donor hospital that allows OPO supervisors to monitor the presence of each OPO staffmember who is approaching a donor hospital and coordinate the activities of different OPO specialists. This coordination is made possible through the OneLegacy Electronic Donor Record and its "digitalDonor Response" module that identifies individual staff on-screen and visbile to our donation team as soon as they arrive at the donor hospital, lets the staff know who they will be working with, and identifies other potential donor referrals in the hospital. The system makes the entire donor record immediately available to all OneLeacy staff, faciltiating a common understanding of the state of the case. This allows the Supervisor and Administrator on-call and the Intensivist on-call to collaborate with the coordinators, ensure they are available to treating MDs, hospital staff, and most of all families; and enables the supervisors to re-deploy staff to meet wiht hospital, MD and family whenever they are ready to address the donation opportunity. SInce digitalDOnor Response was deployed in late 2014, OneLegacy has seen a 10%/ 40+ donors per year.

This combination of technological and human resource investment has enabled OneLegacy to facilitate more than 100 additional transplant sin teh past year and is scalable to any organ recovery program.

Living liver donors may under-report mental health comorbidities

Hillary Braun[1], Garrett R.Roll[2], John PRoberts[2], Nancy L.Ascher[2].
[1]School of Medicine, University of California, San Francisco, San Francisco, United States; [2]Department of Surgery, University of California, San Francisco, San Francisco, United States.

Introduction: Psychiatric implications are the focus of many concerns about living organ donation. At UCSF, potential donors first complete a screening questionnaire that addresses medical history, current medications, and a review of systems. Once donors pass the initial screen, they are interviewed by an independent living donor advocate (ILDA) and/or social worker (SW). Donors deemed to be at increased psychological risk are subsequently evaluated by the consulting psychiatrist. The purpose of this study was to examine the prevalence of psychiatric comorbidities in our living liver donors and to determine the relationship between self-reported conditions and those identified during interviews with medical professionals.

Materials and Methods: We conducted a retrospective chart review of living liver donors at UCSF from January 2012-February 2016. Basic demographic data was obtained. Screening questionnaires were reviewed to determine whether the donor disclosed current or prior psychiatric conditions and/or psychiatric medications. Documented medical and social histories along with SW, ILDA, and psychiatry notes were reviewed for past psychiatric history, past psychiatric medications, current psychiatric diagnosis, current psychiatric medications, and current or prior therapeutic relationship with a psychiatrist or psychologist. Data are presented as median (interquartile range (IQR)) and differences were evaluated using Wilcoxon rank sum tests.

Results: 72 patients underwent living donor hepatectomy at our institution between 2012-2016. Donors were 53% female (38/72) with a median age of 32.7 (16-49.4) years. On self-reported questionnaire, 14% (10/72) of donors disclosed a current/prior psychiatric condition and 11.1% (8/72) reported psychiatric medication use. According to chart documentation, 33% (24/72) of donors had a current or prior psychiatric condition, 24% (17/72) had previously required psychiatric medication, and 39% (28/72) had seen a psychiatrist or psychologist at some point prior to donation (Figure 1).

At the time of donation, 24% (17/72) of donors had an Axis I psychiatric diagnosis, 8% (6/72) were on psychiatric medication, and 9.7% were in a therapeutic relationship. Of those with an Axis I diagnosis, 35% (6/17) reported a psychiatric condition on screening questionnaire. One hundred percent (6/6) of donors on psychiatric medications at the time of donation reported the medication previously. There was no significant association between psychiatric diagnosis and gender (p=0.867), relationship to recipient (related vs. unrelated, p=0.271), or marital status (p=0.402).

	Self-Reported	Reported During Interviews	Present at Donation
Psychiatric Condition	14%	33%	24%
Psychiatric Medication	11.1%	24%	8%
Current/Prior Therapeutic Relationship	N/A	39%	9.7%

Discussion and Conclusion: Potential living donors appear to under-report psychiatric conditions at the time of screening. This may be due to concern over candidacy for donation. These findings underscore the critical importance of thorough mental health screening carried out via in-person interviews prior to donation. It will be vitally important to examine the relationships among pre-donation psychiatric condition, post-operative course, and any complications.

326.4

Kidney transplant patient preferences and trade-offs for outcomes after transplantation.

Martin Howell[1,2], Germaine Wong[1,2,3], John Rose[4], Allison Tong[1,2], Jonathan C.Craig[1,2], Kirsten Howard[2].
[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [2]School of Public Health, University of Sydney, Sydney, Australia; [3]Centre for Transplant and Renal Research, Westmead Hospital, Sydney, Australia; [4]Institute for Choice, University of South Australia, Sydney, Australia.

Background: Patient preferences in clinical decisions are increasingly relevant, yet transplant patient perspectives through structured, quantified preference elicitation methods are unknown. We aimed to evaluate preferences and trade-offs patients may accept to avoid adverse outcomes of long-term immunosuppression.
Method: Preferences and trade-offs between graft duration and the risk of dying, cancer, cardiovascular disease (CVD), diabetes, infection, anxiety/depression, diarrhoea/nausea, and weight gain, was assessed using a best-worst scaling survey. Participants, recruited from three clinics, were shown 10 scenarios with varying outcome probabilities and years of graft duration and asked to choose best, next-best, worst and next-worst outcomes. Responses were analysed with multinominal-logit models.
Results: Ninety-three patients (age 18-69 years, transplant duration 0.9-31 years) completed the survey. The least desirable outcome was graft loss after one year with a preference value of 0.0 (95% CI: -0.05,0.05) and worse than any other outcome including 100% risk of dying with a preference value of 0.19 (95%CI:0.13,0.24). The most desirable outcome was a 0% risk of dying before graft loss with a preference value 1.0 (95% CI:0.92,1.08) which was more important than all other outcomes including 25 years of graft survival with a preference value 0.8 (95% CI:0.64,0.78). A low risk of CVD, cancer and serious depression/anxiety is of equal or greater importance to 15 years of graft duration. A high risk of serious adverse outcomes is equivalent to 5 to 15 years graft survival. Preferences varied with age, gender, comorbidities, years on dialysis years since transplant duration, and number of transplants. To achieve zero risk of cancer, dying, and anxiety/depression participants were willing to trade 3.1 (95%CI:2.10,4.69), 1.66 (95%CI:1.12,2.51), 1.21 (95%CI:0.82,1.83) years of graft survival, respectively, while to achieve a 10% risk, patients were willing to trade less than 1 year of graft survival for all adverse outcomes.
Conclusion: Elicitation of preferences and trade-offs for outcomes after transplantation has demonstrated a focus on long-term adverse outcomes that tend to be poorly addressed in clinical trials. This limits the ability for clinicians to effectively engage with patients in developing individualized care. Graft survival of 15 years represents a 'tipping' point in terms of the relative importance of adverse outcomes compared to duration of graft survival. Beyond 15 years, a low risk of CVD, cancer and serious depression/anxiety is of equal or greater importance than graft survival, while high risks of serious adverse outcomes including dying, are equivalent to (i.e. as bad as) graft survival of 5 to 15 years. The willingness to trade years of graft survival to avoid serious adverse outcomes is contingent on achieving a low, essentially zero risk of the adverse outcome.

326.5

"You killed him so that you can take the organs!" – Exploring novel factors influencing low cadaver organ donor rates in South Africa: Beyond religious beliefs and cultural practices

Harriet Etheredge[1], Claire Penn[2], Jennifer Watermeyer[2].
[1]Wits Donald Gordon Medical Centre, Johannesburg, South Africa; [2]School of Human and Community Development, University of the Witwatersrand, Johannesburg, South Africa.

South Africa (SA) is a low-to-middle-income country of great complexity and diversity. It is multi-lingual[1] and multi-cultural, characterised by significant socio-economic disparities[2] and SA people hail form a plethora of backgrounds. All these factors bring themselves to bear in the healthcare setting, and organ transplantation is no exception. A small number of transplants are performed across SA annually, but the country is faced with very low donor numbers relative to other parts of the world. Often, low donor numbers in SA are generalised to religious beliefs or cultural practices which are said to be fundamentally in opposition to the notion of organ donation[3]-[8]. This research challenged these assumptions, by exploring other potential explicators for low donor numbers, and associated ethical issues, in the unique SA context.
The study took place across 6 institutions using qualitative methods. Thirty in-depth interviews with transplant professionals, two focus groups with coordinators, two interviews with cadaver donor families, and one focus group with living kidney donors were conducted. Thematic analysis was undertaken.
Hospital staff and members of the public were found to sometimes be suspicious of biomedicine, and a perception that donors may be killed for their organs was held amongst both these groups. At the bedside, this translated into healthcare staff possibly influencing the family of a potential donor against organ donation before the transplant coordinator arrived. This could lead to bias and negatively affected meaningful informed consent. Suspicions about biomedicine and transplant were additionally complicated by sensational reporting of transplant happenings in the SA media, which further diminished trust in the institution. Socio-economic challenges in accessing healthcare were highly relevant, and sometimes resulted in a failure to identify potential donors. Moreover, even when they were in the system, it was found that physicians may be unwilling to refer brain-dead patients as potential donors, as this was seen as an admission of failure to fulfil one's professional duty to 'cure' the patient.
Religious beliefs and cultural practices may not influence organ donation decisions as much as published literature suggests, and a combination of multi-layered factors must be considered. To appreciate the reasons for low donor rates, the interplay of suspicions about biomedicine, sensational media-reports, socio-economic issues and clinical factors all require consideration. The complexity of these issues results in a situation where patient-centered care and informed consent may be compromised. The situation is further compounded by an overwhelming lack of donor referral policy or regulation. Recommendations include the need for a paradigm shift when discussing low donor numbers; nationwide, uniform donor policy and the necessity of greater governmental support for organ donation and transplant education.

Mobile apps to improve organ donation rate

Sunil Shroff, Sujatha Suriyamoorthi, Koti Reddy, Pallavi Kumar, Sumana Navin, Hemal Kanvinde.
Trustee, MOHAN Foundation, Chennai, India.

Introduction: Mobile apps have made rapid advances in healthcare and their popularity has been is due to the ease of their use and the dynamic portability on various mobile devices.
MOHAN Foundation, a NGO from India identified key areas where these app could make a difference and help in contributing to the overall increase of deceased donation rate in the country.
Material and Methods: *MOHAN Foundation have developed three apps in the field and include:*
a. e-donor card - for consumers,
b. Donor Optimization app- for ICU staff
c. Organ Registry / Allocation app - for administrators & transplant coordinators
These app were developed for both Android and iphone platform and are available free of cost on their store & on www.mohanfoundation.org website. The brain death app was developed in association with National Health Services & Blood Transfusion, UK .
The app have the following functionality:
The e-donor card app allows users to express their desire to be an organ donor, informs next of kin of their wishes, provides a list of 'FAQ's' related to organ donation, provides the latest news related to organ donation and can be used to invite friends to sign up for pledging organs
The donor optimization app allows an ICU staff to manage brain death and use it as a ready reckoner to manage various clinical scenarios that develop in its management.
The recipient registry /organ allocation app allows easy sharing of info with multiple transplant teams and keeps them updated of the progress of brain death.
Results: The number of downloaded of the app have been increasing from these stores. There have been over 1000 downloads of the e donor card app. The donor optimization app has undergone over 500 downloads. The recipient registry /organ allocation app is currently only for private network.
The app have been easy to use and has had positive feedback and a five star rating on the stores. Intensive care doctors have used the donor optimization app to manage brain deaths iin the odd hours of night. The allocation staff have found the app useful and has saved them from sending multiple sms's. The e-donor card is a popular app with youths and they have used it to popularize organ donation.

Discussion: Technology can be used effectively in the complex feild of transplantaion. The current mobile apps have been developed in India

to address and overcome some of the challenges that were encountered in the programme. India has almost 300 million smart phone users and the e-donor card is looking into tapping this vast pool to popularize the concept of organ donation. Donor optimization was required as many ICU staff who had never managed a brain death. Organ registry as mobile app simplifies access to computers in odd hours for organ allocation.

Conclusion: The three apps were developed to ease some of the key areas in this field and to facilitate the organ donation process with the objective to contribute towards increasing the organ donation rate.

Apps were developed for MOHAN Foundation by www.medindia.net - a leading health website from India

The "Doha model of organ donation" from adoption of the principles and recommendations of the "Declaration of Istanbul " in 2010 to inclusion of the implemented strategies in the new national transplant legislation - 2015

Riadh Fadhil.
Director of Qatar Organ Donation Center , Hamad Medical Corporation , Doha, Qatar.

Introduction: Qatar is a small Gulf country of 2 million people, mostly expatriate workers from South East Asia and the Middle East. Historically, Lack of awareness of organ donation and poor rate of donation in Qatar, compelled many wealthy patients to seek organs in foreign markets, returning to Qatar with high rates of morbidity and mortality. In response to these challenges, Qatar's major provider of health services, Hamad Medical Corporation (HMC) collaborated in 2009 with The Transplantation Society and the Declaration of Istanbul Custodian Group in development of the Doha Donation Accord (DDA). The DDA is an ethical framework that implements the recommendations of the Declaration of Istanbul designed to increase organ donation and prevent transplant commercialism. The DDA together with its strategies is now known as the "Doha Model of Organ Donation".

Materials and Methods: Implementation of the ethical principles and the evolving strategies of the Doha Model like the public education campaign, establishment of the deceased donation program, creation of the Donor Registry, formation of the ethical committee for living donor's evaluation, have increased domestic transplant activity from living related and deceased donors, and reduced travel from Qatar for commercial transplantation.

Results and Discussion: In August 2015, a new national transplant law (No.15) was introduced to ensure maintained implementation of the core strategies of the Doha model, the previous Qatar Organ Transplant Law 21 of 1997 insufficiently addressed the legal and ethical challenges of donation and transplantation. The new complementary sections of law 15 regulate the full implementation of the DDA e.g. recruitment for the donor registry; authority of the ethical committee for psychosocial evaluation of living donation, equitable access to deceased donor organs and transplant services, prohibition of financial incentives to donors and donor's family, removal of disincentives to donation, defining the authority of the Minister of Health in approving the DDA's provisions to the donors and donor families, fight commercialism, and prevention of commercial transplantation arising from Qatar. In addition to reconfirming sections imported from law 21 that regulate altruistic living donation, deceased donation and combat commercialism.

Conclusion: the Doha Model succeeded in adopting the principles and recommendations of the Declaration of Istanbul, customized it to address local challenges successfully and finally secured sustained future implementation through inclusion of the strategies in the local transplant legislation. This couldn't have been achieved without the persistence and commitment of all administrative and professional stakeholders.

Thanks to the support, partnership and guidance of the Declaration of Istanbul Custodian Group, the Doha Model has become a good example to all countries willing to develop successful ethical organ donation programs.

326.8

A qualitative study into the modus operandi, investigation and prosecution of organ trafficking networks in South Africa, Israel and Kosovo

Frederike Ambagtsheer[1], Jessica De Jong[2,3], Martin Gunnarson[4], Susanne Lundin[4,5], Ingela Byström[4], Willem Weimar[1].
[1]Department of Internal Medicine, Section Transplantation and Nephrology, Erasmus MC, Rotterdam, Netherlands; [2]Analysis and Research Dpt, Central Division of the National Police of the Netherlands, Driebergen, Netherlands; [3]Willem Pompe Institute for Criminal Law and Criminology, Utrecht University, Utrecht, Netherlands; [4]Department of Arts and Cultural Sciences, Lund University, Lund, Sweden; [5]Stellenbosch Institute of Advanced Study (STIAS), Wallenberg Research Centre , Stellenbosch University, Stellenbosch, South Africa.

Background: In 2010 a South African hospital plead guilty for allowing its doctors and other employees to conduct over 100 illegal kidney transplants. In 2013 in Kosovo doctors were convicted for participating in 24 illegal transplants. Both cases have a strong connection with Israel. In 2012 and 2013 we travelled to South Africa, Kosovo and Israel to study and compare a) the modus operandi of the criminal networks, and b) the successes and hurdles of authorities in the investigation and prosecution of the networks. This study formed part of the EU-funded HOTT Project on trafficking in human beings for the purpose of organ removal that aims to improve non-legislative responses to the crime.
Methods: We conducted fieldwork in each country. We performed 37 interviews with 49 persons. These were: police, prosecutors, legal experts, policy-makers, ministry representatives, health inspectors, patients, nephrologists, transplant surgeons, health insurance company representatives, defense attorneys, representatives of international organizations and national transplant coordinators. Interview transcripts were analyzed qualitatively. In addition, we studied case materials, including charge sheets, witness statements, indictments, closing statements and legislation.
Results: Using sophisticated modes of operation, both trafficking networks successfully conducted illegal transplants in an organized manner. Most of the recipients were of Israeli descent and were charged up to US$120,000 for a transplant. 'Donors' were recruited from Romania, the Russian Federation, Brazil, Israel, Kazakhstan and other Eastern European countries. They were (sometimes falsely) promised amounts between US$3,000 and $26,000. Both networks operated for a long time with relative impunity because of legal loopholes and corruption, and were discovered and prosecuted very differently. The local disruption of the criminal networks can be defined as the most important success, while the biggest hurdle in both cases comes down to international collaboration.
Conclusion: The prosecutions in these cases were successful but leave room for improvement. First, prosecutions could have been more successful if the appropriate laws would have been in place at the time when the activities took place. Second, investigations and prosecutions could have been initiated earlier if available signals were identified and picked up already at an early stage and if international collaboration would have occurred sooner. Based on this study, we developed indicators and recommendations that will benefit countries worldwide in recognizing, investigating and prosecuting organ trafficking.

326.9

Reporting organ trafficking networks: A survey-based plea to breach the secrecy oath

Frederike Ambagtsheer[1], Linde J.Van Balen[1], Wilma L.L.J.M.Duijst-Heesters[2], Emma K.Massey[1], Willem Weimar[1].
[1]Department of Internal Medicine, Erasmus MC, Rotterdam, Netherlands; [2]Department of Public Health, Radboud University , Nijmegen, Netherlands.

Introduction: The purchase of kidneys is prohibited in almost all countries. Nevertheless, patients buy kidneys and commonly travel overseas in order to do so. Transplant professionals (TPs) who treat these patients pre- and post-operatively can play a role in identifying and reporting kidney purchase. However, TPs report a tension between their obligations to provide medical care and maintain secrecy on the one hand and their duty to prevent harm on the other.
Methods: We present the results of a national survey that describes transplant professionals' experiences, attitudes, behaviors, conflicts of duties, legal knowledge and needs for guidelines towards patients who purchase kidneys abroad.
Results: Of the 546 TPs who were invited, 241 (44%) completed the survey. Between 2008 and 2013, 100 (42%) professionals treated patients that traveled to a country outside the European Union for a kidney transplant. Thirty-one of the 100 TPs (31%) were certain that patients purchased kidneys. Sixty-five (65%) had suspicions that patients had bought kidneys Whereas most professionals (85%) understood why patients bought kidneys, they also felt that they have a duty to prevent organ purchase (72%). Participants experienced a conflict of duties (65%) when suspicions of purchase occurred. Eighty percent reported a need for guidelines in dealing with patients who will or have purchased a kidney.
Conclusion: TPs can contribute to eradicating the harm and suffering inflicted on patients and donors by anonymously disclosing information about organ trafficking networks to law enforcement. Reporting information such as the names of hospitals, clinics, cities, hospital staff and other individuals who are involved in potentially illegal transplant activities, is a more effective way to disrupt and deter organ trafficking than reporting patients. We propose that guidelines are established for TPs to disclose information that supports the police and judiciary in investigating, disrupting and prosecuting the facilitators of illegal transplantations. We offer key components for guidelines on disclosure of these networks.

326.10

A systematic review on the prevalence of patients who purchase organ transplants abroad

Frederike Ambagtsheer[1], Jessica De Jong[2,3], Wichor Bramer[4], Willem Weimar [1].
[1]Department of Internal Medicine, Transplantation and Nephrology, Erasmus MC, Rotterdam, Netherlands; [2]Analysis and Research Dpt, Central Division of the National Police, Driebergen, Netherlands; [3]Willem Pompe Institute for Criminal Law and Criminology, Utrecht University, Utrecht, Netherlands; [4]Medical Library, Erasmus MC, Rotterdam, Netherlands.

Background: Over the years, the trade in human organs has become an object of international concern. Whilst first regarded as an organ theft rumour, organizations including such as the World Health Organization (WHO) the Council of Europe now present it as a lucrative and serious form of organized crime that exploits vulnerable donors worldwide. The WHO estimated in 2007 that 5-10% of the approximately 60,000 kidney transplants performed annually around the globe occur via organ trade. We present a systematic literature review about the number of patients that purchased organs. With this information we discuss whether a scientific basis exists for the claim that organ purchase is a frequent occurrence.
Methods: We searched Embase, Medline, Web of Science, Scopus, PubMed, Cochrane and Google Scholar. The methodology and results of this systematic literature review are in line with the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) guidelines. All English studies published in full text after 1 January 2000 were included. Presentations, abstracts, opinion papers, non-English records and publications lacking methodology were excluded.
Results: Between 2000 and 2015, 86 studies were published. Seventy-six of these presented patients who traveled and 42 stated that the transplants were commercial. Only 11 studies reported that patients paid and 8 described to what or whom patients paid. In total, over a period of 42 years, 6002 patients have been reported to travel for transplantation. Of these, only 1238 were reported to have paid for their transplants. Patients paid between $10,000 and $200,000 for kidney transplants. Liver transplants were more expensive (range $40,000-$300,000). Eight articles describe to what or whom patients paid. These papers report 158 patients in total. Of these, 129 paid their donors, 22 paid brokers, five paid to hospitals, two paid to private companies and an unknown number paid doctors for a transplant. An additional unknown number of patients paid for their transplants in their native countries.
Conclusion: We conclude that the literature is speculative and anecdotal about patients buying organs: their purchases are more often assumed than determined. This hampers the drawing of firm conclusions about the scale of patients' involvement in the trade. The empirical data published in the literature does not provide a basis for the claim that large numbers of patients purchase organs worldwide on a frequent basis. More rigorous quantitative and qualitative research is needed to enable a more reliable picture of the trade's scale. A reporting code for transplant professionals to report organ trafficking networks is a potential strategy to collect and quantify cases.

326.11

A kidney paired donation standard acquisition charge pilot program

Michael A. Rees[1,2], Laurie J.Reece[2], Susan E.Rees[2], Betty Crandall[3], Alan B.Leichtman[4].
[1]Urology, University of Toledo Medical Center, Toledo, United States; [2]Alliance for Paired Donation, Perrysburg, United States; [3]Transplant Surgery, Wake Forest Baptist Health, Winston Salem, United States; [4]Arbor Research Collaborative for Health, Ann Arbor, United States.

Background and Purpose: A United States non-profit Kidney Paired Donation (KPD) organization undertook a demonstration project to redesign payment for KPD transplants with a payment model similar to the current approach for deceased donor cost recovery—utilizing a standard acquisition charge (SAC). A 2012 Consensus Conference on KPD concluded a national SAC would remove many of the financial barriers and create cost certainty for transplant (Txp) centers. Aim One of the grant: Collect actual financial data from a clinically active KPD program to allow calculating the real-life cost per KPD transplant.
Methods: Over a number of months, stakeholders agreed on what costs should be reimbursed. Notably, the group decided on the appropriate tests included in the donor evaluations. Further, they compiled de-identified data on the current costs for the nephrectomy facility charges; the surgeon and anesthesiologist professional fees; and costs to pack and ship a living donor kidney. The de-identified data included the Medicare reimbursement rate for their geographic area plus average commercial insurance reimbursement calculated from 3 commercial payers of their choosing. The study started slowly, as it was necessary not only to achieve consensus, but for the Centers for Medicare and Medicaid Services (CMS) to give the awardee permission to move forward, as the project had direct implications for a Txp center's Medicare cost report. Approval was given in June 2014, and Txp centers formalized with their participation via a written agreement.
Results: The initial study was designed to provide reimbursement to Txp centers only for donor evaluations related to KPD; but it became obvious that in order to attract more centers to participate (thus broadening access for patients desiring KPD), paying centers for KPD donor nephrectomy was highly desired. The project evolved to one that paid participating centers for the cost of: donor evaluation, nephrectomy, surgeon & anesthesiologist's fees, and packing and shipping a kidney donated for KPD. In return, the Txp center receiving the donated kidney agreed to pay the organization a KPD SAC following transplantation of such a kidney. To date, 49 transplants have been performed using the KPD SAC mechanism since initiation in 2015.
Conclusion and Implications: This Agency for Healthcare Research and Quality (AHRQ)-funded project overcomes barriers to creating additional living donor kidney transplants in the United States, leading to improved quality of care, increased access to care, and reduced cost. A similar strategy could be used to facilitate international kidney exchanges involving shipped kidneys.
Grant funding provided by the Agency for Healthcare Research and Quality in the United States, grant number R18 HS-020610

326.12

Research priority setting in solid organ transplantation: a systematic review

Claudia Harper[1,2], Jonathan C.Craig[1,2], Jeremy R.Chapman[3], Allison Tong[1,2].
[1]Sydney School of Public Health, The University of Sydney, Sydney, Australia; [2]Centre for Kidney Research, The Children's Hospital Westmead, Sydney, Australia; [3]Centre for Transplant and Renal Research, Westmead Hospital, Sydney, Australia.

Introduction: The lack of transparency and exclusion of patients in determining research priorities can lead to wasteful allocation of limited resources into areas that may not be important to stakeholders, particularly patients. The purpose of this study is to evaluate approaches to research prioritization for solid organ transplantation and to identify the research priorities of patients in need of an organ transplant, their caregivers, the healthcare providers involved in their care, and policy makers.
Materials and Methods: Electronic databases were searched from inception to December 2015. Studies that elicited patient, caregiver, healthcare provider, or policy maker priorities for research in solid organ transplantation were included.
Results: We identified 26 studies (n=1582 participants) conducted in the United States, the Netherlands, Australia, Canada and internationally. The studies focused on kidney (8 studies), heart (7 studies), liver (3 studies), lung (1 study), and non-specified solid organ transplantation (7 studies). Various priority setting methods were used including the Delphi technique, expert panels, consensus conference, ranking or voting surveys, focus groups and interviews, of which the process was described in detail by 16 (62%) studies. Only eight (31%) studies reported patient involvement. The priority areas for research were: organ allocation (19 studies); immunosuppression (15 studies); transplant complications (15 studies); donor and recipient quality of life (12 studies); organ donation (12 studies); and improving patient-provider communication (5 studies).
Discussion: The priorities identified by organ transplant research priority setting exercises are broad ranging. However, patients explicitly set few of the priorities. Further, the methods used to establish the research priorities in most of the studies lacked clarity.
Conclusion: To ensure that research is done in areas that are relevant to the users of the research, research priorities should instead be set using a prespecified and transparent process that engages patients, caregivers, and healthcare providers, not solely transplant experts.

Health-related quality of life improves further after liver transplantation and is influenced by length of stay

Louis Onghena[1], Wouter Develtere[1], Xavier Rogiers[2], Roberto Troisi[2], Frederik Berrevoet[2], Aude Vanlander[2], Anja Geerts[1], Hans Van Vlierberghe[1], Xavier Verhelst[1], Carine Poppe[3].
[1]Gastroenterology and Hepatology, University Hospital Ghent, Ghent, Belgium; [2]Hepatobiliary Surgery and Transplantation Medecine, University Hospital Ghent, Ghent, Belgium; [3]Transplantation Center, University Hospital Ghent, Ghent, Belgium.

Background and Aims: Liver transplantation (LT) is the only curative treatment for end-stage liver disease (ESLD) with excellent long-term outcomes. However, an important outcome parameter is health-related quality of life (QoL). Improvement of QoL has been described after liver transplantation. We wanted to investigate the evolution in QoL in a period of two years after LT and identify factors influencing this evolution.
Methods: We performed a cross-sectional study in a liver transplant unit. Self-report questionnaires (SF36, ICQ and NEO-FFI) were conducted in 177 patients with ESLD: 60 patients pre-transplantation, 60 post-transplantation and control group of 57 patients without perspective of transplantation. Data were analyzed using the Mann-Whitney U test, Spearman's rank correlation coefficient and correlation matrices.
Results: The post-LT patient group consists of 63,0% male individuals and 20,0% had no complications. Mental QoL shows a 19,0% elevation in two years post-LT whereas physical QoL knows a 54,8% elevation in two years post-LT, of which 46,5% the first six months. We observed a significant increase in physical QoL >3 months compared to £3 months after LT (p=0,027), as well as a significant increase in disease benefits (p=0,018).
In a period of two years post-LT a significant correlation (p<0,001) was found in QoL (physical and mental) compared with length of stay in intensive care (rs=-0,359 and rs=-0,324), length of stay in total (rs=-0,327 and rs=-0,347), helplessness (rs=-,0771 and rs=-0,797), acceptance (rs=0,679 and rs=0,710) and disease benefits (rs=0,514 and rs=0,436). Length of stay on intensive care >6 days post-LT shows a significantly worse physical QoL up to two years post-LT (p=0,023).
Conclusions: These data confirm an increase of QoL during two years post-LT. A better acceptance of illness, a reduction in helplessness and more benefits of the illness after transplantation result in a better QoL. We assume that these findings indicate that patients' illness cognitions are of great influence on QoL. A longer stay in intensive care implies longer immobilization, which negatively influences physical QoL. Patients who spent more than six days on intensive care post-LT deserve a more intense physical rehabilitation. These aspects could give new directions in the approach of liver patients after transplantation.

CD4+CD25+FoxP3+ Treg cells are critical to tolerance induction by SA-FasL-engineered porcine islets transplanted into mice

Esma S.Yolcu[1], Kyle Woodward[1], Hong Zhao[1], Feng Wang[1], Melanie Graham[2], Bernhard Hering[2], Haval Shirwan[1].
[1]Institute for Cellular Therapeutics and Department of Microbiology and Immunology, University of Louisville, Louisville, KY, United States; [2]Schulze Diabetes Institute and Department of Surgery, University of Minnesota, Minneapolis, MN, United States.

Introduction: We have shown that porcine islets engineered to transiently display SA-FasL protein on their surface establish tolerance in mice following transplantation under the kidney capsule or intraportally. This study was designed to elucidate the mechanistic basis of the observed tolerance.
Methods: Islet grafts, graft-draining LNs, and spleen were collected from C57BL/6.FoxP3DTR/GFP recipients of SA-FasL-engineered porcine islets in a time course study (n=6/time point) on days 3, 6, 12 post-transplantation and at experimental end-points (>200 days). Lymphocytes were stained with antibodies to various cell surface markers to identify T effector, T effector memory, T central memory, induced and natural Treg cells, and various innate immune cells using flow cytometry. Lymphocytes were also analyzed for intracellular cytokines following ionomycin and PMA stimulation. Treg cells were depleted early or late post-transplantation using diphtheria toxin. Long-term mice were also challenged with BALB/c allogeneic skin to test the immune competency and islet-specific tolerance.
Results and Discussion: Long-term (>200 days) recipients of porcine islets rejected BALB/ skin grafts in an acute fashion (MST=11.3±1.0) without any detrimental effect on the survival of porcine islets, demonstrating immune competency and antigen-specificity of tolerance. Extensive lymphocyte phenotyping and intracellular cytokines established the increased ratio of Treg/T effectors and induced/natural Treg cells within graft draining LNs of long-term survivors as the correlate of tolerance for both intraportal and subrenal islet transplantation sites. Depletion of Treg cells early (15 days) or late (60 days) post-transplantation resulted in prompt graft rejection in both settings.
Conclusion: Immunomodulation with SA-FasL-engineered porcine islet grafts serves as an effective means of tolerance induction in a xenograft model. Tolerance appears to be localized to the graft and Treg cells are prerequisite for tolerance induction.

327.2

Dual phases and mechanistic basis of tolerance induced by allogeneic pancreatic islets engineered with SA-FasL protein

Esma S.Yolcu, Kyle Woodward, Hong Zhao, Haval Shirwan.
Institute for Cellular Therapeutics and Department of Microbiology and Immunology, University of Louisville, Louisville, KY, United States.

Introduction: We have recently shown that pancreatic islets engineered to display on their surface a chimeric form of FasL with streptavidin (SA-FasL) induce robust allotolerance under the transient cover of rapamycin. Tolerance at the maintenance phase was localized to the graft. We herein tested if tolerance is systemic at induction phase and elucidated underlying mechanisms.
Methods: C57BL/6 mice were transplanted with BALB/c SA-FasL-islets under the transient cover of rapamycin administered on the day of Tx daily for 15 days. BALB/c SA-islets served as control. Systemic tolerance was tested by simultaneously transplanting unmodified donor islets with SA-FasL-engineered islets separately under contralateral kidney capsules. Unmodified islets from C3H mice and skin and heart grafts from BALB/c mice were used to test antigen and tissue specificity of tolerance. To test the role of Treg cells in the systemic and localized tolerance, these cells were depleted early or late post-transplantation.
Results and Discussion: Tolerance was systemic and antigen-specific as recipients with BALB/c SA-FasL-engineered islets rejected unmodified islets from C3H, but not those from BALB/c. Tolerance was also tissue specific as the recipients of SA-FasL-engineered BALB/c islets rejected both skin and heart from the same donor. Importantly, rejection of BALB/c skin and heart grafts precipitated rejection of SA-FasL-engineered islets. Tolerance involved CD4+CD25+FoxP3+ Treg/phagocytes/TGF-b axes as depletion of phagocytes or Treg cells or blockade of TGF-b at the induction phase resulted in acute islet graft rejection. Most importantly, tolerance at the maintenance phase was localized to the graft and required the presence of graft-localized Treg cells.
Conclusion: Immunomodulation with SA-FasL-engineered allogeneic islets results in donor and tissue-specific systemic tolerance that becomes localized to the graft at the maintenance phase. The presence of graft was the key driving factor for retention of Treg cells within graft microenvironment and maintenance of tolerance.

The influence of dissociation enzymes on isolated islets during pancreatic islet isolation procedures

Yuki Miyazaki[1], Takehiro Imura[2], Youhei Yamagata[3], Hiroshi Maeda[3,4], Kazutaka Murayama[5], Kimiko Watanabe[4], Akiko Inagaki[2], Yasuhiro Igarashi[2], Noriaki Ohuchi[1], Susumu Satomi[1], Masafumi Goto[1,2].
[1]Division of Advanced Surgical Science and Technology, Tohoku University School of Medicine, Sendai, Japan; [2]Division of Transplantation and Regenerative Medicine, Tohoku University School of Medicine, Sendai, Japan; [3]Department of Applied Biological Chemistry , Graduate School of Agriculture, Tokyo University of Agriculture and Technology, Tokyo, Japan; [4]New Industry Creation Hatchery Center, Tohoku University, Sendai, Japan; [5]Division of Biomedical Measurements and Diagnostics, Graduate School of Medical Engineering, Tohoku University, Sendai, Japan.

Introduction: It has been reported that tissue dissociation enzymes, especially neutral proteases, impair the viability of isolated islets during pancreatic islet isolation procedures. Here, in the present study, we examined whether the dissociation enzymes *per se* cause damages on isolated islets using highly purified collagenases and neutral protease.
Materials and Methods: Islets isolated from male Lewis rats were co-cultured with Liberase MTF and thermolysin (enzyme group), or digested solutions of pancreatic tissues (solution group) at 37℃ for 120 minutes. The digested solutions were prepared after centrifuging and filtrating the dissociated pancreatic tissues at 30 minutes in digestion procedures. In the control group, islets were co-cultured with HBSS (Hanks' Balanced Salt Solution), and HEPES was added in all groups. After 2 hour co-culture, appearance of islets, ADP/ATP ratio, ATP/DNA, static glucose stimulation test and FDA/PI were evaluated. Furthermore, according to above results, we investigated whether trypsin or chymotrypsin deteriorated islet viability by means of co-culturing islets with five times higher concentration of trypsin or chymotrypsin than that in normal digested solutions of pancreatic tissues.
Results and Discussion: Islet appearance was remarkably aberrant in only the solution group. In the solution group, the ADP/ATP ratio was significantly higher than that of the HBSS group and enzyme group (0.176±0.040 VS 0.002±0.002, 0.012±0.012; p=0.01), and the ATP/DNA was significantly lower than that of the other groups (36.8±2.9 vs 56.1±3.0, 51.4±4.8; p=0.01). Stimulation index of static glucose stimulation test was considerably lower in the solution group than that of the other groups (4.46±0.59 vs 29.42±18.78, 15.66±6.56). These data suggest that isolated islets were damaged by digested solutions of pancreatic tissues, but not by dissociation enzymes. Therefore, the involvement of endogenous proteases, especially trypsin or chymotrypsin which have been considered detrimental to the islets, on islet damages was strongly inferred. However, of particular note, no detrimental effects of trypsin or chymotrypsin on islet viability were observed (ADP/ATP ratio: 0.014±0.008, 0.000±0.000, ATP/DNA: 62.2±2.5, 62.3±1.7).
Conclusions: The present study reveals that tissue dissociation enzymes *per se* seem to be harmless on the islets, but indirectly relevant to the islet damages by activating endogenous proteases derived from pancreatic exocrine tissues. These endogenous proteases, unlike trypsin or chymotrypsin, might be novel strategic targets towards improving the quality of isolated islets.

Pretreatment of donor islets with papain improves allograft survival without systemic immunosuppression in mice

Kenjiro Kumano[1,2], Hitomi Nishinakamura[1,3], Toshiyuki Mera[4], Takeshi Itoh[1,5], Hiroyuki Takahashi[1,4], Toshiyoshi Fujiwara[2], Shohta Kodama[1,5].
[1]Department of Regenerative Medicine and Transplantation, Fukuoka University, Fukuoka, Japan; [2]Department of Gastroenterological Surgery, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan; [3]Department of Pharmacology, Fukuoka University, Fukuoka, Japan; [4]Department of Gastroenterological Surgery, Fukuoka University, Fukuoka, Japan; [5]Center for Regenerative Medicine, Fukuoka University Hospital, Fukuoka, Japan.

Introduction: Current immunosuppression protocols improve the efficacy of clinical allogeneic islet transplantation (tx). However, high-dosage immunosuppressant therapy is a risk factor for the incidence of infection and oncogenesis in the recipients. Thus, the dosage of systemic immunosuppressant should be minimized. One possible approach to minimize the dosage of immunosuppressant is reducing the immunogenicity of donor islet cells. Major histocompatibility complex (MHC) class I on the donor islet cells play a crucial role in T cell-mediated allograft rejection after islet tx in human and mice. It has been previously reported that papain, a cysteine protease enzyme, has the unique ability to cut the extracellular domain of MHC class I heavy chain, and also reported that pretreatment of allogeneic donor lymphocytes with papain inhibited the activation of host human T cells in mixed lymphocyte reaction assay in vitro. From these backgrounds, we hypothesized that pretreatment of donor islets with papain may reduce the expression of MHC class I on islet cell surface, reducing allografts immunogenicity, and contributing to the prolongation of islet allograft survival in mice.
Materials and Methods: BALB/c islets were transplanted into C57BL/6 mice. Prior to the tx, 200 islets were pretreated with papain at 1 or 10 mg/mL for 15 minutes, or left untreated as control, and then transplanted beneath the kidney capsule of streptozotocin-induced diabetic recipient mice.
Results and Discussion: The graft survival of control (n=10), pretreatment with papain 1 mg/mL (n=11) and 10 mg/mL (n=5) was 20.4±2.0, 54.2±13.4 and 13.6±1.2 days, respectively (mean±se, $p<0.05$ between untreated control and papain 1 mg/mL), and papain 1 mg/mL group showed significantly higher graft survival rate in the three groups ($p<0.001$). Flow cytometric analysis revealed that the MHC class I positivity on islet cells was approximately 10% lower in papain 1 same as 10 mg/mL groups when compared to control, indicating that papain treatment reduces the expression of MHC class I on islet cells. To investigate the effects of papain pretreatment on the inhibition of host T cell activation, we performed in vitro T cell proliferation assays. Host T cell activation against allogeneic lymphocytes was inhibited by the pretreatment of donor lymphocytes with papain 1 or 10 mg/mL when compared to control. Furthermore, host T cell activation against allogeneic islet cells was also suppressed by the pretreatment of donor islet cells with papain 10 mg/mL in a mouse model.
Conclusion: Pretreatment of donor islets with papain suppresses MHC class I-mediated allograft rejection, and contributes to the prolongation of islet allograft survival without administrating systemic immunosuppressant in mice. These results suggest that pretreatment of human donor islets with papain may reduce the immunogenicity of the donor islets and minimize the dosage of systemic immunosuppressant required in a clinical setting.

Sustained euglycemia after islet xenotransplantation in diabetic NOD mice using novel purification and encapsulation technologies

Michael Alexander[1], Antonio Flores[1], Sarah Lee[1], Nick Neel[1], Shiri Li[1], Paul de Vos[3], Jonathan Lakey[1,2].
[1]Surgery, University of Calfornia Irvine, Orange, United States; [2]Biomedical Engineering, University of Calfornia Irvine, Irvine, United States; [3]University Medical Center Groningen, Groningen, Netherlands.

Background: Islet transplantation has been demonstrated as potential option for those patients suffering from diabetes. Limitation are lack of sufficient viable pancreatic islets and chronic immunosuppression. Encapsulation islets has been a potential option for decades, however this technology has been limited in its success, especially in autoimmune diabetes. We have addressed current limitations of material selection, purification, and addressed issues of manufacturing to produce consistent 400 µm diameter purified alginate capsules.
Experimental Methods: Sprague-Dawley rat islets were isolated using standard methods of enzymatic distension, collagenase digestion, and Ficoll purification. Aliquots of islets were counted using dithizone stained aliquots and viability was measured using FDA/PI. Islets were then encapsulated using chemically and mechanically purified UPLVM alginate (Novamatrix) (gp 1). Control groups of islets were encapsulated using standard published techniques (gp 2). Non-transplanted diabetic mice (gp 3) served as diabetic control. NOD mice, 9-10 weeks old, were made diabetic using a single injection cyclophosphamide (200 mg/kg). After hyperglycemia was confirmed (3+ days of non-fasting blood glucose from tail capillary over 350 mg/dL) mice received encapsulated islet transplant into the peritoneal cavity (groups 1 and 2, n=10 per group). Mice were monitored daily, with blood glucose 3x/wk, body weight weekly and OGTT at 1 month post-transplant before histological evaluation including CD68, Masson Trichrome, insulin/glucagon.
Results and Discussion: In vitro results: Viability of islets was 93±1% (mean±SEM, n=10) post isolation and 92±2% post-encapsulation (p=ns, t-test). Islets were functional, with a stimulated GSIR of 4.3±1.2, compared to post encapsulation GSIR of 2.4±0.6 (gp 1, p=ns) and 1.9±0.1 (gp 2, p=ns). (gp 2, $p<0.05$). In vivo results: Control mice remained hyperglycemic for >30 days after diabetes induction (n=7). In diabetic NOD mice transplanted with our novel alginate purification methods, 8 of the 10 mice gp 1 showed immediate reversal of hyperglycemia and sustained euglycemia (bg < 200 mg/dL) within 2 days of transplant. Gp 2 mice also reversed hyperglycemia, but within 3-5 days retuned back to the diabetic state ($p<0.05$). OGTT in euglycemic mice at 30 days post txp (gp1) showed equivalent function to non-transplanted controls (p=ns). Histological evaluation of peritoneal cavity flush showed islets within intact capsules (gp 1), compared to free but damaged islets surrounded by immune cells, and debris from destroyed capsules (gp 2).
Conclusion: Using our novel alginate purification strategies an encapsulation system is capable of protecting encapsulated xenogeneic islets in the autoimmune diabetic NOD mouse model, significantly better outcomes than using standard alginate. Our goal is to adapt this novel purification and encapsulation system into large animal model and clinical trial of patients with diabetes.

Cotransplantation of preactivated mesenchymal stem cells inhibits liver natural killer cell–induced islet graft injury during instant blood-mediated inflammatory reaction after syngeneic intraportal islet transplantation

Nobuki Ishida, Kohei Ishiyama, Fumihiro Hirata, Yoshihiro Saeki, Yuka Tanaka, Hideki Ohdan.
Department of Gastroenterological and Transplant Surgery, Hiroshima University, Hiroshima, Japan.

Introduction: Cotransplantation of islets with mesenchymal stem cells (MSCs) improves graft survival by enhancing graft revascularization and causing secretion of antiapoptotic signaling molecules. We previously showed that activation of cytokine-stimulated liver natural killer (NK) cells, which play a crucial role in transplanted islet destruction, was significantly suppressed on coculture with MSCs in vitro. We also found that liver NK cells were activated under instant blood-mediated inflammatory reaction (IBMIR), which occurred immediately after islet transplantation (IT). Inflammatory cytokine stimulation is known to enhance the immunomodulatory function of MSCs; however, little is known about phenotypical and functional alterations of MSCs during IBMIR after cotransplantation with islets. Here, we examined whether cotransplantaion of MSCs preactivated with IFN-γ, TNF-α, and IL-1β, which are actively produced under IBMIR conditions, could suppress liver NK cell activation after intraportal IT.
Methods: To analyze phenotypical alterations in liver NK cells after syngeneic intraportal IT, liver mononuclear cells were collected 3 days after intraportal administration of 300 islets with or without bone marrow-derived MSCs (0.5×10^6) from C57BL/6 mice. Furthermore, to examine the suppressive effect of cotransplantation of preactivated MSCs, MSCs were cultured for 24 hr with inflammatory cytokines (IFN-γ, TNF-α, and IL-1β) before IT.
Results: Liver NK cells are classified into two subsets based on DX5 expression. $DX5^-$ NK cells are considered as liver resident population which expresses high levels of TRAIL and CD69, while $DX5^+$ NK cells are considered as conventional population. $TRAIL^+$ $DX5^-$ NK cells proportion at 3 days after intraportal MSC administration was significantly lower than that in the naive condition (43.1% ± 14.3% vs. 71.9% ± 9.6%, $p < 0.05$). CD69 and TRAIL expression on liver NK cells after intraportal IT was significantly higher than that in the naive condition (72.3% ± 10.1% vs. 29.0% ± 5.6%; $p < 0.01$, 43.2% ± 6.7% vs. 37.4% ± 6.6%; $p < 0.01$, respectively). In contrast, CD69 expression on liver NK cells after cotransplantation of islets with preactivated MSCs was significantly lower than that in IT alone (52.1% ± 4.4%, $p < 0.01$); however, TRAIL expression on liver NK cells did not show a significant difference (36.1% ± 10.7%, $p = 0.21$). CD69 and TRAIL expression on liver NK cells was somewhat suppressed when naive MSCs were cotransplanted with islets ($p = 0.08$, $p = 0.99$, respectively). Furthermore, the $DX5^-$ NK cell proportion after cotransplantation of islets with preactivated MSCs was significantly lower than that in IT alone (37.7% ± 4.4% vs. 50.2% ± 8.7%, $p < 0.05$).
Conclusion: This is the first report to show that IBMIR conditions after IT potentially enhance the immunomodulatory function of cotransplanted MSCs, although IBMIR conditions themselves are considered harmful for islet grafts. Our findings imply that cotransplantation of islets with preactivated MSCs could improve islet graft survival after IT by suppressing NK cell activation in the liver.

SA-FasL-engineered porcine islets induce tolerance in mice following intraportal transplantation

Esma S.Yolcu[1], Hong Zhao[1], Kyle Woodward[1], Melanie Graham[2], Bernhard Hering[2], Haval Shirwan[1].
[1]Institute for Cellular Therapeutics and Department of Microbiology and Immunology, University of Louisville, Louisville, KY, United States; [2]Schulze Diabetes Institute and Department of Surgery, University of Minnesota, Minneapolis, MN, United States.

Introduction: We have recently demonstrated that allogeneic islets engineered to transiently display on their surface a novel form of FasL protein chimeric with streptavidin (SA-FasL) induce tolerance in allogeneic mouse models. In this study, we tested the efficacy of this approach in inducing tolerance to porcine islets transplanted into mice using two different transplant sites; subrenal and intraportal.
Methods: Porcine islets were modified with 5 μM biotin and engineered with SA-FasL protein (~200 ng/1000 islets). SA-FasL-engineered islets were transplanted under the kidney capsule (~2000 islets/transplant) or intraportally (2,500 islets/transplant) in streptozotocin diabetic C57BL/6 mice under a transient cover (20 days) of rapamycin. Unmodified pancreatic islets with rapamycin treatment served as controls.
Results and Discussion: Porcine islets were effectively engineered with SA-FasL protein without a detrimental effect on their viability and function. SA-FasL-engineered islets induced apoptosis in responding mouse T cells in in vitro co-culture experiments. All control grafts with transient rapamycin treatment were rejected within 30 days post-transplantation. In marked contrast, all SA-FasL-engineered porcine grafts showed prolongation and ~60% of intraportal (n=37) and ~80% of subrenal (n=22) grafts survived for a 300-day observation period. Intraperitoneal glucose tolerance test demonstrated normal function of long-term islets, with the subrenal model performing better than the intraportal model. There was no detectable signs of acute or chronic toxicity of the procedure. The long-term euglycemia was due to the transplanted porcine islets as the surgical removal of the grafts resulted in prompt hyperglycemia.
Conclusion: SA-FasL as an immunomodulatory molecule is effective in inducing tolerance to porcine islet grafts transplanted subrenally as a standard site in rodents and intraportally as a clinically applicable yet immunologically more challenging site.

Anti-inflammatory CD169+ TIM-4+ islet resident macrophages induce Tregs and prolong allograft survival

Periklis Kyriazis, Thomas Thornley , Krishna Agarwal , Lingzi Ma, Vaja Chipashvili, Sarantis Korniotis, Terry Strom , Maria Koulmanda.
Department of Medicine - Surgery, Beth Israel Deaconess Medical Center/Harvard Medical School, Boston, MA, United States.

We previously characterized an immunoregulatory islet resident macrophage subset that expresses CD169 and TIM-4, dwells in heart and skin, promotes FoxP3+ Treg generation, and promotes allograft survival. Now, we report on the existence of a kindred CD169+TIM-4+ islet resident macrophage subset that is located within pancreatic islets from C57BL/6 mice and control human subjects. Compared to islet resident DCs (IRDCs), islet resident macrophages (IRMs) express higher levels of immunoregulatory CD39, CD73, and galectin-9. In vitro, bm12(I-Abm12) IRMs induced much greater Foxp3+ Treg conversion (20.9+/-6.12%) as compared to bm12 IRDCs (3.41+/-1.61%, $p<0.001$) in naïve CD4+ABM TCR transgenic T cells that express an alloreactive clonotypic anti I-A bm12 TCR. Surprisingly, genetic TIM-4 deletion increases the survival and absolute number of tissue resident macrophages that migrate to the draining lymph nodes following oxidative stress. Donor TIM-4 deletion promotes long-term islet allograft survival (>110 days) in 2/5 islet transplant recipients as compared to 0/4 mice that received wild type control islets. As CD169+ TIM-4+ IRMs are present in large numbers in donor islets, possess a potent immunoregulatory phenotype, powerfully induce FoxP3+Tregs, and promote islet allograft survival, we believe that CD169+TIM-4+ IRMs are a potential therapeutic target in islet allograft transplantation.

Endoscopic biopsy of islet transplants in the gastric submucosal space provides evidence of islet graft rejection in diabetic pigs.

Hidetaka Hara[1], Takayuki Tanaka [1], Minoru Fujita [1,5], Rita Bottino [2], Jon D.Piganelli[2], Kevin McGrath[3], Jiang Li[1], Whayoung Lee[1], Hayato Iwase[1], Martin Wijkstrom[1], Suzanne Bertera[2], Cassandra Long[1], Douglas Landsittel[4], Ken Haruma[5], David K.C.Cooper[1].
[1]Surgery, University of Pittsburgh, Pittsburgh, PA, United States; [2]Pediatrics, University of Pittsburgh, Pittsburgh, PA, United States; [3]Gastroenterology, Hepatology and Nutrition, University of Pittsburgh, Pittsburgh, PA, United States; [4]Biostatistics and Clinical and Translational Science, University of Pittsburgh, Pittsburgh, PA, United States; [5]Internal Medicine, Kawasaki Medical School, Kurashiki, Japan.

Introduction: Transplantation of islets into the gastric submucosal space (GSMS) has several advantages (e.g., avoidance of the instant blood-mediated inflammatory response [IBMIR], ability to biopsy). The aim of this study was to determine whether endoscopic biopsy of islet allografts transplanted into the GSMS in diabetic pigs can provide histopathological and immunohistochemical information that correlates with the clinical course (e.g., blood glucose level, insulin requirement).
Materials and Methods: Islet allografts (Group1: 10,000IEq /kg [n=4]; Group2: 15,000IEq /kg [n=2]) were transplanted into the GSMS of streptozotocin-induced diabetic pigs under immunosuppression. In Group2, the anti-oxidant, BMX-001 was applied during preservation, isolation, and culture of the islets, and at the time of transplantation. Endoscopic biopsies of the islet grafts were obtained one or two weeks after transplantation, and histopathological features were compared with the clinical course (e.g., blood glucose, insulin requirement).
Results: While Group1 insulin-positive islets were fragmented, Group2 grafts showed preserved islet morphology. Cell infiltration was observed in biopsies and necropsies (4 weeks) from both groups, and most of the infiltrating cells were positive for CD3 and CD68. In Group1, in the absence of anti-oxidant therapy, there was no reduction in exogenous insulin requirement. In Group2, with an increased number of transplanted islets in the presence of BMX-001, more healthy insulin-positive islet masses were obtained, and these correlated with reductions in both blood glucose level and insulin requirement.
Conclusions: After islet transplantation into the GSMS, endoscopic biopsy can provide information on graft rejection as well as the presence of healthy islet grafts, which would be an immense advantage in clinical islet transplantation.

Sphingolipids regulate the podocyte insulin signaling in diabetic kidney disease

Alla Mitrofanova[1], Sandra Merscher[1], Alessia Fornoni[1,2], Linda Chen[3], George Burke[2,3].
[1]Medicine/Division of Nephrology and Hypertension, University of Miami Miller School of Medicine, Miami, United States; [2]Peggy and Harold Katz Discovery Center, University of Miami Miller School of Medicine, Miami, United States; [3]Miami Transplant Institute/Surgery, Jackson Memorial Hospital/University of Miami Miller School of Medicine, Miami, United States.

Disruption of physiological insulin signaling occurs in podocytes in experimental diabetic kidney disease (DKD). Podocytes are insulin sensitive and podocyte-specific deficiency of insulin receptor (IR) in in vivo mouse model recapitulates many features of DKD and affects podocyte actin cytoskeleton. Our studies have demonstrated that podocytes become insulin resistant in the early stages of experimental DKD. Sphingolipids are known to be important regulators of insulin signaling. We have identified sphingomyelin-phosphodiesterase-acid-like-3b (SMPDL3b) as a key lipid raft associated protein that is upregulated in DKD. We hypothesize that SMPDL3b overexpression suppresses pro-survival insulin signaling in podocytes via decreased ceramide kinase dependent C1P production.
Wild type (WT) or SMPDL3b overexpressing (SMPOE) human podocytes were utilized and their lipid content was analyzed by mass spectrometry technique. Further, we tested the response of SMPOE podocytes to insulin (1 nM, 30 min, Sigma), and analyzed changes in ceramide metabolites. We determined the levels of ceramide species, sphimgomyelin, and ceramide-1-phosphate in WT and SMPOE podocytes. Amounts of phospho- and total protein kinase B (AKT) and p70S6 kinase (p70S6K) were measured by Western blotting. The ability of SMPDL3b to immunoprecipitate both insulin receptor subtypes (IRA and IRB) was also tested.
SMPDL3b immunoprecipitated both IR isoforms. SMPOE podocytes are unable to phosphorylate AKT, but demonstrated increased phosphorylation of p70S6K in response to insulin stimulation. Ceramide C16:0 species was primarily detected in podocytes and remained unchanged by SMPDL3b overexpression. Content of total sphimgomyelin was higher in SMPOE podocytes when compared to WT cells. However, SMPOE cells demonstrated lower amounts of C1P ($p<0.05$). Pre-treatment with C1P 16:0 (100uM, 1h, Avanti) restored the ability of SMPOE podocytes to phosphorylate AKT in response to insulin stimulation. Our data indicate that SMPDL3b overexpression suppresses pro-survival insulin signaling in podocytes and might affect C1P production, leading to podocyte insulin resistance in DKD. C1P replacement strategies may protect podocytes in DKD.

Introduction: Pancreatic islet transplantation is a promising clinical treatment for type I diabetes, but success is limited by extensive beta cell death in the immediate post-transplant period, and impaired islet function in the longer term. Following transplantation, appropriate vascular remodelling is crucial to ensure the survival and function of engrafted islets. The ubiquitous sphingosine kinase pathway is an important regulator of vascular beds, however its expression and function in islets is largely undefined. The aim of this study was to investigate the expression and role of sphingosine kinase 1(SK1) in the function of islets in vitro and post transplantation.
Methods: Islets were isolated and density-purified from B6 (WT) or SK1 knockout (SK1KO) mice. SK1 gene expression and SK enzyme activity was determined by quantitative real-time PCR and thin-layer chromatography separation respectively from isolated WT islets. In vitro function of islets was determined by a glucose stimulation insulin release assay, where insulin secretion was determined by ELISA. Flow cytometry was used to enumerate endothelial cell number per islet. In vivo islet function was assessed in WT streptozotocin-induced diabetic mice transplanted with a minimal mass of 200 islets under the kidney capsule (cure=consecutive BGL<11.1mM). All cured animals were subjected to an IP glucose tolerance test (IPGTT).
Results and Discussion: Isolated islets have SK1 gene expression that increases with time in culture, this correlated with the presence of SK1 enzyme activity. Here, we show that sphingosine kinase 1 (SK1) promotes the engraftment of pancreatic islets. We found that donor islets from mice deficient in SK1 (SK1-KO) contain a reduced number of resident intraislet vascular endothelial cells compared to WT ($p=0.0165$). Furthermore, we demonstrate that the main product of SK1, sphingosine-1-phosphate, controls the migration of intraislet vascular endothelial cells in vitro, where SK1 specific inhibitor JTE-013 inhibits MS-1 cell migration by over 50% ($p<0.05$). We found in vivo that SK1-KO islets have an impaired ability to cure diabetes in recipient mice, compared to wildtype controls. Thus SK1-deficient islets not only contain fewer of the building blocks required for revascularisation, but also have a reduced ability to function post transplantation.
Conclusion: Our data suggest that the sphingosine kinase axis is important for islet endothelial cell migration, and islet function following transplantation, thus represents a novel clinical target for improving transplant outcomes.

Hypothermic machine perfusion preservation of non-heart-beating donor pancreas for islet transplantation

Naotake Akutsu[1], Takemichi Ishida[1], Michihiro Maruyama[1], Kazunori Otsuki[1], Tomonori Saitoh[1], Kenichi Saigo[1], Masayuki Hasegawa[1], Hiromichi Aoyama[1], Ikuko Matsumoto[1], Takashi Kenmochi[2], Hirofumi Noguchi[3].
[1]Surgery, Chiba-East National Hospital, Chiba, Japan; [2]Transplantation Surgery, Fujita Health University School of Medicine, Toyoake, Japan; [3]Regenerative Medicine, Ryukyu University School of Medicine, Nishihara, Japan.

Background: In Japan, brain-dead donors have been increased by revised Act of Organ Transplantation, however, insufficiency of deceased donor's number is still serious problem. In islet transplantation in Japan, it is more serious, because we can only procure the pancreas that could not harvest for pancreas transplantation. Then, it is important to use the pancreas from marginal donors such as non-heart-beating donors for solving this problem. Improvement of preservation method would be necessary to use the pancreas from non-heart beating donor. Static cold storage preservation (SCS) with UW or two layer preservation method (TLP) is the most widely used method for islet transplantation. However, hypothermic machine perfusion (HMP) preservation technique has had a major impact in circumventing ischemic injury in kidney transplantation in western countries. In this presentation, we report efficiency of HMP method for preservation of long ischemic pancreas grafts for islet transplantation in beagle.
Methods: Young beagles were used as auto-transplantation model. After general anesthesia of beagles, pancreatic artery and vein were made ligation, after 30 min warm ischemia time (WIT) in situ. Each harvested pancreas was assigned to one of three preservation treatment groups; SCS group (storage in University of Wisconsin solution at 2-4°C for 24h, n=4); TLP group (storage on two-layer preservation method at 2-4°C for 24h, n=4); HMP group (storage on LifePort® (Organ Recovery Systems), a portable hypothermic machine perfusion apparatus, at 2-4°C on pulsatile pressure (10 mmHg) for 24h with KPS-1 solution, n=4). After the storage, wedge biopsies were taken for histological evaluation. With the preserved pancreas islets were isolated by standard technique involving ductal distension of the gland with liberase enzyme, normothermic digestion and density gradient purification. After purification, the islets were evaluated for the yield and function, auto-transplanted to the same beagle in portal vein, and checked graft qualities in the recipients (serum glucose and insulin, IVGTT test).
Results: Each islet yield after purification was 182±175IEQ/g (SCS), 509±222IEQ/g (TLP), and 655±496IEQ/g (HMP). Stimulation index of each group was 1.28±1.22 (SCS), 1.43±1.14 (TLP) and 1.72±1.10 (HMP). Without statistically significant, yield and function of isolated islet of HMP group were better than that of SCS or TLP group. In histological findings, no difference was indicated with each group. Serum glucose level and IVGTT test in auto-transplanted recipient was not significantly different from each group.
Discussions and Conclusions: In this experiment, we indicate that HMP should be better for long term WIT pancreas preservation model for islet transplantation compared with SCS and TLP method in beagles. It suggested that preservation of pancreas on HMP technique should be useful for islet transplantation with non-hear-beating donor in Japan.

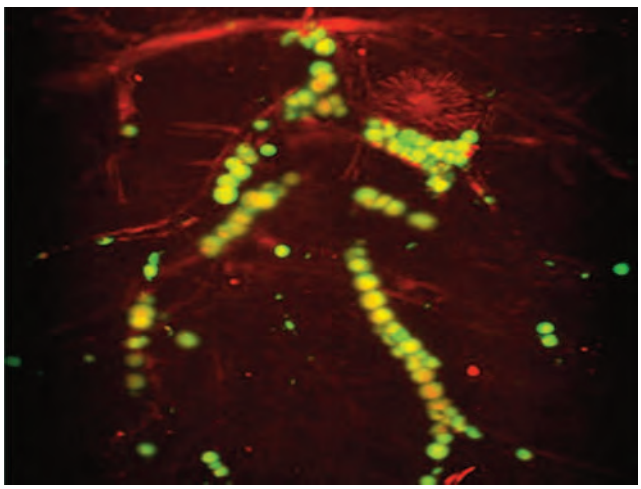
Analysis of post-transplant islet by organ transparency and macro three-dimensional image

Koya Shinohara, Masayuki Shimoda.
Pancreatic Islet Cell Transplantation, National Center,Global Health and Medicine, Tokyo, Japan.

Islet transplantation is a potential treatment for brittle type 1 diabetic patients. The principle of islet transplantation is at first to excise pancreas from donor body, and islets are isolated from the pancreas, then they are implanted into in the liver via portal vein. Then, the engrafted islets become to secrete insulin according to blood glucose levels. However, the detail of how the transplanted islets actually in the portal veins of the liver distribute, survive and function remains unclear. One of the reasons of the difficulty of observation of islets after transplantation is because they are not visible in the liver. Therefore, if the whole liver could be transparentized and the status of the islets after transplantation could be observed comprehensively, it must contribute to understanding of islet transplantation and improving it.
Recently, whole-organ imaging at single-cell resolution and tissue clearing methods have been developed[1]. These methods enables us to analyze the tissue structure of solid organs at the cellular, circuit, and organ-wide scale.
We have recently developed a method to transprantize a mouse liver by the techniques with our modification. As a result, it is possible to check the transparency of the liver, further also visible localization of fluorescent beads of the transplanted islets model in the liver on wide scale.



However, it was still difficult to perfectly clear the center of the organ. In this study, we aimed further improvement. For transparency of tissues, it has been found that treatment with a surfactant agent is very important. It is a process for removing cells from the tissue, which is often used when the artificial organ creation of biological origin. Therefore, we focused on the decellularization of the liver. We investigated some surfactant agents as a pretreatment of Scale / CUBIC, we could reduce the time to clear the liver. Then, we applied the method to islet transplantation model. The islets isolated from GFP transgenic mice were transplanted into nude mice via portal vein, and then the whole liver was transparented. Then, the whole liver was observed by 3D microscope. This method should be useful for the research of islet transplantation.

Maintenance of long-term tolerance by T regulatory cells in a mouse model of heart transplantation

Ning Jin, Weili Chen, Fangna Lu, Maoshu Zhu, Feifei Du, Wei Shao, Chang Gao, Tianshu Lan, Chen Dai, Shuo Han, Qing Li, Shifu Hong, Junjie Xia, Zhongquan Qi.
Xiamen University, Organ Transplant Institute, Xiamen, People's Republic of China.

Background: Regulatory T cell therapy is generally used for bone marrow transplantation and autoimmune diseases but is less frequently applied for transplantation of the heart. In this work, we adopted a drug regimen developed by Battaglia et al. to induce CD4+Foxp3+Tregs and T regulatory type 1 cells in vivo to maintain long-term tolerance after heart transplantation.
Methods: Hearts from BALB/c mice were transplanted into C57BL/6 mice. We then administered (hu)IL-10 and rapamycin to generate CD4+Foxp3+Tregs and Tr1 cells (CD4+IL-10+IL-4-) in vivo. Levels of rejection were analyzed using hematoxylin and eosin (H&E) staining and ELISA, and cell subtypes were identified using flow cytometry.
Results: Combined treatment with (hu)IL-10 and rapamycin induced tolerance to the heart allografts in all recipient mice, and levels of IL-2 and INF-γ were also clearly decreased in the rapa+IL-10 group. Compared to the rapa group, the subset of Th1 was decreased in the combined group. The proportion of CD4+Foxp3+Tregs induced by this treatment continued to be high during the administration period and recovered to normal levels on the 100th day after transplantation, yet the proportion of Tr1 cells remained high after drug withdrawal. Mixed lymphocyte reactions and adoptive transfer experiment showed that the recipient's T cells were tolerant (showed no response) to the donor's antigen presenting cells (APCs) compared to the third-party donor's APCs, and it was the induced regulatory T cells that inhibited this proliferation.
Conclusion: The combination of (hu)IL-10 and rapamycin was able to induce CD4+Foxp3+Tregs and Tr1 cells in vivo . The two subsets showed different regulatory effects and antigen specificity in the mouse model of heart transplantation and were able to maintain a low immune response environment to facilitate long-term graft survival.

Pediatrics, University of Alberta, Edmonton, AB, Canada; [2]Alberta Transplant Institute, University of Alberta, Edmonton, AB, Canada; [3]Canadian National Transplant Research Program, University of Alberta, Edmonton, AB, Canada; [4]Dept. Laboratory Medicine & Pathology, University of Alberta, Edmonton, AB, Canada; [5]Immunology Research Centre, St Vincent's Hospital, Melbourne, Australia; [6]Depts. Surgery and Medical Microbiology & Immunology, University of Alberta, Edmonton, AB, Canada.

Introduction: ABO-incompatible heart transplantation (ABOi HTx) can be performed safely in infants due to lack of natural anti-A/B antibodies, in contrast to adults. Following ABOi HTx, B cell tolerance to donor A/B blood group antigen(s) develops by mechanisms not well understood. For detailed study we developed a model using mice transgenic for expression of human A-antigen as donors (A-Tg, C57BL/6 (B6) background) and B6 wild-type (WT) mice as recipients. We showed that A-Tg heart grafts undergo antibody-mediated rejection (AMR) in adult WT mice with anti-A antibody, whereas A-Tg HTx into juvenile WT mice (4 weeks old) results in tolerance to A-antigen. The present study investigated whether tolerance can be induced in WT mice following administration of A-antigen in a form other than a transplant.
Methods: Neonatal WT mice (<1 day) were injected i.v. with A-antigen expressing splenocytes/bone marrow cells (n=17) from adult A-Tg mice, or were untreated (n=15). As adults (7 weeks), mice were injected i.p. with human A erythrocytes (RBC) in an attempt to induce anti-A antibody. Subsequently mice (neonatal-treated n=9; untreated n=6) received heterotopic A-Tg HTx. Grafts were monitored for function (beating) and assessed for AMR by histology at the experimental endpoint 14-21 days post-Tx or when beating ceased. Serum anti-A and third-party antibodies were assessed by hemagglutination (with A-Tg and reagent human A/O RBC).
Results: Anti-A antibodies were induced to high levels in all mice not treated as neonates (median titre 1:1024, range 1:256-2048) and were undetectable-low in neonatal-treated mice (median titre ≤1:2); anti-human non-A RBC antibodies (third-party) were comparable in both groups. In untreated mice, 5/6 grafts survived to day 14-21 post-Tx despite abundant anti-A antibody, however C4d deposition in capillaries (3/6) and morphologic features of AMR (4/6) were present. In contrast, in neonatal-treated mice, all grafts (9/9) survived to day 14-21 with no C4d deposition; 6/9 grafts had distorted morphology that may be artifact or related to ischemia.
Conclusion: The inability to elicit abundant anti-A antibodies in adult neonatal-treated mice by either injection of A-RBC or Tx of A-Tg heart grafts, together with third-party antibody production, suggests that robust A-antigen-specific tolerance was induced by neonatal exposure to A-expressing cells. This model will prove useful for addressing mechanisms of ABO-tolerance.

Interleukin-5 therapy prevents chronic allograft rejection by induction of antigen specific CD4+CD25+ T regulatory cells

Suzanne J. Hodgkinson[1,2], Bruce M.Hall[1,2], Rachael M.Hall[1,2], Catherine M.Robinson[1,2], Paul Wilcox[1,2], Giang T.Tran[1,2], Chuanmin Wang[3], Alexandra Sharland[3].
[1]Immune Tolerance Laboratory, Department of Medicine, University of New South Wales, Liverpool, Australia; [2]Ingham Institute, Liverpool Hospital, Liverpool, Australia; [3]Australian National Liver Transplantation Unit, Royal Prince Alfred Hospital & Department of Surgery, University of Sydney, Sydney, Australia.

Aim: Naïve $CD4^+CD25^+Foxp3^+$T regulatory cells (nTreg) activated by specific alloantigen and IL-4, not IL-2, express the IL-5 receptor (IL5Rα) and we call these Ts2 cells[1],[2]. Ts2 cells are more potent allo-antigen (Ag) specific Treg than nTreg. Here we examined if IL-5 treatment activated alloAg specific Ts2 cells to prevent chronic rejection.
Methods: Rats recipients of F344 strain with an adult heterotopic heart allografts from Lewis rats received 5000units rIL-5 ip daily for 10d from 7d after grafting, all groups n=5-6. Rejection was scored on a semi-quantitative scale. Changes in the $CD4^+CD25^+$T cells were examined for their numbers, their response in vitro to donor antigen with and without IL-5 and their cytokine and cytokine receptor expression by RT-PCR
Results: Sham treated rats developed rejection at 18d and all grafts were totally rejected by 28d (n=5). IL-5 treatment prevented rejection until cessation of IL-5 ($p<0.01$ vs sham) at 18d post-transplant. At that time $CD4^+CD25^+FoxP3^+$ Treg from IL-5 treated rats, compared to controls, were increased in number (6-8% vs 3-4%), expressed IL-5Rα and proliferated to specific donor antigen in MLC. After cessation of IL-5 treatment, a rejection crisis occurred but all grafts recovered and survived for 60d when they all had good function. In another group, IL-5 treatment was continued and it had less rejection and at 60d had $CD4^+CD25^+$Treg that expressed IL-5Rαand proliferated to specific donor antigen in the presence of IL-5.
Pre-treatment with anti-CD25 or anti-IL-4 abolished benefit of IL-5 treatment consistent with host $CD25^+$T cells being activated to Ts2 cells that were then expanded by IL-5. After 10d of IL-5 treatment, $CD4^+CD25^+$T cells responded to Lewis but not to F344 or third party PVG heat grafts in MLC, showing activation of alloAg specific Treg by IL-5 treatment. $CD4^+CD25^+$T cells from rats treated for 50d with IL-5 had their response to Lewis enhanced by IL-5, consistent with a Ts2 cell. RT-PCR of host $CD4^+CD25^+$T cells found IL-5 treated groups had more IL-5Rα, but remained $FoxP3^+$.
Conclusion: IL-5 prevented heart graft rejection by activation of $CD4^+CD25^+FoxP3^+$ Treg that had been activated by host IL-4 and donor alloantigen. This effect was consistent with induction of Ts2 cells. This study shows promotion of Th2 cytokine induced Treg by IL-5 therapy may have potential to prevent chronic allograft rejection. Chronic rejection remains an unsolved problem in clinical transplant, and induction of antigen specific Treg may be able to control this pathology[2]. Human $CD4^+CD25^+FoxP3^+$Treg activated by IL-4 and alloantigen also are induced to express IL-5Rα. Thus, this IL-5 pathway of activation of antigen specific Treg may be useful if activated in chronic rejection.

Contrasting effects of tacrolimus and everolimus on regulatory T cell activation and mixed hematopoietic chimerism induced by natural killer T cell stimulation

Toshihito Hirai[1], Satoshi Miyairi[1], Yusuyuki Ishii[2], Masayoshi Okumi[1], Kazunari Tanabe[1].
[1]Department of Urology, Tokyo Women's Medical University, Tokyo, Japan; [2]Laboratory for Vaccine Design, RIKEN IMS-RCAI, Yokohama, Japan.

Introduction: Calcineurin-dependent IL-2 production is crucial for regulatory T cells (Tregs) to demonstrate suppressive activity. The mTOR signal is not required for Treg function because IL-2-signaling stimulated Tregs preferentially induce the JAK/STAT signaling pathway rather than PI3K/AKT signaling. Therefore, calcineurin inhibitors and mTOR inhibitors should have different effects on Treg performance. We previously reported Treg-dependent mixed hematopoietic chimerism induction therapy comprising of iNKT cell activation by a liposomal formulation of α-galactosylceramide (lipo-aGC) and CD40/CD40 ligand blockade (MR1). Here, we characterized the impact of tacrolimus (TAC) and everolimus (EVL) on Tregs and donor cell engraftment.
Methods and Results: 3 Gy-irradiated BALB/c ($H2^d$) mice were administered bone marrow cells (2×10^7) from C57BL/6(B6; $H2^b$) mice, followed by a single dose of lipo-aGC plus MR1. The mice showed early expansion of splenic Tregs with high Ki67 expression on day 7 after BMT and establishment of robust permanent mixed chimerism. When TAC was administered consecutively from day 1 until day 14 after BMT, Ki67 expression on splenic Tregs significantly decreased, whereas that on the conventional T cell counterpart did not. On cocultured with naive $H2^{d+}$T cells, $H2^{d+}CD4^+CD25^+$cells isolated from the splenocytes of control chimeric mice suppressed proliferation of naive $H2^{d+}$T cells against $H2^{b+}$cells, whereas those from TAC mice attenuated this suppressive potential against the donor antigen. Although TAC mice showed transient chimerism, the engrafted donor cells dwindled, which resulted in a chimerism brake (fig 1). This abrogation of mixed chimerism induction was reinforced by TAC in a dose-dependent manner. In contrast, when EVL was administered between day 1 and day 14, abrogation of Treg expansion and mixed chimerism induction was not observed (fig 2).
Conclusion: These data collectively suggest that TAC, but not EVL, precluded Treg activation by stimulated iNKT cells.

IFN-gamma/B7-H1 signaling pathways in graft mesnechymal cells mediate liver transplant tolerance

Miwa Morita[1], Daniel Joyce[2], John J. Fung[2], Shiguang Qian[1,2], Lina Lu[1,2].
[1]Immunology, Lerner Reaerch Institute, Cleveland Clinic, Cleveland, OH, United States; [2]General Surgery, Transplant Center, Digestive Disease Institute, Cleveland Clinic, Cleveland, OH, United States.

Induction of transplant tolerance, an ideal solution for organ transplantation, remains elusive in clinic practice. Indeed, transplant tolerance occurs naturally. Thus, 1/4 liver transplants (LT) in farmer pigs were spontaneously accepted. This phenomenon was reproduced in rats and mice. World-wide data showed that ~25% LT patients successfully underwent totally weaning off immunosuppression. Establishment of a mouse LT tolerance model in our lab allowed to scoop out the behind mechanisms. LT tolerance is not related to T cell clonal deletion (as seen in central tolerance) because recipient T cells respond normally to donor antigens in vitro, rather related to apoptotic death of activated T cells. We were inspired by an unexpected observation that LT tolerance absolutely requires IFN-γ, an inflammatory cytokine, mainly produced by Tef cells that should promote rejection. The aim of this study was to determine the underlying cellular and molecular mechanisms. The experiments were performed in the recipients (C3H) of B6 WT (tolerance) or IFN-$\gamma R1^{-/-}$ (rejection) liver graft. We focused on analyzing graft non-parenchymal cells (NPC), because, unlike the whole liver, hepatocyte allografts are acutely rejection, suggesting the tolerance is mediated by NPC. We divided the graft NPC into hematopoietic ($CD45^+$) and mesenchymal ($CD45^-$) groups for analysis, and found that graft $CD45^+$ NPC were rapidly replaced by cells of recipient origin (WT) following transplantation, while $CD45^-$ cells remained IFN-$\gamma R1^{-/-}$, therefore, rejection of tolerance largely depends on the behavior of graft mesenchymal cells (GMC), not hematopoietic cells. Comparison of GMC in WT and IFN-$\gamma R1^{-/-}$ grafts revealed that ligation of IFN-γR on GMC triggered the upregulation of their B7-H1 expression leading to the apoptosis of the infiltrating Tef cells, but did not affect MDSC and Treg activities, indicating a key role of Tef elimination in induction of tolerance. We tested immune regulatory activity of hepatic stellate cells (HpSC) and liver sinusoid endothelial cells (LSEC) in vitro and in vivo. Addition of either HpSC or LSEC markedly suppresses T cell response in vitro (MLR). Co-transplantation with HpSC or LSEC significantly prolongs survival of islet allografts, while HpSC from IFN-$\gamma R^{-/-}$ or B7-$H1^{-/-}$ mice failed to protect islet allografts. These results illustrate a mesenchyme-mediated immune control (MMIC) mechanism in graft to respond to the host immune attacks, leading to LT tolerance. It is likely that graft plays a key role in the equipoise between tolerance and rejection and warrants attention in the search for biomarkers of tolerance. MMCI activity is unlikely exclusive to the liver, as spontaneous acceptance has also been reported in kidney transplants, although less common, reflecting the variant MMIC activities in different organs.

328.6

Liver regeneration was attenuated by deletion of CXCL10 or its receptor CXCR3 via YAP1 signaling

Yuen Yuen Ma, Changxian Li, Wei Geng, Kevin Ng, Chungmau Lo, Kwan Man.
Surgery, The University of Hong Kong, Hong Kong , Hong Kong.

Background: Acute phase liver graft injury after transplantation often causes delayed liver regeneration. Our recent study showed that chemokine (C-X-C motif) ligand 10 (IP10), a pro-inflammatory chemokine, is a specific gene signature of acute phase liver graft injury that promotes tumor cell proliferation and angiogenesis[1],[2]. While other reports suggested IP10 is also hepatoprotective during liver injury[3]. Here, we aimed to investigate the effects and molecular mechanisms of IP10 in liver regeneration and repair.
Material and Methods: IP10-/- and CXCR3-/- mice models with or without fatty liver were subjected to partial hepatectomy (50%) and hepatic ischemia/reperfusion injury. Mouse hepatocyte proliferation was assessed at day 2, 4 and 7 by PCNA staining. Hepatic mRNA expression profiles of PCNA, hepatocyte growth factor (HGF), and Yes-Associated protein 1 (YAP1), Cyclin E1, Cyclin E2, Cyclin A2, MCM2, MCMBP and other cell cycle associated genes. Intragraft expression of IP10, CXCR3 and YAP1 mRNA were evaluated in small-for-size rat orthotopic liver transplantation model and further validated in clinical samples.
Results: Proliferation of hepatocytes in non-fatty liver is significantly higher compared with fatty liver. Wild type mice of the non-fatty liver group also exhibited significantly higher number of PCNA positive hepatocytes in comparison to IP10-/- and CXCR3-/- groups on day 2 (14.7/HPF vs 1.1/HPF vs 1.4/HPF respectively, $p \leq 0.005$), day 4 (5.4/HPF vs 3/HPF vs 2.6/HPF respectively, $p \leq 0.01$) and on day 7 (3.8/HPF vs 1.1/HPF vs 2.6/HPF respectively, $p \leq 0.5$). A significant decrease in YAP1 expression is found in IP10-/- and CXCR3-/- compared to wild type in the non-fatty group ($p \leq 0.005$) while different expression patterns were presented in the fatty group. No significant difference was found in expressions of Cyclin D1, Cyclin E2 and Cyclin A2.
Conclusion: IP10 and its receptor CXCR3 play critical roles in liver regeneration through regulating Yap1 signaling.

Heparin-gelatin mixture improves vascular reconstruction efficiency and hepatic function in bioengineered liver

Kamal Hussein[1,2], Kyung M.Park[1,2], Yun S.Lee[1], Kyung S.Kang[3], Heung M.Woo[1,2,4].
[1]Stem Cell Institute, Kangwon National University, Chuncheon, Korea; [2]College of Veterinary Medicine, Kangwon National University, Chuncheon, Korea; [3]College of Veterinary Medicine, Seoul National University, Seoul , Korea; [4]Harvard Stem Cell Institute, Renal Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States.

Introduction: Whole organ decellularization is a cell removal process that creates a natural extracellular matrix for use in transplantation. A lack of an intact endothelial layer in the vascular network of decellularized organs results in blood clotting even with anti-coagulation treatment. Furthermore, shear stress caused by blood flow may affect reseeded parenchymal cells. We hypothesized that a heparin-gelatin mixture (HG) can act as an antithrombotic coating reagent and induce attachment and migration of endothelial cells (ECs) on vascular wall surfaces within decellularized livers, with subsequent parenchymal cell function enhancement.
Materials and Methods: Portal vein (PV) perfusion was performed for right lateral lobe decellularization of porcine livers. We tested if HG-precoating of isolated decellularized PV could increase EC attachment and migration. Additionally, we coated PV and hepatic artery walls in decellularized liver with HG, and then repopulated it with ECs and maintained it under vascular flow in a bioreactor for 10 days. Re-endothelialized scaffolds were perfused with porcine blood for thrombogenicity evaluation. We then co-cultured hepatocellular carcinoma (HepG2) cells and ECs to evaluate the effect of endothelialization on parenchymal cells. Finally, we transplanted these scaffolds heterotopically in pigs.
Results: HG improved ECs' ability to migrate and adhere to vessel discs. ECs efficiently covered the vascular compartments within decellularized scaffolds and maintained function and proliferation after HG-precoating. No thrombosis was observed after 24 h blood perfusion in HG-precoated scaffolds, indicating a fully endothelialized vascular tree. HepG2 cells displayed a higher function in scaffolds endothelialized after HG-precoating compared to uncoated scaffolds *in vitro* and after *in vivo* transplantation.
Discussion and Conclusion: We have shown that re-endothelialization of a porcine liver scaffold after precoating of blood vessels using HG can be achieved. Blood vessel surface modification can improve ECs attachment and migration with anti-platelet prosperity. *In vivo* results indicated that no coagulation occurred and parenchymal cell functions were maintained. Our results are promising to the pursuit of generating a fully functional human-sized tissue engineered liver scaffold with non-thrombogenic, patent vessels that can be used as liver assist-systems or for *in vivo* transplantation. Supercharging mesenchymal stem cells with Interleukin-17A: An alternative to interferon-gamma enhancement of mesenchymal stem cell immunomodulation

Kisha Sivanathan[1,2,3], Darling Rojas-Canales[1,2], Stan Gronthos[4,5], Shane Grey[6], Patrick T.Coates[1,2,3,7].
[1]Centre for Clinical and Experimental Transplantation, Royal Adelaide Hospital, Adelaide, Australia; [2]School of Medicine, Faculty of Health Sciences, University of Adelaide, Adelaide, Australia; [3]Centre for Stem Cell Research and Robinson Institute, School of Medical Sciences, University of Adelaide, Adelaide, Australia; [4]Mesenchymal Stem Cell Group Laboratory, School of Medicine, Faculty of Health Sciences, University of Adelaide, Adelaide, Australia; [5]South Australia Health and Medical Research Institute , Adelaide, Australia; [6]Transplant Immunology Group, Garvin Institute of Medical Research, New South Wales , Australia; [7]Central Northern Adelaide Renal Transplantation Service (CNARTS), Royal Adelaide Hospital, Adelaide, Australia.

Human bone marrow derived mesenchymal stem cells pre-treated with interleukin-17A (MSC-17) are superior T cell immunomodulators for allotransplantation. We have previously shown that human MSC-17 potently suppressed PHA-induced T cell proliferation (3H-thymidine) and T cell activation (downregulated CD25, IFN-γ, TNF-α, IL-2) by inducing Tregs expressing functional Treg markers (CD39, CD73, CD69, OX40, CTLA-4, GITR). Here we aimed to identify potential mechanisms by which human MSC-17 mediate their superior immunomodulatory function. Untreated-MSC (UT-MSC), IFN-γ treated MSC (MSC-γ) and MSC-17 were assessed for their gene expression profile (microarray, 3 human MSC donors). Significantly regulated genes ($p<0.05$, fold change (FC)<-2 or >2) were identified for their biological functions (Database for Annotation, Visualisation and Integrated Discovery, DAVID). Microarray analysis identified 1278 differentially regulated genes (902 upregulated; 376 downregulated) between MSC-γ and UT-MSC; and 67 genes (39 upregulated; 28 downregulated) between MSC-17 and UT-MSC. MSC-γ were enriched for gene sets involved in the regulation of programmed cell death, apoptosis, TGF-β receptor signaling pathway (eg. FMOD. CCL2, MAPK3K1, SMAD6, GDF15 and TGFB2) and in positive regulation of defense response (eg. IL-6, TLR3, TLR4 and IDO). MSC-γ genes were also enriched for cell migration (eg. CXCL10, CXCL16, ICAM1, IL-6 and VEGFA). Despite the enhanced immunosuppressive and migratory properties, MSC-γ therapy is likely to be immunogenic in allogeneic hosts. MSC-γ exhibited the highest enrichment of genes associated with antigen processing and presentation via MHC class I. Enriched genes sets included aminopeptidases that hydrolyses antigenic peptides for MHC class I peptide binding and antigen presentation (eg. ERAP1 and ERAP2), peptide transporter genes (eg. TAP2) and other genes involved in the antigen processing and presentation pathways (eg. TAPBL, B2M and CD74). Other biological processes enriched in MSC-γ included immune response activation, humoral response and complement pathways activation. This microarray data is consistent with the upregulation of MHC molecules in MSC-γ (flow cytometry) and in other studies showing increased MSC-γ immunogenicity in vivo. MSC-17 genes were associated with chemotaxis responses, which may be involved in T cell recruitment for MSC-17 immunosuppression. MSC are known to express MMP molecules with chemotaxis and immunosuppressive properties. MMP13 was highly expressed specifically in MSC-17 (FC 15.6) and was validated by RT-PCR. Hence, MMP13 may mediate the superior immunomodulatory function of MSC-17. MSC-17 represent a potential cellular therapy to suppress immunological T cell responses in allotransplantation, with minimal immunogenicity. Studies on the functional role of the key candidate molecule MMP13 in MSC-17 immunomodulation are currently underway.

An increase in CD8+ effector memory T cells precedes rejection in a primate cardiac transplant model

Natalie A. O'Neill, Tianshu Zhang, Wenji Sun, Gheorghe Braileanu, Ivan Tatarov, Wessam Hassanein, Selin Sendil, Richard NPierson, Agnes M.Azimzadeh.
Department of Surgery, University of Maryland, Baltimore, MD, United States.

Purpose: Costimulation blockade prolongs graft survival but does not induce tolerance in primates. The mechanisms of rejection are incompletely understood, but costimulation blockade resistant rejection may be due to $CD28^-$ T cells. Here we evaluate changes in the proportion of $CD28^-$ T cells and naïve, central memory, and effector memory T cell populations over time in a non-human primate (NHP) transplant model in the context of αCD28, αCD40, and αCD80/86 immunomodulation.
Methods: Cynomolgus heterotopic (intraabdominal) cardiac transplant recipients were treated with either αCD80/86 (Belatacept, n=3), αCD28 (FR104, n=7), αCD40 (2C10R4, n=6), or αCD28 + αCD40 (n=2) for 90 days. Primary graft survival was defined by diminished pulse pressure or a drop in heart rate (by telemetry), and confirmed by histology. Peripheral blood $CD4^+$ and $CD8^+$ T cells were analyzed for CD45RA, CD95, CD28, and CD62L using flow cytometry. $CD4^+$ and $CD8^+$ T cells were categorized as naïve (N: $CD45RA^+CD62L^+$ or $CD95^-CD62L^+$ phenotype), central memory (CM: $CD45RA^-CD62L^+$ or $CD95^+CD62L^+$), or effector memory (EM: $CD45RA^{+/-}CD62L^-$ or $CD95^{+/-}CD62L^-$).
Results: Survival of grafts treated with αCD80/86 (median 122 days, 8 – 125), αCD28 (164 days, 52 – 181), αCD40 (125 days, 90 – 179), and αCD28 + αCD40 (138 days, 102 – 172) was similar. Proportion of $CD8^+CD28^-$ T cells increased from baseline to day of rejection in the αCD28 (1.66±0.43) and αCD40 (1.42±0.77) groups, but not with αCD80/86 (0.75±0.44; p=0.24) therapy. CM $CD4^+$ and $CD8^+$ T cells were a low proportion and exhibited minimal changes in these treatment groups. Two EM distribution patterns were found at baseline, with either a low (n=4, $CD45RA^{+/-}CD62L^-$; mean: 38.9%, SD±4.9) or high (n=10, $CD45RA^{+/-}CD62L^-$; 65.1%±8.8; p=0.0001) proportion of EM among $CD3^+CD8^+$ T cells. The proportion of T cell subsets was similar whether phenotyping was based on CD45RA or CD95. The proportion of $CD8^+$ EM increased significantly from baseline (58.3%±14.6) to time of rejection (75.3%±11.2; $p<0.0001$) across all drugs and profiles. Two of the four low CD8+ EM phenotypes switched to a high phenotype within three weeks of transplantation and subsequently experienced rejection during immunomodulation therapy, but no correlation was observed between baseline $CD8^+$ EM proportion and graft survival.
Conclusions: $CD8^+$ effector T cells significantly increased before graft rejection, and $CD8^+CD28^-$ T cells trended upwards in the αCD28 group. Monitoring these phenotypic changes could allow for early intervention prior to allograft rejection, and specifically targeting this "escape" mechanism of co-stimulation-independent effector T cells may help promote tolerance in transplantation.

Donor-specific cell-free DNA as a non-invasive marker of organ rejection after liver transplantation: A pilot study

Su Kah Goh[1,2], Hongdo Do[2], Vijayaragan Muralidharan[1], Alexander Dobrovic[2], Christopher Christophi[1].
[1]Department of Surgery, Austin Health, Melbourne, Australia; [2]Translational Genomics and Epigenomics Laboratory, Olivia Newton-John Cancer Research Institute, Melbourne, Australia.

Introduction: Despite modern immunosuppressive agents, up to 20% of patients will develop an episode of rejection in the first 12 months after liver transplantation (LTx)[1]. Conventional means to diagnose organ rejection is either inaccurate or invasive. Clinical findings and liver function tests are non-specific and do not necessary correlate with the severity of organ rejection[2]. Although liver biopsy is the gold standard for the diagnosis of organ rejection, this procedure is invasive and carries reasonable risks[3]. Better biomarkers for the non-histological diagnosis of organ rejection are required. Recent studies have proposed the use of donor-specific circulating cell-free DNA (dscfDNA) as a non-invasive marker of organ rejection[4],[5]. Unlike current methodologies adopted to evaluate dscfDNA, we have developed a novel digital PCR approach based on deletion/insertion polymorphisms to accurately measure dscfDNA levels. Using this technique, we monitored a cohort of patients who underwent LTx.
Materials and Methods: Eight patients who underwent LTx were prospectively recruited. Genotyping of a set of deletion/insertion polymorphisms was performed to identify donor-specific alleles. Droplet digital PCR was then utilized for the precise serial quantification of dscfDNA in the circulation of the recipient. Levels of dscfDNA were measured in pre-transplant and post-transplant bloods for each recipient at days 1, 3, 7, 14, 28 and 42. Findings were correlated with routine liver function tests and clinicopathological factors.
Results and Discussion: Levels of dscfDNA were reflective of graft health. In six recipients who underwent uneventful transplantation, levels of dscfDNA markedly reduced within 3 days and rapidly plateaued to a very low level 7 days after LTx. We also found that dscfDNA levels were independent of cholestasis in a separate recipient. On the other hand, dscfDNA levels significantly increased in a patient who developed an episode of acute cellular rejection 7 days after LTx. These findings of dscfDNA as a biomarker for organ rejection after LTx are promising. Furthermore, as the measurement of dscfDNA is attainable under 5.5 hours, our workflow will be supportive of same-day clinical decision-making.
Conclusion: In this pilot study, we demonstrated the robustness of our methodology for the detection and quantification of dscfDNA. We also highlighted the potential of dscfDNA as a clinically applicable biomarker of organ rejection. However, larger validation studies are required to confirm the diagnostic performance of dscfDNA, especially in the setting of other common post-transplant complications.

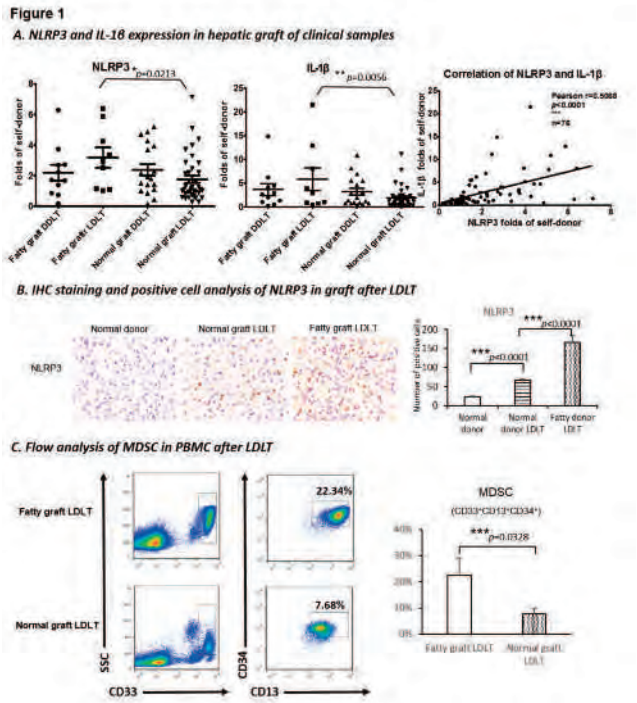
Inflammasome exacerbated fatty graft injury with accumulation of myeloid-derived suppressor cells after living donor liver transplantation

Hui Liu, Nancy Kwan Man, Jiang Liu, Oscar Wai Ho Yeung, Yuen Yuen Ma, Yan Shao, See Ching Chan, Chung Mau Lo.
Surgery, The University of Hong Kong, Hong Kong, Hong Kong.

Introduction: Acute phase fatty liver graft injury will deteriorate when graft is small-for-size, which is common in living donor liver transplantation (LDLT). Inflammasome plays critical roles in inflammation initiation. Hepatic steatosis promotes myeloid-derived suppressor cells (MDSC) accumulation. Here, we aimed to explore the regulatory role of inflammasome on MDSC in fatty graft injury after LDLT.
Materials and Methods: Expression pattern of inflammasome and its association with IL-1β was investigated in 76 transplant recipients and a rat orthotopic liver transplantation model using small-for-size fatty graft. The regulatory role of inflammasome on MDSC accumulation and mobilization was examined both in rat model and in vitro.
Results and Discussion: Clinically, the expressions of NLRP3 and IL-1β in fatty living graft were significantly higher and associated with poor liver function after transplantation. Intragraft NLRP3 positive cells were associated with more neutrophils infiltration in fatty living graft ($p<0.0001$). The circulatory MDSC in fatty graft LDLT group was significantly accumulated.



In rat model, hepatic expression of NLRC4 and IL-1β was significantly increased in fatty graft group. NLRC4 overexpression was positively correlated with IL-1β and poor liver function. Consistently, MDSC was also increased in fatty graft group and correlated with IL-1β expression ($p=0.02$).IL-1β administration induced the MDSC mobilization.
Conclusion: Inflammasome, associated with MDSC accumulation, played an important role in exacerbating acute phase inflammatory injury in fatty graft after LDLT.

Optimizing immunomodulatory properties and immunogenicity of MSC for immunotherapy following organ transplantation

Samantha de Witte[1], Marcella Franquesa[1], Tanja Strini[1], Sander S.Korevaar[1], Franka Luk[1], S. J.Elliman[2], P. N.Newsome[3], M. Gargesha[4], D. Roy[4], Ana M.Merino Rodriguez[1], Carla C.Baan[1], Martin J.Hoogduijn[1].
[1]Nephrology and Transplantation, Department of Internal Medicine , Erasmus MC, Rotterdam, Netherlands; [2]Orbsen Therapeutics Ltd, Galway, Ireland; [3]Department of NIHR Liver Biomedical Research Unit and Centre for Liver Research , University of Birmingham, Birmingham, United Kingdom; [4]BioInVision Inc., Mayfield Village, OH, United States.

Mesenchymal stromal cells (MSC) are attractive candidates for immunotherapy after organ transplantation as well as targeting immune mediated disorders. MSC contain promising immunomodulatory capacities and are low immunogenic, due to low MHC I and lack of MHC II expression. These properties are favorable for their applicability as immunotherapy, however there is evidence that MSC are more immunogenic than previously thought. Design strategies which improve these qualities would be advantageous for their application within the transplantation field. This study aims to optimize MSC into less immunogenic cells with improved immunomodulatory capacities.
Umbilical cord-derived MSC were treated for 3 days *in vitro* under various conditions, i.e. in the presence of pro-/anti-inflammatory cytokines, vitamins and serum-deprivation. Their immunogenicity and immunosuppressive capacity were examined by gene-expression analysis, surface-marker expressions, IDO-activity and inhibition of Tcell proliferation. Subsequently, the susceptibility to NK cell and CD8 Tcell lysis was investigated via CD107a expression. Furthermore, the immunomodulatory capacity as well as the survival of the treated MSC was examined in a CCL4-induced liver disease mouse model.

Treatment	Immunogenicity		Immune modulation	
IFNγ	↑ HLA type-I ↑ HLA type-II ↑ protection NK lysis	** * *	↑ PD-L1 ↑ IDO activity ↑↑ inhibition CD4 and CD8 proliferation	*** * *
IFNβ	↑ HLA type-I ↑ Protection NK lysis	* *	↑ PD-L1	*
TGFβ1	↑ Protection NK lysis	*	↑ PD-L1 ↑ inhibition CD4 and CD8 proliferation	*
Serum deprivation (Starv)	↓ HLA type-II	**	↓ PD-L1 ↑ inhibition CD4 and CD8 proliferation	*
Vitamin B6 (VitB6)	↑ HLA type-I ↑ HLA type-II	** *		
Retinoic Acid (RA)			↑ inhibition CD4 and CD8 proliferation	
Starvation + Vitamin B6 (StarvVitB6)	↑ HLA type-II	**	↑ inhibition CD4 and CD8 proliferation	

Table 1. Effects of treatments on ucMSC for three days compared to unstimulated ucMSC. Significance levels p<0.5 (*), p<0.01 (**) and p<0.005 (***)

In vitro results show increased immunomodulatory capacity of IFNγ-, IFNβ- and TGFβ- treated MSC. IFNγ-MSC were the most potent inhibitors of Tcell proliferation plus their IFNγ production. Furthermore, increased HLA levels were observed in IFNγ-, IFNβ-, VitB6- and StarvVitB6- treated MSC. These MSC were significantly protected against NK lysis, which correlates to increased HLA type I levels. In addition, TGFβ-MSC were significantly protected against NK lysis while HLA levels remained unchanged. Table 1 displays *in vitro* effects of the most prominent factors on immunogenicity and immunomodulatory capacity. *In vivo*, TGFβ-MSC had improved persistence after infusion while clearance of VitB6- and StarvVitB6-treated MSC was accelerated compared to untreatedMSC. Nonetheless, *in vivo*, a trend of improvement in liver function after TGFβ- and Starv-treated MSC administration was observed.
These data show the versatility of MSC to culture conditions and the possibility of optimizing MSC into less immunogenic cells with improved immunomodulatory properties, which is important for further application of MSC as immunotherapy for immune mediated disorders and after organ transplantation.

Transplantation of graft from older donors: does age still matter?

Nicholas Gilbo, Ina Jochmans, Mauricio Sainz, Jacques Pirenne, Diethard Monbaliu.
Abdominal Transplantation Surgery and Coordination, University Hospitals of Leuven, Leuven, Belgium.

Background: Improved outcome after Liver Transplantation (LT) has led to an imbalance between patients waiting and availability of suitable grafts. As an attempt to reduce this gap, selection criteria have become less restrictive including elderly donors (>70y). However, registry data have previously raised concerns that advanced donor age is associated with impaired graft and recipient survival.
Methods: We retrospectively compared donor and recipient demographics, transplant and outcome data between recipients of liver grafts procured from donors >70y (D>70) and <70y (D<70) in a cohort of 643 consecutive LT in (01/2003-12/2014). The influence of LT of elderly grafts on recipient and graft survival was investigated by means of multivariable regression. Data presented as median and IQR.
Results: 98/643 (15%) LT were performed with grafts procured from D>70. D>70 [71-90y] were all brain dead and when compared to D<70, peak AST/ALT was lower, most were locally procured (71.4% vs 45.3%, p<0.0001), had shorter graft extraction time [30min (24-36) vs 38min (28.5-50), p<0.0001] and higher DRI [2.6 (2.4-2.8) vs 2.1 (1.7-2.4), p<0.0001]. Recipients of D>70 were older [62y (56-68) vs 57y (48-64), p<0.0001] with similar MELD but higher BAR score [4 (2-4) vs 2 (1-4), p<0.0001] and more frequently transplanted for HCC (44.9% vs 28.3%, p=0.002). Cold ischemia [7.24h (6-9.5) vs 7.98h (6.2-9.5), p:0.1] and anastomotic time [80min (67-91) vs 78min (67-90), p=0.3] was similar. Peak AST post-LT was lower in D>70 [527IU/L (298-1071) vs 721IU/L (383-1386), p=0.025]. No difference in early allograft dysfunction (D>70 26.3% vs D<70 28.9%, p=0.71) or acute kidney injury (D>70 22.7% vs D<70 22.7%, p=1) was observed. The incidence of non-anastomotic biliary strictures within 1y post-LT was lower in D>70 (6.2% vs 13.4%, p=0.045). One and five year graft survival were similar between D>70 and D<70 (89.7% vs 87.7%, 73.5% vs 70.6% respectively, p=ns); likewise 1 and 5 y patient survival did not differ (92.8% vs 91.1%, 76.1% vs 75.9% respectively, p=ns). Multivariable Cox regression did not reveal an impact of donor age on patient and graft survival (D>70 HR:0.95, 95%CI:0.55-1.63 and HR:0.78, 95%CI:0.46-1.33) in contrast to CIT which was an independent risk factor of impaired recipient survival (HR: 1.11, 95%CI:1.04-1.2, p=0.004).
Conclusion: In our experience, transplantation of grafts >70y did not increase post-LT morbidity and achieved survival comparable to that one reached by younger grafts in the long-term. Careful selection of graft from D>70 to be procured by experienced team and stable recipients seems essential to safely use these elderly grafts.

Dynamic Liver Compliance- A new radiological metric to predict peri-operative course of donor hepatectomy

Mettu Reddy, Abdelrrhaim Dabora, Sripriya Srinivas, Ilankumaran Kaliamoorthy, Rajesh Rajalingam, Gomathy Narasimhan, Venugopal Kota, Mohamed Rela.
Institute of Liver Disease & Transplantation, Global Health City, Chennai, India.

Background: Minimising donor morbidity remains the cornerstone of successful LDLT. The most important variable predicting donor outcome after right lobe donation is how the partial liver remnant copes with portal hyperperfusion. Multiple biochemical, radiological and histological parameters have been used to evaluate this aspect. We devised a new radiological metric- dynamic liver compliance (ΔLV) and evaluated its utility in predicting peri-operative course after donor right hepatectomy.
Methods: Potential liver donors underwent contrast enhanced triple phase CT as part of standard donor assessment. Donors underwent plain CT after overnight fasting. This was followed by intravenous infusion of normal saline (10ml/kg) over 30 minutes. The patient then underwent standard triphasic CT after intravenous contrast injection. Liver volumes in the plain scan and the hepatic portal phase were compared. Dynamic liver compliance (ΔLV) was calculated as (Portal phase volume- Plain volume)*100/Plain volume. The intra-operative and post-operative course of these donors was prospectively followed. Relationship between ΔLV and standard intra-operative and post-operative variables was explored.
Results: 16 donors completed the protocol CT and proceeded to right lobe donation. Post hydration volumes increased by a mean of 82±56ml. Mean dynamic liver compliance (ΔLV) was 5.9%±3.4%. ΔLV showed significant negative correlation (Pearson's correlation) with intra-operative blood lactate levels (p=0.004) and day 1 transaminase levels (AST: p=0.044, ALT: p=0.033). Donors with ΔLV less than 6% had significantly higher end intra-operative blood lactate (3.4 vs 2.1, p=0.008) and day 1 transaminase levels (ALT: 151 vs 244, p=0.049, AST: 133 vs 214, p=.054). There was no difference in peak bilirubin, peak INR, ICU or hospital stay or morbidity between the two groups.
Discussion: Donors who have a compliant liver as measured by a high ΔLV appear to have better intra-operative blood lactate and post-operative transaminase profiles, suggesting lesser peri-operative hepatocyte injury. In this pilot study, ΔLV appears to be an interesting new metric to predict peri-operative course of liver donors. Larger studies are necessary to identify the ability of this metric to predict clinical course of these donors.
Conclusion: Dynamic Liver Compliance (ΔLV) has the potential as a new non-invasive radiological metric to predict donor liver quality & the peri-operative course after donor hepatectomy.

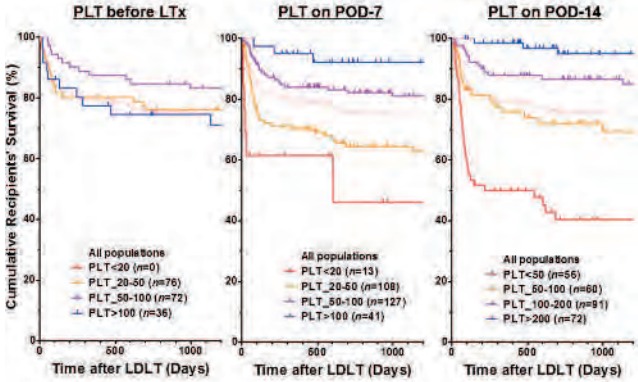
329.3

Post-operative thrombocytopenia determines the fate of adult-to-adult living donor partial liver transplantation; Proposal of "Thrombotic Microangiopathy (LTx-TMA) Score"

Koichiro Hata[1], Hirokazu Tanaka[1], Kayoko Endo[2], Hirofumi Hirao[1], Yusuke Okamura[1], Toyonari Kubota[1], Osamu Inamoto[1], Ichiro Tamaki[1], Yermek Nigmet[1], Hideaki Okajima[1], Toshimi Kaido[1], Akira Shimizu[2], Shinji Uemoto[1].
[1]Department of Surgery, Division of Hepato-Biliary-Pancreatic Surgery and Transplantation, Kyoto University Graduate School of Medicine, Kyoto, Japan; [2]Institute for Advancement of Clinical and Translational Sciences, Kyoto University Hospital, Kyoto, Japan.

Background: It has recently been reported that peri-operative thrombocytopenia may predict the outcome of liver transplantation (LTx), however, the underlying pathophysiologies have not been elucidated. Here we propose the concept of "LTx-associated thrombotic microangiopathy (LTx-TMA) ", as a crucial pathology in LTx.
Methods: We retrospectively analyzed the clinical characteristics/data in the consecutive 290 cases of primary adult-to-adult living donor partial LTx (LDLT) in our single center between April 2006 and March 2013, with special interest to the diagnostic criteria of TMA, as follows: i) thrombocytopenia (<50,000/mm), ii) hemolytic anemia (Hb<8.0g/dl), iii) LDH elevation (>500 IU/L), and iv) manifestation of schistocytes. Baesd on these, we calculated "LTx-TMA" score, as detailed in the lower table in Fig.2, which was analyzed in correlation with recipients' survival.
Results: Among various clinical parameters, only post-LTx platelet count was significantly associated with 6-months mortality. Moreover, patients' survival was clearly deteriorated according to the degree of thrombocytopenia (p<0.0001, Fig.1). Regarding the TMA criteria, thrombocytopenia occurred in 253 out of 290 cases (87.2%), hemolytic anemia was observed in 271 (93.4%), LDH elevation in 166 (57.2%), and schistocytes in 205 (70.7%). Of note, 95.2% (276 cases) exhibited at least 2 characteristics of TMA, and surprisingly, 112 cases (38.6%) met all 4 criteria by 60 post-operative days, indicating that almost all LDLT cases were accompanied by TMA-like disorder. Furthermore, the recipients' survival in 21 cases whose LTx-TMA score was only 0 point (4 cases) or 1 (17 cases) was 100% with significantly less morbidity and shorter hospital stay, while 17 out of 25 cases (68%) whose score reached 7 points died within 3 months after surgery (p<0.0001). As summarized in Fig.2, the higher the score was, the more deteriorated the patients' survival was.

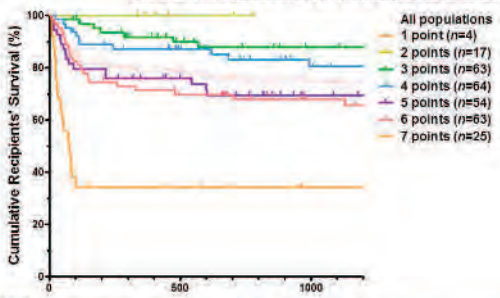
Fig.1 ***Post-operative thrombocytopenia determines Patients' Survival after LDLT***



Discussion: Almost all ADAMTS13 is produced by hepatic stellate cells, therefore, lowered activity of ADAMTS13 is always concurrent with up-regulation of von Willebrand factor (vWF) multimers just after

LTx. This imbalance, in turn, leads to platelet thrombus formation both in hepatic and in systemic microcirculation, resulting in prolonged dysfunction of transplanted livers, as well as in functional disorder of remote organs. Thus, we would like to propose such critical pathology as "LTx-TMA", which seems not only to be an important predictor of prognosis, but to be a novel therapeutic target for improving high mortality and morbidity after LDLT.

Fig.2 ***Impact of "LTx-TMA Score" on Patients' Survival after LDLT***



LTx-TMA Score

Points	Platelet Counts ($x10^3$/L)	Schistocytes	Hemolytic anemia	LDH elevation
3	<20			
2	20≤ , <50	+		
1	50≤ , <100		+	+

329.4

Impact of the Share 35 liver allocation policy on candidates with MELD exception scores

Elaine Cheng[1,2], Matthew Everly[2,3], Douglas Farmer[1], Fady Kaldas[1], Ali Zarrinpar[1], Vatche Agopian[1], Ronald Busuttil[1].
[1]Division of Liver and Pancreas Transplantation, University of California Los Angeles, Los Angeles, CA, United States; [2]Terasaki Research Institute, Los Angeles, CA, United States; [3]Department of Medicine, University of California Los Angeles, Los Angeles, CA, United States.

Introduction: Liver allocation policies in the United States have typically favored candidates listed with MELD exception scores, and the use of exceptions has increased yearly since the inception of the MELD era. A change to the allocation system was implemented on June 18, 2013 which mandates the regional sharing of deceased donor (DD) livers for candidates with MELD scores of 35 or higher. Our aim is to investigate the impact of the Share 35 policy on liver transplant (LT) candidates with exception points, with a focus on patients with hepatocellular carcinoma (HCC).

Methods: We reviewed the 73,508 LT candidates added to or removed from the United Network for Organ Sharing (UNOS) waitlist between June 18, 2010 and June 5, 2015. Candidates listed for multiple organs (except liver-kidney), pediatric patients and those with fulminant liver failure are excluded, and the remaining 67,119 candidates are included in the analysis. Patient data and donor characteristics are analyzed on a yearly basis (Years 1-5).

Figure. Reasons for Removal from the Waitlist by Year in the PRE-Share 35 and POST-Share 35 eras for **(A)** All waitlisted candidates and **(B)** Candidates with HCC exceptions only.

Results: The proportion of candidates added to the waitlist with exception scores have increased each year (21.5% in Year 1 vs. 24.4% in Year 5), with approximately 70% of the exception candidates carrying the diagnosis of HCC. The percentage of DD organs being used for exception cases have also increased over time (34.4% in Year 1 vs. 41.3% in Year 5). Candidates with HCC exceptions are more likely to receive DD transplants compared with the overall waitlisted population. After implementation of the Share 35 policy, however, a lower percentage of HCC candidates received DD transplants (82.9%

POST vs. 84.8% PRE, P=0.017), while a higher percentage died or experienced medical deterioration while on the waitlist (7.4% vs. 6.2%, P=0.032). These observations are in contrast to the overall cohort which has witnessed higher transplant rates and a lower waitlist mortality since Share 35 has taken effect.

Time on the waiting list for HCC candidates has increased with each given year. There is a significant rise in the proportion of HCC candidates with allocation MELD scores (including exception points) ≥35 at the time of LT in the POST-Share 35 era (2.5% vs. 0.8%, P<0.001), and a decrease in the proportion of HCC patients transplanted within 6 months of listing (45.7% vs. 50.5%, P<0.001). Additionally, high-risk donor organs are being preferentially used in exception cases, as shown by the increased median donor risk index in the POST-Share 35 era (1.40 vs. 1.38, P=0.010). Nevertheless, 1-year patient and graft survival rates have not been affected with implementation of Share 35.

Table. Summary of deceased donor liver transplant recipients with HCC exceptions during the PRE-Share 35 (Years 1, 2, and 3) and POST-Share 35 (Years 4 and 5) eras. AMELD = allocation MELD score (with exception points); IQR = interquartile range.

	PRE-Share 35			POST-Share 35	
	Year 1	Year 2	Year 3	Year 4	Year 5
Median [IQR] AMELD at time of transplant	29 [22, 29]	29 [22, 29]	29 [22, 29]	29 [22, 29]	29 [22, 29]
Number [%] AMELD ≥35 at time of transplant	5 [6.2%]	10 [9.3%]	11 [9.5%]	12 [9.5%]	30 [9.5%]
Median [IQR] time on waitlist (days)	130 [64, 331]	181 [83, 363]	190 [84, 395]	193 [80, 378]	205 [104, 406]

Allocation Type					
Local	1080 [81.8%]	1176 [82.2%]	1170 [81.8%]	1181 [81.4%]	1116 [77.8%]
Regional	198 [15.7%]	239 [20.0%]	202 [14.2%]	217 [15.0%]	227 [15.8%]
Median [IQR] distance travelled (miles)	50 [6, 147]	45 [6, 143]	42 [6, 142]	50 [6, 135]	49 [7, 149]
Median [IQR] cold ischemia time (hours)	6.2 [5.0, 8.0]	6.0 [4.7, 7.6]	6.0 [4.6, 7.6]	5.8 [4.5, 7.3]	5.8 [4.4, 7.3]

Conclusions: The Share 35 policy for liver allocation in the United States has reduced the relative advantage of MELD exception candidates, as evidenced by reduced transplant rates, a rise in waitlist mortality, prolonged waiting times, and the use of higher-risk donor organs. These recent changes have not affected short-term post-LT outcomes in these patients.

Live donor champion program for liver transplantation: Time to redefine the strategy

Jingzhou Wang [1], Melissa Donovan[1], Curtis Argo[2], Anita Sites[1], Daniel Maluf[1].
[1]Transplantation, UVA, Charlottesville, VA, United States; [2]Medicine, UVA, Charlottesville, VA, United States.

Background: Live Donor Champion (LDC) Programs promote the advocacy for living donor transplantation and has not been tested yet in liver transplantation. We conducted a prospective 9-month pilot trial of this novel educational intervention.

Patients and Methods: Patients evaluated for liver transplantation (LT) and without contraindications for living donor liver transplantation (LDLT) were invited to voluntarily attend the LDC training session designed to establish a collaborative approach from patients and health care team members (HCT), to develop an environment to promote donation, and test the feasibility of this pilot program. The LDC intervention includes (a): an initial face-to-face meeting (focus groups) with a presentation that enhances the knowledge on living donation, (b): personalized education provided by HCT to target all levels of health literacy, (c): follow-up phone calls for ongoing patient education, and video-conference consults. A historic control group was included. Metrics for evaluation of the intervention were established.

Results: From a total of 167 evaluated end stage liver disease (ESLD) patients, 72 were enrolled and 57 (79.2%) ESLD patients identified a care giver / donor champion interested to advocate for them. During this period of time, a total of 72 intakes (67 directed and 5 non-directed donors) were received on behalf of 38 participants (1.76 donors per ESLD patient). Data show that LDC program increased the number of intakes for liver donors during the study period (p-<.05). Furthermore, the number of completed donor evaluations increased.

Conclusion: LDC Programs improve patient knowledge of the live donor LT and increase access to living donation.

329.6

Factors associated with worse outcome in Korean split-liver transplantation: analysis of the 10-year Korean Network for Organ Sharing data base

Nam-Joon Yi, Sanghee Song, Ok-Kyung Kim, Hyeyoung Hong , Kyung Chul Yoon, Hyo-Sin Kim, Hyo-Sin Kim, Kwang-Woong Lee, Kyung-Suk Suh.
Surgery, Seoul National University College of Medicine, Seoul, Korea.

Background and Aim: Organ shortage has been a hot issue especially in the field of liver transplantation (LT) in Asian countries including Korea. In order to increase the donor pool, the policy of split LT (SLT) has been recently changed and recently number of SLT has been increased in Korea. However the outcome of SLT in Korea has not been reported.
Methods: This study evaluated the outcomes of SLT using the Korean Network for Organ Sharing (KONOS) between January 2005 and December 2014. Cases with two recipients from one deceased-donor were considered as SLT. A total of 200 cases of 100 pairs of SLT were examined.
Result: The recipient population was 107 adults and 93 children. The type of SLT composed of adult/children pair in 87 (87.0%). The median donor age and body weight were 25.0 (9 ~ 48) years and 66.3 (38 ~ 120) kg. Adult recipients' median age was 53.1 (25~77) years, and body weight 62.2 (35~101) kg. UNOS status 1 and 2A was 57 (53.3%) in adult recipients. The median donor / recipient weigh ratio (DRWR) was 1.12 (0.56 ~ 1.95); the DRWR < 1.0 was 37.4%. Pediatric recipients' median age was 2.82 (0~16) year and body weight was 13.2 (range, 3.6~55) kg. The median DRWR was 6.80 (1.09 ~ 17.04); the DRWR > 10.0 was 22.6 %. UNOS status 1 in pediatric recipients was 10 (10.8%). The overall patients' survival outcome was 75.5 %, but it was worse in adult recipients (67.3% vs. 84.9%) (Fig.1) ($p=0.004$). In adult recipients, prolonged prothrombin time (INR >1.5) of the donor and center sharing were poor prognostic factors in multivariate analysis ($p<0.05$).
Conclusion: Although the outcome of SLT in Korea was acceptable, the outcome was worse in urgent and big adult recipients, especially in cases of marginal donor with prolonged INR and low volume center. Further evaluation should be performed to make a good guideline for allocation of the deceased donor for SLT.

329.7

Principles from high volume living donor liver transplantation centre doubles the donor pool in deceased donor liver transplantation

Shishir Pareek, Nilesh Patil, Neerav Goyal, Subash Gupta.
Centre for Liver and Biliary Sciences, Indraprastha Apollo Hospital, New Delhi, India.

Aim: To study the contribution and need of LDLT experience in increasing the donor pool in DDLT.
Material and Method: Deceased donor transplantation is very uncommon in the south Asian countries due to ethical reasons.
With vast experience of over 1900 LDLT at our centre from Sept 2006 till date, steps helpful in havesting two Hemiliver in special circumstances from single deceased donor for two adult patients were analysed *without* the need for preoperative CT angiogram or intra-operative Doppler.
Results: LDLT differs from DDLT in following principles and Hemiliver grafts are utilized for donation.
1. Miticulous porta dissection with retrieval of first and second order vascular branches as inflow vessels.
2. Division of first and second order biliary radicles for anastomoses with recipient ductal opening with idea of maintaining a non obstructed biliary continuity in the remnant Hemiliver.
3. Miticulous bloodless insitu parenchymal transection is performed with- out the preoperative CT scan or intra-operative Doppler with the end point of keeping the MHV to Left lobe and retrieving sizeable reconstructable segment five and eight veins for anterior sector drainage of right lobe, hence two healthy grafts can be retrieved.
4. Main portal vein as well as CHD is kept with Right hemiliver whereas CHA is kept towards left hemiliver as greater anatomical variation of portal vein and biliary radicles are found in right Hemiliver and multiple segmental arterial branches are found in left Hemiliver.
5. The Inferior vena-cava along with caudate lobe is kept with the Left lobe.
6. Inflow vessels and ducts with small size and caliber are joined under magnification by keeping the recipient stumps long and with multiple openings with high porta dissection.
7. GRWR as low as 0.6 is acceptable with favourable recipient outcomes
Adult recipients with this insitu splitting technique had no difference in post-operative recovery and complication, day of normalization of LFT, coagulation profile, platelets, drain output, hospital stay.
Conclusion: Principles and experience from high volume LDLT centre can double donor pool in DDLT centre as well outcomes
Transplant surgeons in DDLT centres should have adequate exposure in LDLT setting as well.
More people will become motivated for organ donation as twice as many lives can be saved.

329.8

Changes in liver allograft steatosis and its impact on early graft function and long term survival

Jason Davis, Spencer Fuller, Chandrashekhar A.Kubal, Jonathan A.Fridell, A. J.Tector, Richard S.Mangus.
Department of Surgery, Transplant Division, Indiana University School of Medicine, Indianapolis, IN, United States.

Background: Deceased organ donor liver transplant allografts with steatosis have an increased risk of primary non-function and initial poor function post-transplant. A large percentage of donor livers have significant steatosis.Previous research suggests improvement in steatosis in the immediate post-transplant period. This study compares reperfusion and early post-transplant surveillance biopsies, and correlates the results with initial graft function and long-term outcomes.
Methods: Records of all liver transplants performed at a single center over a 14-year period were reviewed.The original biopsies were reviewed by experienced liver pathologists. Liver biopsies are obtained at the time of transplant and 3 days after transplant. Total steatosis is calculated as the sum of both micro- and macrovesicular steatosis, and is categorized into four study groups: (1) none (0%), (2) mild (<10%), (3) moderate (10-20%) and (4) severe (>20%). For this analysis, change in liver steatosis is calculated as moving from one study group to another. Early post transplant liver function is assessed by biochemical analysis of liver enzymes (alanine aminotransferase (ALT); liver injury), total bilirubin (TB; excretion), international normalized ratio (INR; synthesis). Long-term survival is assessed using Cox regression analysis.
Results: Data were available for 1572 adult subjects. Among the patients with steatosis, there was a significant and rapid decrease in steatosis.The median group change was greatest for severe steatosis groups (Group 3, >20%: -1.54; Group 2, 10 to 20%: -0.93; Group 1, 1 to 10%: -0.47 ($p<0.001$).Moderate and severe steatosis was associated with more acute liver injury ($p<0.05$ for days 1 to 6), and delayed graft function (higher TB and INR ($p<0.05$ on days 1, 3)). These values decreased for all study groups until they were similar by day 7 (ALT) and day 14 (TB and INR). Systemically, steatotic groups demonstrated an acute decrease in glomerular filtration rate from 1 to 3 days post transplant, ranging from -12 to -22% change, compared to only a -5% change for the nonsteatotic group. Graft survival was worse at all time periods for moderate and severe steatosis livers. Subgroup analysis was employed to identify groups that have a more dynamic decrease in steatosis. Those groups with better clearance of severe steatosis included recipients who were younger, more obese, male, and those with fatty liver disease.

Table 1 Study group demographics

		Transplant Liver Percent Steatosis at day 0				
	Overall	0% (none)	1-10% (mild)	11-20% (moderate)	> 20% (severe)	p-value
Number	1572	994 (63%)	382 (24%)	135 (9%)	61 (4%)	
Donor characteristics						
Age (years, median)	41	39	43	44	44	0.001
Male (%)	57%	56%	58%	58%	61%	0.87
Race (% white)	1278 (81%)	79%	84%	86%	87%	0.09
BMI (median)	26	25	28	30	28	<0.001

Table 2 Change in median liver steatosis from Day 0 to Day 3 post transplant

Day 0 biopsy		63%	24%	9%	4%	
Day 3 biopsy		71%	20%	6%	3%	
Median group change		0.19	-0.47	-0.93	-1.54	0.001

Conclusion: These results confirm a marked post-transplant decrease in allograft steatosis that occurs within 3 days of transplant. Subgroup analysis suggests that younger male patients who are obese or have fatty liver disease are more able to clear steatosis in this period. Allografts with moderate to severe steatosis have worse early injury, delayed graft function and worse early and late survival. Steatotic grafts are associated with a substantial acute decrease in renal function early post transplant.

Table 3 Subgroup Analysis (BMI, Age, Gender)

	Group Percent steatosis	Overall	0 0% (none)	1 1-10% (mild)	2 11-20% (moderate)	3 >20% (severe)	p-value
			994 (63%)	382 (24%)	135 (9%)	61 (4%)	
Recipient BMI							<0.001
< 25.0	Normal	-0.12	0.18	-0.5	-1.1	-1.2	
25.0 to 29.9	Overweight	-0.1	0.22	-0.43	-0.89	-1.5	
30.0 to 34.9	Obese	-0.22	0.15	-0.49	-1	-2.1	
> 35.0	Very obese	-0.09	0.26	-0.44	-0.67	-0.75	
Recipient age							<0.001
18 to 39 years		-0.05	0.19	-0.28	-1	-2	
40 to 59 years		-0.17	0.17	-0.49	-1.05	-1.6	
60 years and older		-0.08	0.25	-0.46	-0.68	-1.35	
Recipient gender							<0.001
Male		-0.018	0.18	-0.47	-0.95	-1.81	
Female		-0.04	0.22	-0.46	-0.87	-1.27	

329.9

Evaluation of the potential impact of inter-regional sharing for high MELD patients waiting for liver transplantation

Michael A. Fink[1,2], Glenda A.Balderson[3], Christopher Christophi[1], Robert M.Jones[1,2].
[1]Department of Surgery, Austin Health, The University of Melbourne, Melbourne, Australia; [2]Liver Transplant Unit Victoria, Austin Health, Melbourne, Australia; [3]Australia and New Zealand Liver Transplant Registry, Brisbane, Australia.

Background: Patients with high MELD or PELD scores have a risk risk of death on the liver transplant waiting list and a short window of opportunity during which rescue by liver transplantation is possible. A system of inter-regional sharing for patients with high MELD or PELD scores might enable a greater chance of transplantation
Aim: To evaluate the potential impact of an inter-regional sharing program in Australia and New Zealand for patients with high MELD or PELD scores.
Method: Prospective data of patients on the waiting lists of the six liver transplant units in Australia and New Zealand with a MELD or PELD score of at least 25 were collected during the period 1 October 2013 to 30 April 2015. The MELD or PELD score at the time of liver transplantation was obtained for all non-urgent patients transplanted using deceased donor grafts in Australia and New Zealand during the study period using data from the Australian and New Zealand Liver Transplant Registry. Simulation of inter-regional sharing of blood group compatible livers was performed using Filemaker Pro 13.0. The variables assessed in the model were the MELD/PELD threshold at or above which the patient would be eligible to receive an inter-regional offer and the minimum difference in MELD/PELD between the potential recipient of an inter-regional offer and the local recipient (who was transplanted in reality). The outcomes of the models that were assessed included the number of livers that would be required to be shipped, the number of patients potentially rescued from waiting list death by inter-regional sharing, the additional cold ischaemia time and the additional distance between donor and recipient hospital.
Results: During the 19-month prospective study period, 388 liver transplants, excluding urgently listed patients and those transplanted using living donor livers, were performed in Australia and New Zealand. During the same period across Australia and New Zealand, 102 patients had a MELD or PELD score of at least 25 at some time while waiting. Of these, 27 (26%) died waiting. Simulation of models of inter-regional sharing revealed that the lower the MELD/PELD threshold and the lower the MELD/PELD difference in the model, the greater the number of patients rescued from waiting list death. However, this is at the expense of a greater number of livers shipped, increased transport distance and cold ischaemia time.
Conclusion: Simulation of models of inter-regional sharing for patients with high MELD and PELD scores has demonstrated that this approach has the potential to rescue patients at a high risk of waiting list death. A trial of voluntary inter-regional sharing of deceased donor livers for patients with a MELD or PELD score of at least 35 has begun in Australia and New Zealand.
Liver and Intestinal Transplantation Advisory Committee of the Transplantation Society of Australia and New Zealand

329.10

Histologic change after body weight reduction of potential living liver donors with fatty liver

Young Rok Choi, Suk-Won Suh, Jeong-Moo Lee, Hyeyoung Kim, Hae Won Lee, Nam-Joon Yi, Kwang-Woong Lee, Kyung-Suk Suh.
Surgery, Seoul Nation University College of Medicine, Seoul, Korea.

Background: Fatty liver is critical for donor selection, which has been associated with a risk of complication for both donor and recipient after liver transplantation. After living donor weight reduction for a short-term, the change of liver fat percentile and pathologic findings were investigated.
Methods: A total of 356 living donor candidate were between January 2011 and November 2013 at a single center. Of them, 18 donors tried to lose their weight reduction. Fat fraction was estimated on preoperative non-invasive MR spectroscopy. And liver biopsy findings were analyzed before and after weight reduction.
Results: Eighteen donor candidates lose mean 3.6 ± 3.1 kg of their weight for mean 43.9 ± 31.0 days (range 7-107 days) and BMI was significantly decreased to 25.9 ± 3.1 kg/m2 from 27.1 ± 3.2 kg/m2 ($p < 0.001$). Their fat fractions were also significantly decreased to 6.8 ± 4.5% from 11.4 ± 4.7% ($p < 0.001$). Although preoperative liver biopsy showed that ballooning change (n=3, 23.1%), inflammation (n=9, 69.2%), fibrosis (n=2, 15.4%) and necrosis (n=3, 16.7%) before weight reduction, intraoperative biopsy showed no fibrosis, no necrosis, decreased inflammation (n=2, 17.6%) and improved ballooning change of hepatocyte (n=1, 5.9%) after weight reduction [table 1]. Although one candidate could not donate his liver finally because of steatohepatitis, the others recovered uneventfully.
Conclusions: Donor body weight reduction can expand donor pool and contribute to improving donor safety.

329.11

Prediction of nonalcoholic fatty liver in apparently healthy living liver donors: a large histology based comparison to normal controls

Narendra S. Choudhary[1], Sanjiv Saigal[1], Neeraj Saraf[1], Rahul Rai[1], Tarun Piplani[2], Dheeraj Gautam[3], Lipika Lipi[3], Amit Rastogi[1], Sanjay Goja[1], Prashant Bhangui[1], Sumana K.Ramchandra[1], Yalakanti R.Babu[1], Vikram Raut[1], Thiagrajan Srinivasan[1], Arvinder S.Soin[1].
[1]Institute of Liver Transplantation and Regenerative Medicine, Medanta The Medicity, Gurgaon, India; [2]Department of Radiodiagnosis, Medanta The Medicity, Gurgaon, India; [3]Departments of Histopathology, Medanta The Medicity, Gurgaon, India.

Background: Patients with milder grades of non-alcoholic fatty liver (NAFL) are often not picked up by ultrasound abdomen. Conventionally LDLT centers use CT based liver attenuation index (LAI) to rule out fatty liver in living related liver donors.
Materials and Methods: The study group included all prospective liver donors who had a liver biopsy during work-up due to high body mass index (>28 Kg/M^2), dyslipidemias, presence of metabolic syndrome or borderline remnant/graft to recipient weight ratio. Non-alcoholic fatty liver was defined as >5% hepatocytes having steatosis and no changes of steatohepatitis and/or fibrosis. Data is shown as mean (SD) or median (25-75 IQR). Following metabolic risk factors were calculated: BMI>25 Kg/M^2 (Asian Indian cut-off for obesity), diabetes/impaired fasting glucose, triglycerides >150 mg/dl, high-density lipoprotein (<40 in males and <50 mg/dl in females) and blood pressure>130/85 mmHg or hypertension.
Results: The study group comprised of 521 prospective liver donors (280 females), age 35.1±10.3 years, BMI 25.7±3.8 Kg/M^2. A total of 243 donors (46.6%) were diagnosed as having nonalcoholic fatty liver, the amount of steatosis ranged from 5-40%. When subjects with NAFL were compared with subjects with normal histology; NAFL group had higher BMI (26.4±3.6 versus 25.1±3.8 kg/M^2, p=0.000), higher values of ALT [33(24-41) versus 27(21.2-32.7), p=0.000], GGT [23(16-33.5) versus 18(13.2-26), p=0.000], triglycerides (135.5±65.3 versus 111.6±52.2 mg/dl, p=0.000), low density lipoprotein (108.5±31.5 versus 102.4±29.4 mg/dl, p=0.017), lower high-density lipoproteins (40.5±14 versus 42.9±10.7 mg/dl, p=0.029) and CT LAI values [9(4-13) versus 12(8-16), p=0.000]. NAFL group had higher number of metabolic risk factors [2(1-3) versus 1(1-2), p=0.000]. Presence of CT LAI<5 had a sensitivity of 25.7% and specificity of 91.4% for prediction of NAFL. Presence of ≥2 metabolic risk factors predicted NAFL with a sensitivity of 67%.
Conclusion: Presence of ≥2 metabolic risk factors has better sensitivity for prediction of NAFL than CT LAI in living liver donors and thus combination of both is better.

329.12

Significance of living domino donor liver transplantation in the context of limited number of deceased organ donors in Japan - A single center experience

Yukihiro Inomata, Shintaro Hayashida, Yasuhiko Sugawara, Hidekazu Yamamoto, Masaki Honda, Kaori Isono, Daiki Yoshii, Kohei Miura, Keita Shimata, Shinnichi Kawabata, Koushi Uchida. Transplantation and Pediatric Surgery, Kumamoto University Hospital, Kumamoto, Japan.

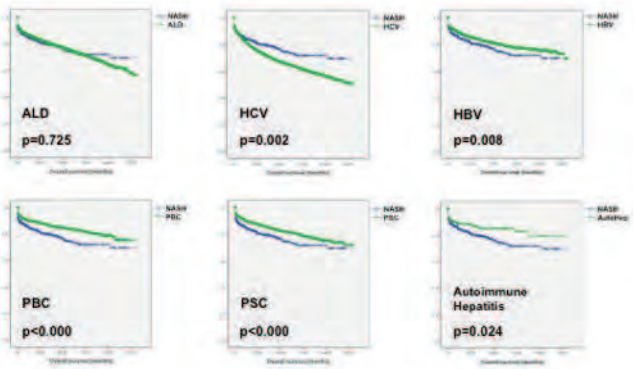
Background: Domino liver transplantation (DLT) using the liver from familial amyloid polyneuropathy (FAP) can expand the donor pool, although there is substantial risk of de novo onset of FAP in the recipient. With the reform of the organ transplant law in Japan, annual umber of deceased donor (DD) increased around 5 times, from 10 to 50. There is no nation-wide principle of the selection criteria of domino liver recipient using FAP liver. Benefit and risk of living domino donor liver transplantations (LDDLT) was analyzed in the cohort of one institution in the situation of still-limited number of deceased donors.
Patients and Methods: From 2003 to 2010, fifteen cases were done before the reform of the law (pre-group), and the other 6 were done after (post-group), from 2014 to February 2016. Selection process of the domino recipients (whether the candidate was on the DD liver transplant list or not), outcome of the LDDLT, and the onset of FAP, according to the timing of the transplant were analyzed.
Results: The original indication for LDDLT were; end-stage liver diseases in 12 (4 with HCC), re-transplant in 2, and congenital absence of portal vein with encephalopathy in 1, and in the post-group, ELD in 5 (3 with HCC), and re-transplant in the other 1. The mean age of the pre-, and post-group was 45.1 (18-58 yo) and 57.5 (51-62 yo), respectively. Only 4 out of 15 in the pre-group, and all of the post-group had been registered on the waiting list for DLT in Japan. Six-month post-transplant survival was 100% in both groups. Three patients of the pre-group died of malignancy. In 2 patients of the 8 long survivors in the pre-group, there are objective signs of FAP with least subjective symptoms.
Discussion: In the pre-group, younger patient were selected in consideration of hopeless possibility for DDLT. In the post-group, older patients with HCC were more common, as the traditional standards of the domino LT in the world, although, highly urgent patients (status 1) were not included.
Conclusion: Domino liver transplant had results of excellence and significance in the limited number of DD liver transplants. However, small increase of DD in Japan made the selection criteria a little difficult because the highly urgent patients will have substantial possibility of DD liver transplantation without the domino.

329.13

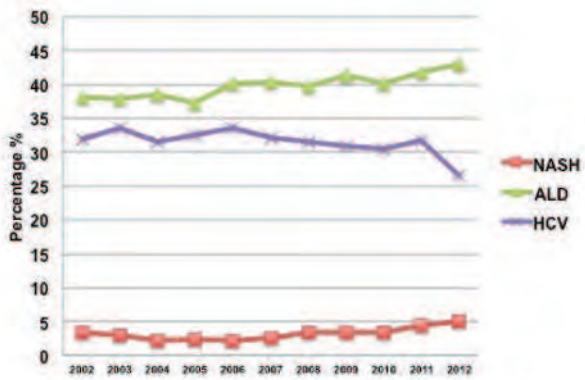
Nonalcoholic steatohepatitis as indication for liver transplantation in Europe. Clinical analysis of over 37.000 patients

Barbara Kern[1], Philip Newsome[2], Vincent Karam[3], Rene Adam[3], Gabriela Berlakovich[4], Josef Fritz[1], Benedikt Feurstein[1], Paolo Muiesan[5], Dietmar Öfner[1], Stefan Schneeberger[1].
[1]Operative Medicine, Innsbruck Medical University, Innsbruck, Austria; [2]Institute of Immunology and Immunotherapy , University of Birmingham, Birmingham, United Kingdom; [3]Centre Hépatobiliaire, Hôpital Paul Brousse, Villejuif, France; [4]Transplant Surgery, Medical University of Vienna, Vienna, Austria; [5]Queen Elizabeth Hospital, University of Birmingham, Birmingham, United Kingdom.

Background: Over the past years, nonalcoholic steatohepatitis (NASH) has emerged to become the third leading cause for liver transplantation (LT) in the US. Since 2002, chronic liver failure due to NASH has increased constantly.
Aim: The aim of this study was to investigate all adult patients with NASH, who underwent LT in Europe between 2002 and 2012.
Methods: We analyzed the European dataset of over 37.000 adult liver transplant recipients in collaboration with the European Liver Transplant Register (Paris – France) between 2002 and 2012. NASH was defined by clinical and histopathological findings. Patients with cryptogenic cirrhosis and a BMI over 30kg/m2 were also included.
Results: 37.612 adult patients underwent orthotopic LT in Europe. The most common indication for LT was alcoholic cirrhosis with 39.8% (14956/37612), the incidence of NASH was documented with 3.3% (660/37612). Except for ALD and HCV, overall survival was poor compared to other indications (HBV: p=0.0; PBC p<0.00; PSC: p<0.00; Others: p=0.02).



The male percentage accounted for 73.7% (27727/37612), female patients were only 26.1% (9855/37612; in less than 0.1% no sex was documented). Female patients and gender mismatch were identified as independent risk factor within the NASH cohort. Donor age over 55 years showed decreased overall survival in the nonNASH cohort, but not in the NASH group (p<0.00; p=0.5; respectively). Recipient BMI >40 did not impact on overall survival in the nonNASH patient group, but was identified as significant risk factor in the NASH cohort (p=0.1; p=0.02; respectively). Donor steatosis stratified as steatosis to mild, moderate and severe had no influence on the outcome in the NASH group, whereas in the nonNASH patient cohort, the difference was significant (p=0,01). In the multivariate analysis, donor BMI over 30m2/kg was identified as risk factor (p=0.023). The incidence of NASH reached 5%, ALD showed a slight increase, whereas HCV dropped below 30% by the year 2012.
Conclusion: Patients, who underwent LT due to NASH, did have decreased survival rates when compared to other indications except for ALD and HCV. Within the NASH group, female patients, gender mismatch, donor BMI over 30m2/kg and recipient BMI over 40m2/kg were identified as significant risk factors. A precise donor selection and the reduction of risk factors within the female population should be considered in patients with NASH undergoing LT.



350.1

Utilization and clinical outcomes of belatacept-based immunosuppression in U.S. renal transplant recipients

Xuerong Wen[2], Michael JinCasey[2], Alfonso H.Santos[2], Abraham Hartzema[1], Karl Womer[2].
[1]Department of Pharmaceutical Outcomes and Policy, University of Florida, Gainesville, FL, United States; [2]Nephrology/Medicine, University of Florida, Gainesville, FL, United States.

Introduction: In the BENEFIT and BENEFIT-EXT trials[1],[2], belatacept demonstrated non-inferior incidence of acute rejection and improved renal function in kidney transplants compared to a cyclosporine-based regimen. However, the drug's performance in a real clinical setting compared to tacrolimus has not been reported. A retrospective cohort study based on the Scientific Registry of Transplant Recipients data was conducted to compare 1-year utilization and outcomes of belatacept- and tacrolimus-treated U.S. kidney transplant recipients (KTR).

Methods: Solitary adult KTR who received belatacept+tacrolimus- or belatacept- (without CNI, termed belatacept alone) or tacrolimus (without belatacept, termed belatacept alone)-based regimens at hospital discharge from 6.1.2011 through 12.1.2014 were included. The primary outcome for this study included: one-year composite patient death or graft loss and one-year incidence of biopsy-proven acute rejection (BPAR). The secondary outcomes included mean estimated glomerular filtration rate (GFR) at 1 year and the one-year incidence of new-onset diabetes after transplantation (NODAT). Recipient demographic and clinical characteristics were adjusted in a multivariate Cox proportional hazard model. Further subgroup analyses were conducted in patients with high panel reactive antibody (PRA), with or without lymphocyte-depleting (LD) induction, and in individuals who met the same inclusion/exclusion criteria as the BENEFIT and BENEFIT-EXT trials[1],[2].

Results and Discussion: 50 244 adult recipients underwent solitary kidney transplantation during the study period, with 417 receiving belatacept+tacrolimus, 458 receiving belatacept alone, and 49 369 receiving tacrolimus alone at hospital discharge. The rates of 1-year composite patient death or graft loss in the two belatacept regimens were noninferior to that in the tacrolimus group. The rates of 1-year BPAR were numerically similar between belatacept+tacrolimus and belatacept alone in all recipients, BENEFIT-eligible patients, and BENEFIT-EXT-eligible patients (Figure 1A). However, these rates were significantly higher than those in the tacrolimus alone group for all three patient groups. The use of LD induction drugs was associated with lower 1-year BPAR rates in the recipients who received belatacept alone (14.6% vs 23.1%, P=0.02) (Figure 1B). In multivariate analyses, increased risk of BPAR associated with belatacept alone was identified in the overall study cohort compared to tacrolimus alone, (aHR: 2.36; 95%CI:1.82 – 3.05, P<.0001) with highest rates associated with non-LD induction (aHR: 2.65; 95%CI: 1.90-3.70, P<.0001), in BENEFIT-eligible patients (aHR: 2.51; 95%CI: 1.79 – 3.52, P<.0001) and in recipients with high PRA (aHR: 2.36, P<.0001). No significant difference in BPAR was demonstrated between belatacept+tacrolimus and tacrolimus alone. Renal function was significantly greater in belatacept- versus tacrolimus-treated BENEFIT-EXT-eligible patients (Figure 2). The risk of NODAT was significantly lower in the two belatacept groups than in the tacrolimus alone group (1.7% vs 2.2% vs 3.8%, respectively, P=0.01).

Conclusion: Despite improved graft function and fewer metabolic complications, it may be advisable to add short-term tacrolimus to belatacept the first year post-transplant and/or consider LD induction in high-risk patients, as the risk to benefit ratio allows.

Figure 1 A. 1-Year BPAR in All Recipients, BENEFIT-eligible Recipients, BENEFIT-EXT-eligible Recipients.
1 B. 1-Year BPAR in All Recipients with or without LD induction.

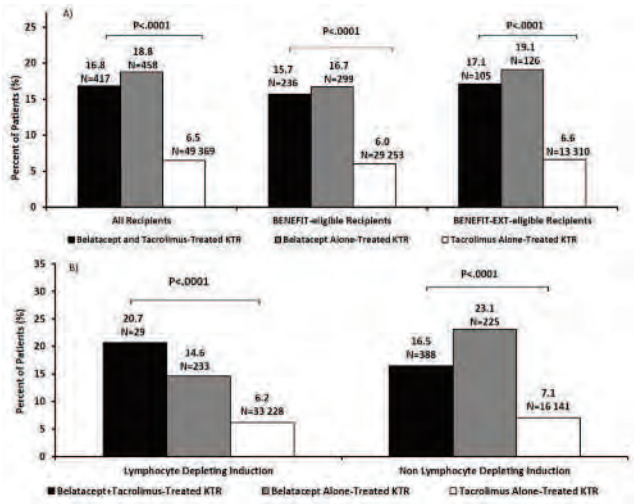


Figure 2. Renal Function Outcomes at 1 Year.

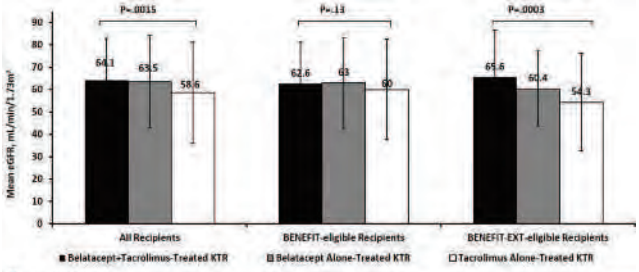

Recipients at 1 Year

Groups	All Recipients	BENEFIT-eligible Recipients	BENEFIT-EXT-eligible Recipients
Belatacept+Tacrolimus-Treated KTR	195	115	46
Belatacept Alone-Treated KTR	218	143	58
Tacrolimus Alone-Treated KTR	32 480	19 339	8530

Outcomes of de novo belatacept versus tacrolimus in kidney recipients of high risk donors

Mahmoud Alameddine, Jeffrey Gaynor, Linda Chen, Zhobin Moghadamyeghaneh, Gaetano Ciancio, Mohammed Osman, Rodrigo Vianna, George Burke, Mahmoud Morsi, Vincent Chia, Warren Kupin, Adela Mattiazzi, Giselle Guerra.
Transplant Surgery, Miami Transplant Institute, Miami, United States.

Background: The new kidney allocation system (KAS) has increased the incidence of delayed graft function (DGF) or slow graft function (SGF) in the United States. The benefit of a calcineurin sparing regimen using Belatacept (Bela) in this population may be offset by the reduced quality of the allograft. We report our preliminary experience with Bela vs Tacrolimus (TAC) in patients with kidneys from high risk donors (HRD) in KAS.
Material and Method: 24 patients received Bela from 1/2014 – 3/2015 after obtaining a kidney with one or more of the following: KDPI≥85%, Donation after Cardiac Death, terminal creatinine >2, cold ischemia time CIT > 30 hrs, donor age ≥ 70 year, or imported kidneys. We compared them to a similar control group (n=35) who received steroid free TAC regimen. Both groups received Thymoglobulin induction for three days after transplantation and maintenance with Myfortic. The Bela group remained on steroids. Outcomes were assessed for 6 months post-transplant (eGFR, white blood cell count (WBC), cytomegalovirus (CMV) and polyoma (BKV) viremia, and rejection).
Results: Mean eGFR was higher in the Bela vs TAC arm at months 2 (63.8 mL/min vs 50.2 mL/min) and 3 (62.8mL/min vs 51.7mL/min) P=0.0004 and P=0.007, respectively; however this decreased by 6 months, 56.3 vs. 54.7mL/min, respectively (P=0.73). The percentage of patients with DGF was higher with Bela 58.3% vs. TAC 17.1%, (P=0.001). Freedom-from-CMV Viremia was worse with Bela 11/24 events vs. 5/35 with TAC (P=.008). Freedom-from-BK Viremia was also poorer in Bela (P=.04), with 7/24 observed events vs. 3/35 in TAC. The occurrence of biopsy proven acute rejection (BPAR) was higher in Bela (4/24) vs. TAC (3/35), with actuarial BPAR at 12 months being 14.4% % + 7.9% vs. 6.8% + 4.7% in the Bela and TAC groups, respectively (P=0.20).
Conclusion: After 6 months, allograft function is similar for Bela and TAC but concerns exist with rejection, CMV, and BK viruses in the Bela for recipients receiving HRD from KAS.

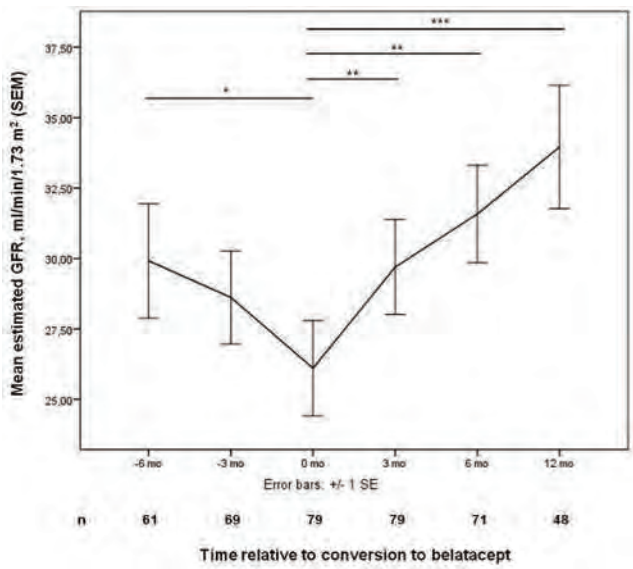
Belatacept rescue therapy in kidney transplant recipients with severely impaired renal function

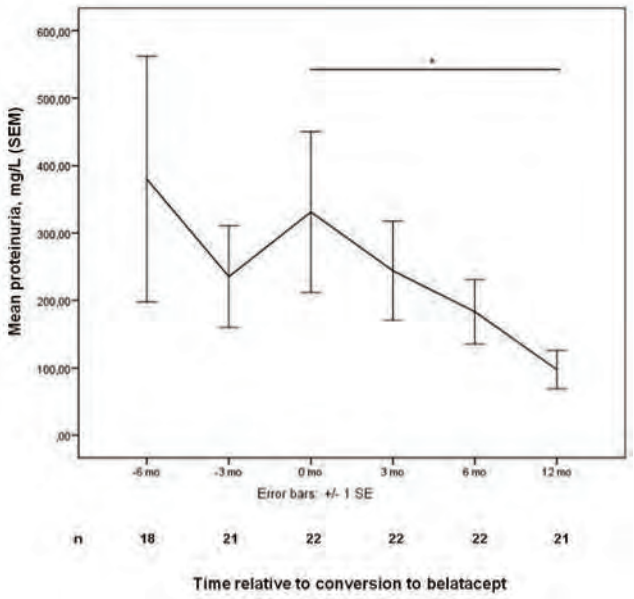
Klemens Budde[1], Michael Wiesener[2], Dennis Kannenkeril[2], Michael Dürr[1], Tobias Braun[2], Friederike Bachmann[1], Susanne Brakemeier[1].
[1]Nephrology, Charité, Berlin, Germany; [2]Nephrology, University Erlangen-Nürnberg, Erlangen, Germany.

Background: In kidney transplant recipients (KTRs) with chronic graft dysfunction, long-term immunosuppression with calcineurin inhibitors (CNIs) or mTOR inhibitors (mTORi) can be challenging due to adverse effects, such as nephrotoxicity and proteinuria.
Methods: 79 KTRs treated with CNI-based or mTORi-based maintenance immunosuppression who had CNI-induced nephrotoxicity or severe adverse events were switched to Belatacept. Mean time from transplantation was 69 months. The most common reason for conversion to belatacept was biopsy-confirmed CNI-induced nephrotoxicity (58.2%). The majority of patients (pts) were converted from tacrolimus (50.6%) followed by cyclosporine (21.5%), everolimus (20.2%), and sirolimus (7.6%). Prior to conversion, 50 (63.3%) pts were receiving steroids, 73 (92.4%) were receiving mycophenolate, and 6 (7.6%) azathioprine. Twenty-seven (34.2%) patients were DSA-positive at the time of conversion.



Results: Patient survival at 12 months post-conversion was 96.2%; two pts died (n=1 myocardial infarction and n=1 non-small–cell lung carcinoma (NSCLC). Graft survival at 12 months post-conversion was 86.1%, including 3 pts who died with a functioning graft. Of the 8 pts who lost their graft in the first year after conversion, 5 (62.5%) were DSA-positive at baseline and had a baseline estimated GFR of 21.9 mL/min/1.73 m2 and baseline proteinuria of 697±273 mg/L. Following conversion to Belatacept, 9 (11.4%) pts experienced biopsy-confirmed acute rejection (grade IB, n=4; grade IIA, n=1; grade IIB, n=3; grade III, n=1), with 2 graft losses due to fulminant rejection after conversion. Of the 9 pts presenting with acute rejection, 3 had switched to belatacept because of compliance issues. Mean eGFR (Figure 1) at baseline was 26.1 increasing to 34.0 mL/min/1.73 m2 at 12 months ($p<0.001$). Renal function improvements were also seen in pts with either low eGFR (<25 mL/min/1.73 m2) or high proteinuria (>500 mg/L) at conversion. Among the 22 pts who were using an mTORi prior conversion, mean proteinuria decreased significantly ($p<0.05$) from 331±119 mg/L at baseline to 244±74, 183±48, and 98±28 mg/L at 3, 6, and 12 months post-conversion, respectively (Figure 2). Discontinuation rate due to adverse events was 7.9%. During treatment

with Belatacept 46 pts (58.2%) were not hospitalized, but 33 (41.8%) pts were hospitalized for a total of 57 serious AEs, most commonly infection (n=19). Twelve of the 19 reported infections were severe (urosepsis n=6; CMV n=2; Pneumocystis jirovecii pneumonia n=1; miliary tuberculosis n=1; phlegmon n=1; Candida septicemia n=1). Four pts developed a malignancy (NSCLC [9 months after conversion]; Kaposi's sarcoma [8 months after conversion]; basal cell carcinoma [4 months after conversion]; CNS PTLD [17 months after conversion]).
Conclusion: Belatacept-based immunosuppression may be an alternative regimen for KTRs with CNI- or mTORi-induced toxicity.



350.4

Patterns of improvement in kidney function among patients converted to belatacept from calcineurin inhibitors for kidney allograft dysfunction

Dhiren Kumar[1], Anil Regmi[1], Hasan Fattah[1], Hitarth Dave[1], Justin Joseph[1], Pamela Kimball[2], Amit Sharma[2], Chandra S.Bhati[2], Hugh D.Massey[3], Anne L.King[1], Gaurav Gupta[1]. [1]Nephrology, Virginia Commonwealth University, Richmond, United States; [2]Transplant Surgery, Virginia Commonwealth University, Richmond, United States; [3]Pathology, Virginia Commonwealth University, Richmond, United States.

Background: Belatacept might be an alternative to Calcineurin Inhibitors (CNI) to avoid short and long-term nephrotoxicity. We have previously reported our initial experience on six patients suggesting improved renal function in high immunologic risk kidney transplant recipients (KTxp) switched from CNI to belatacept (Gupta et al, Am J Transplant. 2015 Oct). Here we present extended cumulative data on the use of a belatacept conversion regimen in patients with impaired graft function.
Methods: EBV seropositive patients were converted to belatacept from tacrolimus for biopsy proven acute CNI toxicity and/or interstitial fibrosis/tubular atrophy. Belatacept was initiated based upon prior published protocols. Mycophenolate mofetil dose was increased from baseline dose of 1-2g/d to a dose of 2-3g/d to minimize risk of rejection.
Results: Thirty one (mean age=46±11 years) patients were switched from tacrolimus to belatacept at a median of 7 months post-KTxp. A majority were African-American (23/31; 74%). Eleven patients (35%) were sensitized (mean PRA=27%; range=0-99%). Overall, renal function improved significantly from a peak mean GFR of 28±12 ml/min/1.73m2 to 36±15ml/min/1.73m2 (p=0.001) at a median follow-up of 14 (range=3-37) months post-conversion. Analysis of various metabolic parameters (lipid profile, hemoglobin A1c and hypertension) demonstrated a significant decline in a need for hypertension medications from a mean of 2.2 pre-conversion to 1.9 post-conversion (p=0.037). A comparison of patients who had an improvement in GFR (defined as >5ml/min/1.73m2; n=17) vs. those who did not (n=14) showed that increasing length of therapy with belatacept (21±10months vs 9±7months, p=0.001) was the only factor associated with improvement in graft function. Surveillance biopsies performed on 17 (out of 31) patients revealed 1 (6%) case of subclinical rejection. Cumulative chronicity scores pre- (3.6±1.6) and post-conversion (4.0±1.6) remained unchanged (p=0.49). In 28/31 (90%) patients there was no evidence of de-novo donor specific antibody (DSA). Two highly sensitized patients with stable creatinine had rising DSA after an infection. There were no new cases of BK viremia, CMV disease or malignancy.
Conclusions: In this extended experience on KTxp patients with significantly reduced GFR, we report remarkable improvement in renal function in patients converted from tacrolimus to belatacept with acute CNI toxicity and chronic allograft fibrosis without a significant concurrent increase in risk of rejection, worsening chronicity and DSA. Further follow-up and protocol biopsies are planned to ensure safety and wider applicability of this approach.

350.5

Early conversion to belatacept in patients with poor or delayed graft function

Luz Liriano-Ward, Vinay Nair, Ron Shapiro, Sander S.Florman. Recanati/Miller Transplantation Institute, Icahn School of Medicine at Mount Sinai, New York, NY, United States.

Background: The lack of nephrotoxicity makes belatacept a useful agent for patients experiencing calcineurin inhibitor (CNI) nephrotoxicity. Limited data exist on early conversion from CNI to belatacept (<6 months). We present our experience with early conversion from CNI to belatacept in patients with presumed CNI nephrotoxicity manifested by either prolonged delayed graft function (DGF) or poor function. We hypothesized that conversion to belatacept would lead to improved graft function and facilitate recovery from DGF.
Methods: We performed a chart review between 2012 and 2014 to identify all patients converted from CNI to belatacept < 6months post transplantation.
Results: Ten patients were converted from CNI to belatacept. Three had DGF for 3, 30, and 46 days prior to conversion. Seven patients were converted for poor renal function (eGFR<30 ml/min/1.73m MDRD). Eight were converted to belatacept with a starting dose of 10mg/kg on days 1, 5, and every two weeks with a median duration of 130 days post-transplantation and then transitioned to 5mg/kg monthly. CNI was withdrawn 1 to 5 days after the initiation of belatacept. This approach is based on de novo dosing to facilitate early withdrawal of CNI. Conversion to 5mg/kg was also based on de novo dosing where 5mg/kg dosing starts 4 months post-transplant. For 2 patients, belatacept conversion was performed > 4 months post-transplant. In these patients, belatacept was dosed 5mg/kg every 2 weeks for 2 months, then monthly while CNI was withdrawn over 1 month. This is based on a published study including patients > 6 months post-transplant (Rostaing L. CJASN. 2011). All 3 patients with DGF had renal recovery after 6, 15, and 64 days post CNI discontinuation with a current creatinine of 1.4mg/dl, 1.3mg/dl, and 3.6 mg/dl respectively. Median creatinine for the 7 patients with poor function was 2.9mg/dl (average 4.2mg/dl) prior to conversion, 1.9mg/dl one year post conversion, and 1.6mg/dl at a median follow up of 591 days. One patient had a borderline rejection after conversion to belatacept. There were no opportunistic infections or malignancies.
Conclusion: We report safe and effective early conversion from CNI to belatacept in patients with DGF or poor graft function. In both groups we observed an improvement in renal function without an increase in rejection, infection or malignancy. Additional studies are needed to evaluate the safety of early conversion and whether early conversion can improve renal function.

Tofacitinib in renal allograft recipients: long-term efficacy and safety in an active-comparator-controlled extension trial

Philip J. O'Connell[1], Stephan Busque[2], Flavio Vincenti[3], Helio Tedesco Silva[4], Atsushi Yoshida[5], John J.Friedewald[6], Steven J.Steinberg[7], Klemens Budde[8], Emine N.Broeders[9], Yon Su Kim[10], Carolyn Hahn[11], Huihua Li[11], Gary Chan[12].
[1]Westmead Hospital, Sydney, Australia; [2]Stanford University, Stanford, United States; [3]University of California, San Francisco, United States; [4]Hospital do Rim e Hipertensão, São Paulo, Brazil; [5]Henry Ford Hospital, Detroit, United States; [6]Northwestern University, Chicago, United States; [7]Sharp Memorial Hospital, San Diego, United States; [8]Charité Universitätsmedzin, Berlin, Germany; [9]Renal Transplantation Clinic, ULB Hospital Erasme, Brussels, Belgium; [10]Seoul National University College of Medicine, Seoul, Korea; [11]Pfizer Inc, Collegeville, United States; [12]Pfizer Inc, Groton, United States.

Introduction: Tofacitinib is an oral Janus kinase inhibitor. In a Phase 2b study, tofacitinib was effective in preventing acute renal allograft rejection in the first 12 months (mos) post-transplant but with an increased risk of serious infection events (SIEs) and three cases of post-transplant lymphoproliferative disease (PTLD)[1]. Here we evaluate the long-term efficacy and safety of tofacitinib in renal allograft patients (pts) over the next 60 mos.
Materials and Methods: Kidney transplant pts who completed 12 mos of randomised treatment with cyclosporine (CsA) or a Less Intensive (LI) or More Intensive (MI) tofacitinib regimen were enrolled in a Phase 2b, open-label extension study (NCT00658359). Pts continued their previous treatment of CsA or tofacitinib with mycophenolic acid products for 5 years, through Mo 72 post-transplant. Pts receiving tofacitinib MI/LI continued 10 mg twice daily (BID), decreasing to 5 mg BID by Mo 18. Primary outcomes were the incidence of first biopsy-proven acute rejection (BPAR), treated clinical acute rejection and adverse events (AEs). Secondary outcomes included glomerular filtration rate (GFR), chronic allograft nephropathy (CAN) and pt and allograft survival.

Table 1. Clinical outcomes through Month 72

	CsA (N=64)	Tofacitinib LI (N=60)	Tofacitinib MI (N=54)
Patients discontinued, n (%)	28 (43.8)	45 (75.0)	46 (85.2)
Patient survival, KM% (SE)	94.1 (3.4)	100 (0)	91.0 (4.5)
Graft survival (death censored), KM% (SE)	96.5 (2.4)	100 (0)	100 (0)
BPAR, KM% (SE)	13.3 (4.4)	10.0 (3.9)	7.4 (3.6)
Treated clinical acute rejection, KM% (SE)	29.7 (5.9)	11.7* (4.1)	11.1 (4.3)
CAN (IF/TA), KM% (SE)	69.3 (5.9)	60.2* (8.3)	62.2* (10.5)
Least square means eGFR by MDRD, mL/min (SE)	49.6 (3.5)	64.3 (3.6)†	59.2 (3.8)
Patients with AEs, n (%)	62 (96.9)	58 (96.7)	53 (98.1)
Patients with SAEs, n (%)	40 (62.5)	32 (53.3)	31 (57.4)
Patients with severe AEs, n (%)	31 (48.4)	20 (33.3)	22 (40.7)
TE SIEs, n (%)	18 (28.1)	21 (35.0)	14 (25.9)
TE malignancies, n (%)	6 (9.4)	6 (10.0)	8 (14.8)
Patients with PTLD, n	0	0	2
TE herpes zoster, (any) n (%)	5 (7.8)	14 (23.3)‡	6 (11.1)
TE serious herpes zoster, n (%)	2 (3.1)	2 (3.3)	1 (1.9)

Inferential statistical comparisons of tofacitinib LI, MI vs CsA were applied only to KM estimates, eGFR and % of patients with TE herpes zoster.
*p<0.05 vs CsA based on Log-Rank test comparing the overall survival curves through Mo 72.
†p<0.05 vs CsA using a linear mixed-effects model with repeated measures.
‡p<0.05 vs CsA based on exact test.

Treated clinical acute rejection was defined as an acute rejection episode that was diagnosed clinically and received anti-rejection treatment.
Serious herpes zoster infection was defined as herpes zoster infections that were serious AEs.
eGFR was calculated per the MDRD formula using LOCF and imputation (eGFR=0 for graft loss and death).
TE events do not include events in the first 12 months during the parent study.
CAN rate was based on all protocol-required and for-cause biopsies.

AE, adverse event; BPAR, biopsy-proven acute rejection; CAN, chronic allograft nephropathy; CsA, cyclosporine; eGFR, estimated glomerular filtration rate; IF, interstitial fibrosis; KM, Kaplan-Meier estimate; LI, Less Intensive; LOCF, last observation carried forward; MDRD, modification of diet in renal disease; Mo, month; MI, More Intensive; PTLD, post-transplant lymphoproliferative disease; serious adverse event, SAE; SE, standard error; SIE, serious infection event; TE, treatment emergent; TA, tubular atrophy.

Results: 178 pts were enrolled (CsA: n=64; tofacitinib LI: n=60; tofacitinib MI: n=54). Pt demographics were similar in all groups. Clinical outcomes are presented in Table 1. All groups had a similar BPAR rate but the treated clinical acute rejection rate was higher for CsA vs tofacitinib (CsA 29.7%, LI 11.7%, MI 11.1%). Estimated GFR was higher in tofacitinib pts than CsA pts by 10–15 mL/min/1.73m^2 but the rate of CAN was ≥60% in all groups. Pt and allograft survival rates, and AE and serious AE frequencies were comparable among groups. The SIE rates were: CsA 28.1%, LI 35.0% and MI 25.9%. The rates of malignancies were: CsA 9.4%, LI 10.0% and MI 14.8%. Two new cases of PTLD occurred in the tofacitinib MI group after Mo 12 post-transplant. A protocol amendment was implemented to discontinue 43 pts who had above-median tofacitinib exposure in the first 12 mos post-transplant, since all 5 cases of PTLD occurred in above-median exposure pts. No PTLD cases occurred in pts who continued after the protocol amendment.
Conclusion: Long-term tofacitinib treatment was effective in preventing acute allograft rejection. At Mo 72, tofacitinib pts had better renal function but similar cumulative CAN rates vs CsA. Long-term SIE risk remained but the magnitude of risk relative to CsA was reduced vs the first 12 mos post-transplant. Above-median tofacitinib exposure appears to be associated with increased PTLD risk. No new safety signals were reported.

Efficacy of a chimeric anti-human ICAM-1 monoclonal antibody, MD-3, for kidney transplantation in Rhesus monkeys

Sang-il Min[1], Min-Ji Cho[1], Sungshin Cho[1], Chang Hwan Lee[1], Song-Yi Kim[1], Ahram Han[1], Chanjoong Choi[1], Sanghyun Ahn[1], Seung-Kee Min[1], Kyeong Cheon Jung[2], Seong Hoe Park[2], Sang Joon Kim[1], Jongwon Ha[1].
[1]Department of Surgery, Seoul National University Hospital, Seoul, Korea; [2]Department of Pathology, Seoul National University College of Medicine, Seoul, Korea.

Introduction: The MD-3 is a newly developed chimeric anti-human intracellular adhesion molecule 1 (ICAM-1) monoclonal antibody (mAb). The effects of this monoclonal antibody in solid organ transplantation have not been elucidated.
Methods: Five rhesus monkey renal allograft recipients treated with MD-3 induction and one recipient without MD-3 treatment were studied for the incidence of acute rejection and donor-specific antibody development. Cellular immune response was tested with ELISPOT assay. Development of anti-drug antibody was also tested. Maintenance immunosuppression included anti-CD154 mAb (hu5C8), mycophenolate mofetil and corticosteroid.
Results: No recipient monkey developed acute rejection as long as 8 months after transplantation. Donor-specific antibody was not developed in monkeys treated with MD-3. A monkey without MD-3 induction started to produce donor-specific antibody 3 weeks after cessation of anti-CD154mAb and persisted. No anti-drug antibody was detected during the study period.
Conclusions: MD-3 can be a highly promising agent for clinical use in human allotransplantation and MD-3 treatment can allow optimization of kidney transplant outcome. Further studies for refining dosages and dosing schedule of MD-3 in kidney transplantation are required.

350.8

A novel non-invasive blood transcriptional assay, kSORT, monitors alloimmune response in the SAILOR randomized multicenter EU trial

Per Lindner[1], Jana Ekberg[1], Bente Jespersen[2], Karin Skov[2], Tara Siegdel[3], Sue Hsieh[3], Minnie Sarwal[3].
[1]Transplant Institute, Sahlgrenska University Hospital, Gothenburg, Sweden; [2]Department of Renal Medicine, Skejby Hospital, Aarhus, Denmark; [3]Department of Surgery, University of California, San Francisco, San Francisco, CA, United States.

Background: Non-invasive diagnosis and prediction of acute rejection (AR) is a critical unmet need. A In a randomized multicenter trial of a target enrollment of 222 renal transplant recipients treated with steroid minimization and a tacrolimus, MMF based regimen, a novel blood transcriptional assay, kSORT (Roedder et al, PlosMedicine, 2014) was evaluated for its accuracy in diagnosing and predicting biopsy confirmed AR.
Methods: Serial peripheral blood samples were drawn at day 0, 10, months 3, 6, 12 at clinical graft dysfunction, prior to treatment intensification in PAXgene tubes to for blinded analysis of kSORT, a customized 17 gene assay (CFLAR, DUSP1, IFNGR1, ITGAX, MAPK9, NAMPT, NKTR, PSEN1,CEACAM4, EPOR, GZMK, RARA, RHEB, RXRA, SLC25A37, RNF130, RYBP) that provides AR high or low immune risk scores. The assay has a ~15% assay read out of intermediate (non-confirmatory) scores where repeat sampling is recommended. Serial DSAs were monitored. Biopsies were done on all study patients by protocol at engraftment and 12 months post-transplantation and when clinically indicated; central histology was read by Banff scores. The kSORT assay was run on 338 blood samples obtained from the first 79 enrolled patients, of which 98 blood samples were matched with protocol or indicated biopsies. 22 patients had clinically suspected acute rejection (AR) of which 18 were biopsy confirmed. RNA was extracted and QPCR for all 17 genes was normalized to 18S; data was profiled using a customized algorithm kSAS to produce an immune risk score for rejection.
Results: Of the 18 biopsy confirmed AR episodes, all were cellular and DSA negative; 15 had definite kSORT scores and 3 were intermediate; 14/15 AR had high-risk KSORT scores. 11 AR episodes had prior blood samples collected per protocol in the previous 4 months; 8/11 of the pre-AR samples had high kSORT scores, in the absence of clinical graft dysfunction. Of the 80 biopsy matched blood samples without histological AR, 73 had definite kSORT scores, and 7 had intermediate calls. 67/73 blood samples matched with biopsies without AR, had low-risk kSORT scores. There are no cases to date of BKVN, but 13 blood samples were positive by BK QPCR, and 12/13 of these blood samples had low-risk scores for kSORT and 1 was intermediate.
Conclusion: Interim results of the diagnostic accuracy of the kSORT assay in a randomized prospective multicenter trial in renal transplantation, confirms that the assay has 93.3% sensitivity and 90% specificity and 98.6% NPV for the non-invasive diagnosis of AR, and is not confounded by BK viremia. 73% of AR could have been diagnosed by the kSORT assay days-months prior their current time-line for diagnosis based on the serum creatinine alone, supporting the use of this assay for serial monitoring of rejection risk and proactive immunosuppression customization to alloimmune risk.

Immunologic basis for a novel organ-specific therapy: Immunocloaking

Lauren Brasile[1], Bart Stubenitsky[2], Nicholas Henry[1], Karina Kizjakina[1].
[1]Research and Development, BREONICS Inc., Watervliet, NY, United States; [2]Surgery, University of Maastrict, Maastrict, Netherlands.

Introduction: We have previously reported on an organ-specific immunomodifying therapy referred to as immunocloaking (IC) that provides protection from early allograft rejection without immunosuppressive drugs. The IC membrane is comprised of extracellular matrix proteins and is applied during ex vivo warm perfusion where it binds to the luminal surfaces of the vasculature within kidneys. The IC membrane functions by interrupting the interface between the donor vascular endothelium (VEC) and recipient immune cells; without adversely affecting renal function. The result is a newly engineered non-thrombogenic/non-immunogenic apical surface. We now report the underlying protective mechanisms involved with IC.
Materials: The IC membrane was applied to human VEC. The immunologic testing included: effect of IC on antigen presentation, T cell activation & diapedsis using standard methodology with flow cytometry, Luminex screening and chemotactic-driven diapedesis. The testing used responding mononuclear cells (MNC) stimulated by allogeneic VEC without IC (positive control) and the same VEC that were IC (test). Transendothelial migration involved VEC grown on filters in Transwell™ plates. MNC were added to the upper chambers and the chemoattractant SDF-1, a potent chemotactic factor for lymphocytes, was added to the lower chambers to form chemokine gradients.
Results: The immunocloaking membrane prevents antigen presentation and early T cell activation, thereby eliminating T cell proliferation. The results from mixed lymphocyte/VEC studies demonstrate that VEC strongly stimulated MNC. Immunocloaking the same VEC inhibited the responses by >99% (Figure 1).

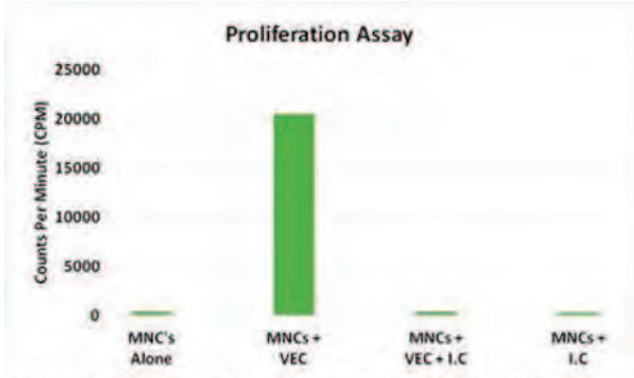

Figure 1 : A mixed lymphocyte-endothelial reaction was performed in a standard 96 well plate. Mononuclear Cells (MNC) were plated alone, with allogeneic vascular endothelial cells (VEC) or on Immunocloaked (IC) VEC. Cells were allowed to proliferate for 4 days prior to pulsing with [3H] thymidine. The cells were then allowed to incubate for 18H and read on a scintillation counter.

Transmigration: In negative controls without SDF-1 few MNC migrated through VEC layers into the lower chambers. In positive controls >65% of the cells migrated through the VEC into the lower chambers containing the SDF-1. When VEC monolayers were IC, the MNC migration into lower chambers with the SDF-1 was inhibited by a mean of 86.7% (Figure 2).
Conclusions: We previously demonstrated that IC prevents renal allograft rejection for a mean of 30 days in the absence of systemic immunosuppression. How the IC prevented rejection was previously

unknown. We now show that IC temporarily prevents alloresponses. Significantly, IC prevents chemokine-stimulated transmigration. Eliminating the need for nephrotoxic drugs during the early posttransplant period could help to ameliorate the severity of delayed graft function.

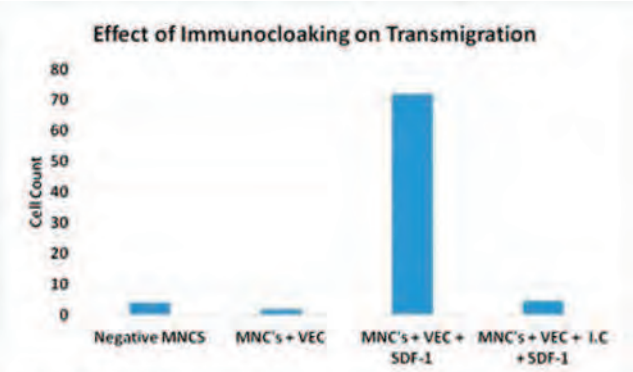

Figure 2: Chemotactic driven migration of mononuclear cells through Transwell. A concentration gradient was created with SDF-1 (10ug/ml). N=3. Cells were incubated for 3 hours and final counts were performed using a Nexcelom Cellometer and the mean of graphed. Immunocloaking provided an 86.7% reduction in migration of MNC.

351.1

Composite pancreatic islet grafts with adipose tissue-derived stem cells enhance the survival and insulin function of islet grafts in diabetic mice

Masahiro Tanemura[1,2], Yoshiaki Ohmura[2], Hiroaki Nagano[2], Hidetoshi Eguchi[2], Hideshi Ishii[2], Yuichiro Doki[2], Masaki Mori[2].
[1]Department of Surgery, Osaka Police Hospital, Osaka, Japan; [2]Department of Gastroenterological Surgery, Osaka University Graduate School of Medicine, Suita, Japan.

Introduction: Combined transplantation of allogeneic islets and adipose tissue-derived stem cells (ADSCs) under the kidney capsule promoted survival and reduced the islet mass required for reversal of diabetes in our previous study. [Aim] The aims of this study are to determine similar outcome can be obtained by islet transplantation (ITx) combined with ADSCs into the portal vein.
Materials and Methods: Isolation of islets and ADSCs: Anesthetized male BALB/cA mice underwent pancreatic inflation. The inflated pancreas was digested by collagenase (VIII), followed by purification using a Ficoll gradient. The adipose tissues from male EGFP-C57BL/6 mice were digested by collagenase (II). Generation of composite graft: Isolated islets were co-cultured with ADSCs in RPMI1640 medium for 24 hr. All islets were entirely covered with GFP-ADSCs. ITx into the liver: Streptozotocin(STZ)-induced diabetic male C57BL/6J mice were divided into five experimental groups (n=5/group) to receive allogeneic islets into the liver. ITx groups included group A: islet alone (600 IEQ) and group B: islet alone (400 IEQ). Hybrid group included group C: injection with islet (400 IEQ) + syngeneic GFP-ADSCs (4x105cells). Composite group included group D: composite graft with islets (400 IEQ) + syngeneic GFP-ADSCs (4x105 cells). 4x105cells of GFP-ADSCs were implanted as group E. After ITx, the non-fasting blood glucose level was monitored. Islet graft rejection was defined when two consecutive blood glucose levels exceeded 250 mg/dl. IPGTT was performed at day 7.
Results: The data were summarized in table 1.

Table 1

Group	Graft survival (n=5, days)	Mean graft survival (n=5, mean ± SD days)	Glucose pattern of IPGTT (n=5)	Blood glucose at 120 min during IPGTT (n=5, mg/dl)
A: Islets alone (600 IEQ)	20, 20, 19, 19, 18	19.2 ± 0.8	Normal pattern	130 ± 43*
B: Islets alone (400 IEQ)	0, 0, 0, 0, 0	0	DM pattern	347 ± 54
C: Hybrid ITx (: mixture) (islets 400 IEQ + 4 × 10^6 ADSCs)	3, 0, 0, 0, 0	0.6 ± 1.2	DM pattern	435 ± 48
D: Composite graft ITx (islets 400 IEQ + 4 × 10^6 ADSCs)	22, 17, 16, 13, 12	16.0 ± 3.5	Normal pattern	129 ± 19*
E: ADSCs alone (4 × 10^6 ADSCs)	0, 0, 0, 0, 0	0	Not done	Not done

*: blood glucose of non-diabetic mice: 110 ± 26 mg/dl

- Transplantation of 600 IEQ islets only achieved normoglycemia, whereas that of 400 IEQ allogeneic islets never reversed diabetes. Composite graft transplantation with 400 islets and ADSCs reversed diabetes and significantly prolonged graft survival.
- Few number of fragmented islet grafts were barely detected in 400 IEQ islets-ADSCs hybrid transplant, whereas insulin positive islets covered with GFP-ADSCs, which were well-preserved islets structure were found in islets-ADSCs composite transplant.

Conclusions: Our innovative methods may improve the efficiency of islet transplantation and could have a significant clinical impact on the patients with type 1 diabetes.

What are factors affecting insulin independence in patients after total pancreatectomy and islet autotransplantation (TPIAT)?

Julia Solomina[1], Sabrina Matosz[1], Celeste Thomas[2], Andres Gelrud[2], Zehra Tekin[1], Justyna Golebiewska[3], Maciej Sledzinski[4], Karolina Golab[1], Lindsay Schenck[1], W. James Chon[2], Sabarinathan Ramachandran[1], Martin Tibudan[1], Jeffrey B.Matthews[1], Piotr Witkowski[1].
[1]Surgery, University of Chicago, Chicago, United States; [2]Medicine, University of Chicago, Chicago, United States; [3]Nephrology, Transplantology and Internal Medicine, Medical University of Gdańsk, Gdańsk, Poland; [4]General Surgery, Endocrinology and Transplantology, Medical University of Gdańsk, Gdańsk, Poland.

Background: Islet autotransplantation allows preserving glucose control with or without insulin supplementation after total pancreatectomy. Insulin independence has been correlated with higher islet beta cell mass transplanted[1]. However, there are still patients who require insulin treatment despite receiving high islet mass. In this study, we looked for other factors influencing insulin independence after islet autotransplantation.
Material and Method: Twelve recent patients after TPIAT were submitted to the Mixed Meal Tolerance Test (MMTT) on day 75 after pancreatectomy and islet transplantation. Patients with peak blood glucose below 180mg/ml on MMTT were asked to stop insulin supplementation. Patients with subsequent hyperglycemia and rising A1c over 6.5 mg/ml had insulin reinstalled or increased, and those with episodes of hypoglycemia- insulin reduced or stopped.
Results: Six patients became insulin free and remaining 6 required insulin support. Five patients, who were off insulin, received at least 200,000 islet equivalents (IEQ). Although our last patient from this group was infused with only 175,000 IEQ, it constituted over 2,500 IEQ/kg body mass due to his low body weight. His glucose level oscillated between 90mg/ml and 120mg/ml with relatively low peak serum c-peptide concentration- 0.72pmol/ml but high- 4.4 fold increase in MMTT, indicating his high insulin sensitivity.
On the other hand, 4 patients who received less than 100,000 IEQ (<=1,000 IEQ/kg) required chronic insulin support, as expected. However, 2 remaining patients required insulin treatment despite receiving islet infusion in relatively high doses of 3,6000 IEQ and 4,100 IEQ/kg. First patient had peak of glucose at 200mg/ml with relatively low peak c-peptide of 0.8pmol/ml in MMTT, indicating low islet engraftment. In the next 6 months, the same patient gradually intensified physical exercise and required only 2 units of insulin daily. She lowered her daily blood glucose excursion from 300mg/ml to below 180ml/mg, most likely due to increased insulin sensitivity, with serum A1c declining from 6 to 5.4.
Second patient presented normal MMTT results with peak blood glucose of 154mg/ml and c-peptide of 1.75pmol/ml. Patient still requires at least 10 units of insulin per day to prevent hyperglycemia due to high sugar diet (>50 carbs per meal).
Conclusion: Insulin independence strongly correlates with higher infused islet mass but it can be compromised by poor islet engraftment, high glucose intake with meals, and with increased insulin resistance. Luckily, physical exercise and low sugar diet can improve glucose control and insulin sensitivity as well as lower insulin requirements. Such observations are consistent with borderline beta cell islet mass and function in patients after TPIAT.

Cyanidin-3-O-glucoside (C3G) improves the cell viability of human islets treated with human amylin or Abeta1-42 in vitro

Josue Rodrigues Silva[1], Wen Fu[2], Jack H.Jhamandas[2], Gina R.Rayat[1].
[1]Department of Surgery, University of Alberta, Edmonton, Canada; [2]Department of Medicine, University of Alberta, Edmonton, Canada.

Background: Amyloid deposition is linked to different diseases such as type 2 diabetes and Alzheimer's disease in which amyloid is formed by islet amyloid polypeptide (IAPP, also called amylin) and amyloid β (Aβ), respectively. Amyloid aggregation has been thought to induce processes that lead to a perturbation in the structure of lipid membranes, which subsequently disturb cellular ion homeostasis and trigger a cascade of events, including the formation of reactive oxygen species (ROS). Flavonoids are known to have antioxidant property and are capable of protecting islets from the harmful effect of ROS. Previously we showed that C3G a flavonoid found in Chinese bayberry (Myrica rubra) enhanced the function of mouse and pig islets after transplantation into diabetic mice[1],[2]. In this study, we tested the effect of C3G on human islets *in vitro*.
Methods: Human islets were cultured with or without C3G for 24 hours, and then treated with human amylin or $A\beta_{1-42}$ at physiological conditions. Samples were stained with Thioflavin-S, Calcein/Ethidium and dichlorodihydrofluorescein diacetate to evaluate the amyloid aggregation, cell viability and ROS by ImageJ and stereological analysis. The ultrastructure of islets was also assessed using transmission electron microscope (TEM).
Results: Treatment of human islets with C3G reduced the amyloid-like deposition compared to untreated islets. C3G treatment also improved the survival of islet cells and reduced the presence of ROS in the islets that were exposed to human amylin or $A\beta_{1-42}$. TEM images of islet cells treated with C3G showed an increased autophagic activity in contrast with other conditions.
Discussion: The natural electron deficiency of anthocyanins such as C3G, endows these compounds with high reactivity toward ROS, and they are therefore among the most powerful natural antioxidants in dietary plants. In this study, we found that human amylin and $A\beta_{1-42}$ are toxic to human islets similar to what was reported in neurons[3],[4]. However, C3G attenuated this effect and enhanced the viability of human islets as well as decreased the levels of ROS in the presence of human amylin and $A\beta_{1-42}$. Further analysis of TEM images of human islets showed that selective degradation of organelles such as mitochondria and endoplasmic reticulum as well secretory granules was prominent in islets treated with C3G. It is possible that this selective autophagy plays an important role in protecting islets against cell death in the presence of C3G.
Conclusion: Our preliminary results indicate that C3G could enhance the survival of human islets *in vitro* by reducing amyloid-like aggregates and ROS and by increasing autophagy as a survival mechanism under oxidative stress. It remains to be determined whether C3G could also enhance insulin secretion of human islet beta cells.

The protective effect of dimethyl fumarate on human pancreatic islets

Shiri Li[1], Nosratola D. Vaziri[2], Chie Takasu[3], Lourdes Robles[1], Akihiro Shimomura[1], Clarence E. Foster[1], Michael J Stamos[1], Hirohito Ichii[1].
[1]Department of Surgery, University of California, Irvine, Orange, CA, United States; [2]Department of Medicine, University of California, Irvine, Orange, CA, United States; [3]Department of Digestive and Pediatric Surgery, Tokushima University Graduate School, Tokushima, Japan.

Background: It is well known that pancreatic islets contain low level of antioxidants which renders them vulnerable to oxidative stress. Activation of Nuclear factor erythroid 2-related factor 2 (Nrf2) pathway induces up-regulation of numerous genes encoding antioxidant and phase II detoxifying enzymes and related proteins. Our previous study showed that treatment of human pancreatic islets with Nrf2 activator, dh404, protected beta cells against oxidative stress by significantly increasing expression of anti-oxidant enzymes. Dimethyl fumarate (DMF), a novel anti-inflammatory drug, was recently approved by the FDA for the treatment of multiple sclerosis. DMF has been shown to activate the cytoprotective Nrf2 pathway, inhibit production of pro-inflammatory mediators, and modulate the immune system. In this study, we tested the hypothesis that treatment with DMF in vitro may protect human pancreatic islets and improve islet function in vivo.
Methods: Human islets obtained from cadaveric donors were cultured in media containing DMF or vehicle. After culture, Nrf2 translocation of islet was examined by immunofluorescence and confocal microscopy. The expressions of key antioxidant proteins in islet were also assessed by western blot. To evaluate the potency of islets in vivo, 2000 IEQ of human islets were transplanted to diabetic nude mice. Glucose tolerance test was performed four weeks after transplant.
Results: Nrf2 nuclear translocation confirmed by confocal microscopy 6 hours after DMF treatment, revealed a concentration-dependent increase in expression of anti-oxidant enzyme, including NQO-1, GCLC and GCLM. Transplantation with 2000 IEQ islets in both DMF and vehicle groups reversed diabetes in all diabetic nude mice. Nevertheless, DMF treatment group showed significantly lower blood glucose value at 10, 30 min and the area under the curve of the IPGTT graph.
Conclusion: Treatment of human pancreatic islets with DMF significantly up-regulated expression of the key anti-oxidant enzymes and improved islet function in vivo.

Optimization of pre-vascularization procedures for improving islet engraftment under the skin

Satomi Uematsu[1], Akiko Inagaki[2], Kozue Imura[2], Yasuhiro Igarashi[2], Noriaki Ohuchi[1], Susumu Satomi[1], Masafumi Goto[1,2].
[1]Division of Advanced Surgical Science and Technology, Tohoku University School of Medicine, Sendai, Japan; [2]Division of Transplantation and Regenerative Medicine, Tohoku University School of Medicine, Sendai, Japan.

Introduction: The current standard procedure of islet transplantation, intraportal injection, has several issues to be solved including strong innate immune reactions, risk of portal vein embolism, and limitation of repeated injections. By contrast, in subcutaneous site, the procedure of islet injection is minimally invasive, thus it is possible to repeat islet transplantation. However, it is well known that subcutaneous site has poor vascularization. Therefore, optimization of pre-vascularization procedures prior to islet transplantation is crucial for improving the outcome of subcutaneous islet transplantation. Although the effectiveness of basic fibroblast growth factor (bFGF) was previously reported, the detailed procedures including heparin necessity remain uncertain. Here, we sought to optimize pre-vascularization procedures to subcutaneous transplant site.
Materials and Methods: The releasing devices including bFGF (0, 10, 20, or 30 ug) with or without heparin were implanted into the subcutaneous space of diabetic C57BL/6 mice 5-7 days after Streptozotocin injection. Vascularized area was assessed using contrast enhanced computed tomography (CECT). Marginal amount of syngeneic islets were transplanted into the pre-vascularized space 9-11 days after removal of the devices. Blood glucose, body weight, intra-peritoneal glucose tolerance test of the recipients, and immunohistochemistry of the grafts were evaluated.
Results and Discussion: The curative rates of diabetic recipients in both the bFGF 30 ug without heparin group and 20 ug with heparin group were significantly higher than that in the control group ($P<0.05$). According to the CECT, irrespective of bFGF dosage, pre-vascularized area in the heparin-supplemented groups was apparently expanded comparing with bFGF alone groups. In contrast, no beneficial effects on graft survival were observed by heparin addition in any dosages of bFGF groups. The curative rate in the highest dosage of bFGF combined with heparin group was even worse compared to the bFGF(-) group. Most likely, this is due to effusion and bleeding caused by synergistic effects of bFGF and heparin. Of particular interest, the curative rate in the bFGF(-) group was considerably higher than that in the control group (66.7% vs 16.7%), and was comparable to those in the bFGF groups. Especially in severe diabetic models, the duration to cure was significantly higher in the bFGF 20 ug and 30 ug groups ($P=0.03$, $P=0.01$, respectively), and also glucose tolerance was significantly ameliorated in the bFGF 10 ug group ($P=0.04$), suggesting that bFGF could additionally contribute to raising the graft function by promoting pre-vascularization to the subcutaneous site.
Conclusion: These data suggest that not only chemical effects by bFGF, but also mechanical stimulation based on foreign-body reactions might be crucial for pre-vascularization to the subcutaneous transplant site. Material compatibility for efficient pre-vascularization would therefore be a novel strategic target towards improving islet engraftment under the skin.

Y1 receptor antagonism enhances insulin secretion and improves islet transplantation efficiency

Stacey Walters[1], Kim Loh[2], Yan-Chuan Shi[2], Kailin Lee[2], Herbert Herzog[2], Shane Grey[1].
[1]Immunology, Garvan Institute, Darlinghurst (Sydney), Australia; [2]Neuroscience, Garvan Institute, Darlinghurst (Sydney), Australia.

Introduction: Islet transplantation for the treatment of type-1 diabetes is hampered due to insufficient availability and quality of donor islets. One option to improve this is to enhance β-cell function through pharmacological modulation therefore reducing the number of donor islets required. Efforts have previously focused on pathways that stimulate insulin secretion with limited success; here we investigate a novel role for the neuropeptide YY (PYY) in the termination of insulin secretion. PYY can act upon the Y1 receptor which is widely expressed in pancreatic β-cells. Y1R is a G-protein coupled receptor that preferentially associates with Gi/o G-protein and can act as an inhibitor for intracellular cyclic AMP (cAMP) levels. It has been demonstrated cAMP reduction can reduce insulin release, indicating potential for an inhibitory effect of Y1 receptor signalling induced by locally produced PYY in regulating insulin release.
Materials and Methods: $Y1^{lox/lox}/INS2^{cre/+}$ mice were generated. Isolation & transplantation of islets, glucose stimulated insulin release (GSIS) & intravenous glucose tolerance test (IVGTT) were conducted as per standard protocols.
Results: GSIS on C57/BL6 mouse islets in the presence of PYY exhibited reduced insulin release; however this reduction was abolished in the presence of a Y1 selective antagonist, highlighting the critical role of Y1 signaling as a negative regulator of insulin release. Moreover islets from β-cell-specific $Y1R^{-/-}$ mice exhibited increased cAMP and insulin secretion (GSIS). To further explore these findings islet transplantation was performed. Using a minimal mass transplant model, $Y1R^{-/-}$ islets showed significantly better glucose control compared to controls and restored normoglycaemia in 100% of cases. Mice harboring $Y1R^{-/-}$ islets had improved glycemic control and increased insulin secretion compared to controls (IVGTT), demonstrating that lack of Y1 receptor signaling is advantageous for islet function especially where islet numbers are of limited supply. To see whether these effects could be induced pharmacologically transplant experiments were repeated using C57/BL6 islets +/- Y1R antagonist administered orally. Compared to controls treated mice rapidly regained normoglycaemia and were able to maintain this after the treatment regime had ceased (10 doses). This suggests that even short-term blockage of Y1 signaling in islet transplantation is sufficient to improve insulin secretion and normalize glucose homeostasis. Furthermore these experiments were repeated using human islets and the results were duplicated.
Conclusion: Together these data demonstrate that manipulation of Y1R signaling can enhance β-cell function in situations where islet mass is limited. Importantly utilizing this finding via pharmacological intervention has the potential to improve clinical islet transplant efficiency and help overcome the limited availability of transplant material.

Human mesenchymal stromal cells improve survival and function of pancreatic islets by cell-to-cell contact through N-cadherin

Elisa Montanari[1], Redouan Mahou[1,2], Solene Passemard[2], Francois Noverraz[2], Philippe Morel[1], Raphael Meier[1], Domenico Bosco[1], Jorg D.Seebach[3], Christine Wandrey[2], Sandrine Gerber-Lemaire[2], Carmen Gonelle-Gispert[1], Leo H.Buhler[1].
[1]Department of Surgery, Cell Isolation and Transplantation Center, Geneva, Switzerland; [2]Ecole Polytechnique Fédérale de Lausanne, Institut d'Ingénierie Biologique et Institut des Sciences et Ingénierie Chimiques, Lausanne, Switzerland; [3]Division of Immunology and Allergy, Division of Immunology and Allergy, Geneva, Switzerland.

Background and Aim: The aim of this study was to evaluate the survival and function of human pancreatic islets co-encapsulated with human Mesenchymal Stromal Cells (MSC) both in vitro and in vivo after transplantation in diabetic mice.
Methods: Human MSC and islets (or pseudo-islets, obtained after digestion and reaggregation of islet cells) were coencapsulated in new hydrogel microspheres composed of calcium alginate and covalently crosslinked polyethylene glycol. Encapsulated cells were transplanted intraperitoneally in streptozotocin-induced diabetic mice. Islet function was evaluated by intraperitoneal glucose tolerance test (IPGTT). Grafts were retrieved after 15 days for morphological analysis. Cell function was tested in vitro by static incubation for islets or pseudo-islets alone and together with MSC. Anti-N-cadherin antibody was added on islets alone or together with MSC for 24h and in vitro insulin secretion was tested by static incubation.
Results: Encapsulated islets alone reversed diabetes in mice after intraperitoneal transplantation after 2 days and allowed to maintain normoglycemia up to 70 days, compared to free islets, that were rejected in 6±1 days ($p<0.0001$, Mantel Cox). Transplantation of co-encapsulated islets and MSC maintained normoglycemia in mice up to 90 days ($p<0.05$, Mantel Cox). IPGTT was performed at day 15 and mice transplanted with combined MSC-islets showed an improved glycemic response compared to mice with islets alone ($p<0.001$). Graft histology showed MSC located within and around the islets (or pseudo-islets), serving as stromal structure. In vitro, insulin secretion was significantly improved when MSC were in cell-cell contact with islets (or pseudo-islets) compared to islets that were only in paracrine exchange with MSC (co-culture in dual chambers, $p<0.05$). When N-cadherin was blocked, glucose-induced insulin secretion was decreased in islets cocultured with MSC and not affected in islets incubated alone.
Conclusions: The adhesion molecule N-cadherin is essential for MSC and islets cell-to-cell contact to improve function and survival of islets of Langerhans.

Protection of stem-cell-derived insulin-producing cells from ischemic injury

Gaetano Faleo[1], Holger Russ[2], Vinh Nguyen[1], Jonathan Freise[1], Annie Albright[1], Steven Wisel[1], Karina Villanueva[2], Matthias Hebrok[2], Qizhi Tang[1,2].
[1]Department of Surgery, Transplantation Research Laboratory, UCSF, San Francisco, United States; [2]Diabetes Center, UCSF, San Francisco, United States.

Introduction: Insulin-producing cells can now be reproducibly generated in large numbers from human embryonic stem cells, providing a renewable source of beta cells for the treatment of type 1 diabetes. Past experiences in experimental and clinical islet transplantation show that a large proportion of islets die shortly after transplant due to ischemia, contributing to poor long-term outcomes. In this study, we investigated the impact of ischemia to human stem-cell-derived insulin-producing cells (SCIPC). Ischemia leads to both hypoxia and nutrient deprivation and each can independently kill islet cells.
Materials and Methods: We exposed SCIPC and mature islets to hypoxia, nutrient deprivation, or both *in vitro* and measured cell viability using flow cytometry.
Results and Discussion: Our results show that SCIPC are more resistant to hypoxia or nutrient deprivation alone than mature islets. However, combined hypoxia and nutrient deprivation synergistically killed SCIPC (Figure 1).

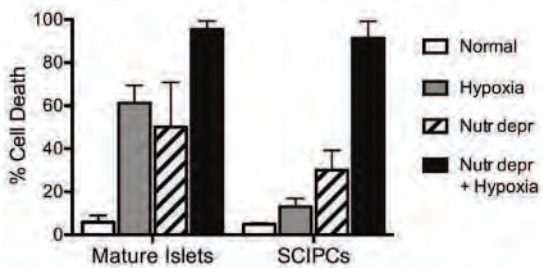

Figure 1. Impact of hypoxia and nutrient deprivation on islet cell death. Mature mouse islets and SCIPC were cultured in normal, hypoxic, nutrient deprived, or both hypoxic and nutrient deprived conditions for 24 hours. Cell viability was measured using flow cytometry after staining the cells with propidium iodide.

Similarly, using luciferase-expressing SCIPC, we found that more than 50% of SCIPC die within 3 days after transplantation into the subcutaneous space of immunodeficient mice. Grafts that survived ischemia contained lower percentages of insulin-producing cells than before transplant suggesting more differentiated cells were more susceptible to ischemia. We next investigated approaches to mitigate ischemia damage to SCIPC. We intentionally exposed SCIPC to 5% oxygen instead of the normal 21% oxygen during their *in vitro* differentiation culture. This did not affect the efficiency of SCIPC differentiation, but made the cells resistant to later challenge to extreme hypoxia (Figure 2A).
We explored nutrient supplementation as a strategy to protect against nutrient deprivation. We found that addition of glucose to base medium was ineffective in protecting SCIPC in nutrient-limiting cultures. In contrast, single amino acid supplementation with alanine or glutamine, but not phenylalanine, could rescue SCIPC from nutrient deprivation (Figure 2B). Protection by amino acids was intact in the presence of rapamycin suggesting that it was independent of amino-acid-induced mTOR activation. Instead, amino acids likely served as cellular fuels by being substrates of the tricarboxylic acid cycle because pyruvate was similarly effective at protecting SCIPC. Lastly, we found hypoxia preconditioning along with local supplementation of alanine and glutamine improved SCPIC survival after transplantation *in vivo*.

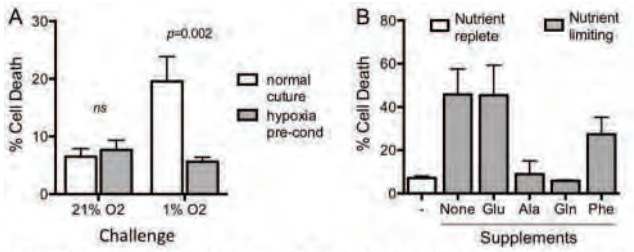

Figure 2. Protecting SCIPC against hypoxia and nutrient deprivation. (A) SCIPC were differentiated under normal culture condition or at 5% oxygen (hypoxia pre-cond). The cells were then challenged with exposure to 1% oxygen and cell viability was measured after 24 hours. (B) SCIPC were cultured in nutrient-replete or nutrient-limiting condition without supplements or with glucose (Glu), alanine (Ala), glutamine (Gln), or phenylalanine (Phe). Cell viability was measured after 5 hrs.

Conclusion: Taken together, our results demonstrate that SCIPC are susceptible to ischemic injury and rationalized interventions can effectively protect them from ischemia after transplantation.

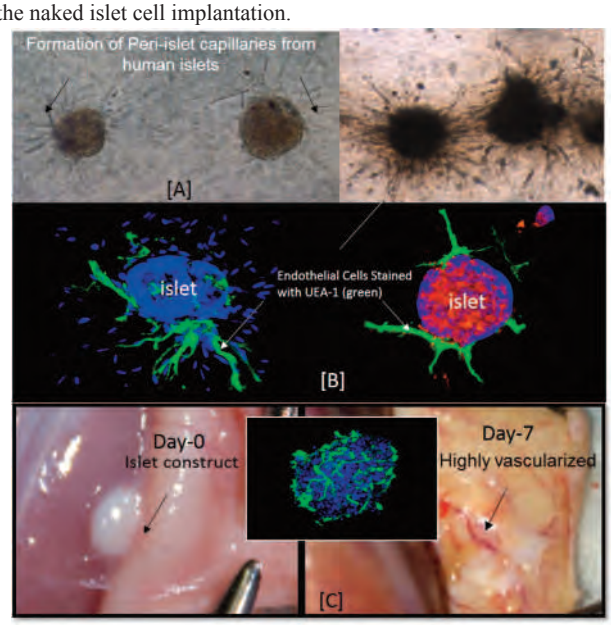
Sprouting of Intra-islet endothelial cells to form peri-islet vessels in human islets

Balamurugan Appakalai, Gopalakrishnan Loganathan, Venkat M.Ramakrishnan, Nolan L. Boyd, Jason E.Beare, Michael J. Hughes, James B.Hoying, Stuart K.Williams .
Cardiovascular Innovation Institute, Department of Surgery, University of Louisville, Louisville, United States.

The current islet isolation technique completely severs the vasculature to islets. As such, these islets become avascular and are susceptible to ischemic damage. Stimulation of intraislet endothelial cells (IIEC) to form peri-islet capillaries (PIC) in vitro prior to transplantation may accelerate post-implant islet revascularization. In this study we accelerated the formation of a functional microcirculation to human islets by stimulating the intra-islet endothelial cells with the addition of ECGS (a mixture of endothelial growth factors) in a 3D-culture system.
Human islets cells were isolated from brain-dead cadaveric donor pancreas (n=10). In in vitro experiments, human islets (200 per well) were cultured with ECGS in a 3D collagen-I gel for 14 days. Confocal microscopy was used to assess islet-derived PIC growth. Human endothelium was identified via labeling with UEA-1 staining. To study inosculation potential, the aforementioned collagen gel construct were be implanted in nude mice at subcutaneous site.
Naked islets cultured in a 2D environment did not form any sprout. However, the presence of ECGS and 3D-culture system induced cellular sprouting from human islets within 7 days (Figure). Many of these sprouts appeared to be PIC since they resembled a vasculature that arose from the islets. UEA-1 FITC Green and RedDot 2 (nuclear label) labeling indicated that several of these sprouts were endothelial. We speculate that our isolated islets gave rise to peri-islet sprouts. 3D-cultured islets maintained >90% cellular viability after 14 days, whereas 2D-cultured islets displayed disintegration of their borders as well as reduced viability. And also, we have confirmed, the inosculation ability of islet construct with the host blood circulation was better than that the naked islet cell implantation.



Here, we demonstrate that 3D matrix support and ECGS are required to elicit successful, spontaneous PIC formation in human islets. This may provide unique avenues to accelerate islet neovascularization following implantation.

Background: Uncontrolled donation after circulatory death (uDCD) or Maastricht II DCD refers to organ donation from persons who have died following an unsuccessfully resuscitated cardiac arrest (CA). In Spain, national recommendations establish, *inter alia*, a maximum donor age of 60 years, maximum warm ischemia time (WIT) of 150 min and maximum time under abdominal preservation strategies of 180 min for in situ cooling (ISC) and 240 min for normothermic (nRP) or hypothermic regional perfusion (hRP). Single-centre studies have provided information on successful outcomes following the transplantation of kidneys from uDCD donors, but there is limited information on the factors that have an impact upon kidney graft survival.
Objective: To report the Spanish experience with kidney transplantation from uDCD donors, and to identify factors related to graft loss during the first year after transplantation.
Patients and Methods: A dedicated data collection on DCD donors and recipients is being undertaken at a national level since 2012. Information has been analysed for kidney recipients transplanted from uDCD donors during 2012 and 2013. Univariate (Kaplan-Meier) and multivariate survival analysis (Cox-model) have been performed to identify factors related to graft loss during the first year.
Results: During 2012-2013, 275 kidney transplants from 152 uDCD donors were performed in Spain.
Demographics and clinical characteristics of donors and key aspects of the uDCD process are depicted in **table 1**.

Table 1: Demographics and clinical characteristics of uDCD kidney donors and key aspects of the uDCD process. Spain 2012-2013.

* Modified Maastricht Classification for Donors after Circulatory Death (Madrid, Spain, 2012)

Mean recipient age was 49.5 (SD=11.7) years, 68.6% were male and 7% had a previous history of kidney transplants. *Ex situ* preservation of kidneys was performed with machine perfusion in 43.4% and cold storage in 56.6%.
The incidence of primary non function was 3% and that of delayed graft function (dialysis during the first week) was 78.8%. 1 year death-censored graft survival was 87%, with no statistically significant differences between those recipients with (85.5%) or without (92.6%) delayed graft function (p=0.162).
In the univariate analysis, 1 year death-censored graft survival was lower when the donor CA had occurred in the hospital (p=0.044), ISC of kidneys was used instead of hRP or nRP (p=0.004), and the recipient had a history of previous transplants (p=0.001). No statistically significant differences were observed by donor age (p=0.211), WIT (p=0.144), recipient age (p=0.404) or type of *ex situ* preservation of kidneys (p=0.973).
In the multivariate analysis (**table 2**), in-hospital donor CA, ISC of kidneys (*versus* hRP or nRP) and recipient´s previous history of kidney transplants were identified as independent risk factors for 1-year graft loss.

Table 2: Factors related with death-censored graft loss during the first year after transplantation among kidney recipients transplanted from uDCD donors (Cox-Model). Spain 2012-2013.

	OR	CI 95%		p
Donor in-hospital CA *(ref. out-of-hospital CA)*	**6.5**	**1.6**	**27.0**	**0.010**
Donor age > 55 years *(ref. donor age ≤ 55 years)*	1.7	0.7	4.0	0.219
WIT > 120 min (ref ≤ 120 min)	2.0	0.8	5.0	0.121
Type of abdominal preservation *(ref. normothermic Regional Perfusion)*				0.005
In situ cooling	**3.6**	**1.4**	**9.0**	**0.006**
hypothermic Regional Perfusion	1.0	0.4	2.2	0.927
Recipient age > 55 years *(ref. recipient age ≤ 55 years)*	0.6	0.26	1.4	0.233
Recipient with a history of previous transplants *(ref. no previous transplants)*	**5.2**	**2.1**	**12.7**	**<0.001**

Conclusion: Kidney transplantation from uDCD donors in Spain provides good outcomes during the first year. Abdominal hRP or nRP is preferred over ISC of kidneys. When the first technique is not available, more stringent donor and recipient selection criteria should be used.

Largest US OPO DCD Experience: 1014 DCD Donors over two decades

Howard Nathan[1], Richard Hasz[1], Sharon West[1].
[1]Gift of Life Donor Program, Philadelphia, PA, United States.

Purpose: To demonstrate that an effective DCD program can lead to an increase in the procurement of transplantable organs while simultaneously increasing DBD.
Methods: This was a single OPO, multi-center study evaluating the procurement and utilization of DCD donor organs. Ongoing hospital education on early referral and DCD protocols was initiated prior to DCD donor recoveries.
Results: Since the implementation of its DCD program in June 1995 through December 2015, this OPO has procured 1014 DCD organ donors. DCD donor procurement increased the donor pool by 13% and resulted in the transplantation of 1832 organs. This increase was achieved while simultaneously achieving a 83% increase in annualized DBD donor procurement for 2015 versus 1995. Mean donor age was 39 years (r = 0.5 - 76). The mean time from donor extubation to cross-clamp, or warm ischemic time (WIT), for kidneys transplanted (N=1597) was 32 minutes (r = 2 - 214). The mean WIT for livers transplanted (N=203) was 23 minutes (r = 2 - 69). The kidney ATN rate was 46% and kidney graft survival was 86% at 1 year, 75% at 3 years and 64% at 5 years. Liver graft survival was 72% at 1 year, 63% at 3 years and 56% at 5 years.

2013	447	386 (86%)	61 (14%)	99/119 (83%)	6/17 (35%)	0/1 (0%)	7/16 (44%)	112
2014	447	371 (85%)	66 (15%)	102/132 (77%)	12/26 (46%)	0/1 (0%)	0/4 (0%)	114
2015	483	402 (83%)	81 (17%)	124/161 (77%)	10/24(42%)	1/1 (100%)	3/11 (27%)	138
Total	7,769	6,745 (87%)	1,014 (13%)	1597/1995 (80%)	203/382 (53%)	14/30 (47%)	18/41 (44%)	1,832

Conclusion: An effective DCD program increased the donor pool by 13%. DCD donor procurement was achieved while simultaneously achieving a 83% increase in DBD donor procurement over the two decade evaluation period.

352.3

Experience with donation after circulatory death (DCD) in donors aged 56-65: A preliminary report on kidney utilization and initial outcomes

Jeffrey P. Orlowski[1], Chad C. Muse[1], Janice F. Whaley[1], Jan Foutch[1], Ronald A. Squires[1,2].
[1]LifeShare Transplant Donor Services of Oklahoma, Oklahoma City, OK, United States; [2]Department of Surgery, University of Oklahoma Health Science Center, Oklahoma City, OK, United States.

Introduction: One U.S. organ procurement organization (OPO) achieved 96% growth in total deceased organ donors and 66% growth in organs transplanted in 24 months (comparing year-end 2013 to year-end 2015 data). One contributing factor has been aggressive pursuit of DCD initiated in 2012 including use of DCD donors aged 56-65 years. The following is a preliminary report on our experience utilizing these older DCD donors.
Methods: A retrospective review of DCD donors recovered between 2012 and 2015 was conducted. DCD donors 0-55 years of age (DCD 0-55) were compared to those aged 56-65 years (DCD 56-65). Time from extubation to arrest, time from extubation to organ perfusion, duration of agonal period, kidney transplantation rates, initial function, and function at time of data analysis were compared.
Results and Discussion: Between 2012 and 2015, 93 total DCDs were recovered (18.7% of 498 total deceased donors); in 2012 DCDs were 10 of 94 total deceased donors (10.6%) which increased to 42 of 174 total deceased donors (24.1%) in 2015. Overall, 14 of 93 DCD's during the 4 years (15.1%) were age 56-65. For DCD 0-55, 83% (131/158) of kidneys were transplanted; for DCD 56-65 utilization was 68% (19/28). Extubation to arrest and perfusion averaged 21 and 38 minutes respectively in DCD 0-55 vs 14 and 32 minutes in DCD 56-65; average agonal time was 3 minutes in both groups. Delayed graft function (DGF) was 34% for DCD 0-55 and 21% for DCD 56-65. Current function at time of data analysis was 95% for DCD 0-55 and 79% for DCD 56-65. With the exception of 6 DCD 0-55 kidneys, all kidneys underwent pulsatile perfusion.
Conclusions: Our data suggest DCD donors aged 56-65 years can be recovered with careful selection. While kidney utilization was higher in the DCD 0-55 group, the DCD 56-65 group's kidney utilization was 68%, which we accept as a very reasonable rate of transplant for this population that many U.S. OPOs do not pursue. The fact that DGF in DCD 56-65 was 21% compared to 34% for DCD 0-55 kidneys was unexpected and may be related to shorter time from withdrawal to arrest or may also indicate we are overly selective in DCD 56-65. While current kidney graft function in the DCD 56-65 group is lower (79%) than the 0-55 group (95%), not enough data is known about the recipients' characteristics or reasons for graft failure to draw any conclusions. We are committed to continue selective use of these donors and plan a thorough multivariate analysis of donors and recipients with a larger sample size; at our current DCD recovery rate, we expect to approximately double our DCD experience in the next 24 months which will allow for a statistically more powerful analysis.

World first report of liver transplantation from an HIV-positive donor to an HIV-positive recipient

Christian van Delden[1,3], Alexandra Calmy[3], Emiliano Giostra[1], Christian Junet[3], Laura Rubbia Brandt[2], Sabine Yerly[3], Jean-Pierre Chave[3], Thierry Berney[1].
[1]Service of Transplantation, University Hospitals Geneva, Geneva, Switzerland; [2]Department of Pathology, University Hospitals Geneva, Geneva, Switzerland; [3]Service of Infectious Diseases, University Hospitals Geneva, Geneva, Switzerland.

Introduction: HIV-positive candidates for solid organ, and especially liver, transplantation remain disadvantaged on waiting lists because of faster evolution towards organ failure. Transplantation of organs from HIV-positive donors is illegal in most countries due to concern of HIV donor-recipient transmission. Only transplantation of kidneys restricted to treatment-naive or first-line treated HIV-positive donors to HIV-positive recipients have been reported from South Africa so far. This discriminates HIV-positive patients on successful Anti Retroviral Therapy (ART) from organ donation, and reduces the donor pool for HIV-positive potential recipients. In 2007 the Swiss Transplantation Law included the opportunity to transplant organs from HIV-positive donors to HIV-positive recipients, independently of previous ART and resulting potential viral resistance phenotypes. We report the first liver transplantation from an ART-experienced HIV-positive deceased donor to an ART-experienced HIV-infected recipient in Switzerland.
Methods: A patient infected by HIV since 1987, treated with dolutegravir, tenofovir and emtricitabine with undetectable viremia despite multiple nucleoside retrotranscriptase inhibitor resistance mutations died of a cerebellar haemorrhage. He had previously provided written explicit consent for organ donation. We therefore identified a 53-year-old Caucasian male, HIV-infected since 1987, successfully treated with a combination regimen of rilpivirine/tenofovir/emtricitabine for an HIV and HBVco-infection, awaiting a liver donation.
Results: The transplantation candidate was informed about potential virus transmission and the requirements to adapt his anti-HIV therapy. He accepted the risk and signed an informed consent for liver transplantation. Post-transplant the liver graft showed immediate function, and no medical or surgical complications occurred. The immunosuppressive regimen was standard associating tacrolimus and mycophenolate mofetil. The recipient's antiretroviral therapy was modified by the addition of raltegravir and enfuvirtide to his ongoing regimen. This regimen covered the HIV-resistance mutation patterns of both donor and recipient. We documented no interactions between the anti-HIV therapy and the immunosuppressive drugs based on normal target tacrolimus plasma levels. No rejection episodes occurred. The patient could be discharged on day 22 post-transplant. Plasma HIV-RNA remained undetectable throughout the four-month follow-up.
Conclusion: We report here the world first successful liver transplantation from a non-treatment naive HIV+ donor to an HIV-positive recipient. Despite numerous resistance mutations in both the donor and recipient's viruses the HIV-infection remained controlled at 4 months follow-up by modifying the ART. This encouraging observation should lead policy makers to lift the restriction limiting the transplantation of organs from non-treatment naive HIV-positive donors towards HIV-positive recipients, increasing thereby the pool of potential donors to this disadvantaged transplant candidates.

Initial experience of en-bloc kidney transplantation from donors less than two months of age in the United Kingdom: A potential new donor pool

Imeshi Wijetunga[1], Rupaly Pande[1], Sonsoles Martinez-Lopez[1], Shahid Farid[1], Muhammed Jameel[1], Vivek Upasani[1], Lutz Hostert[1], Matthew Wellberry-Smith[1], Chas Newstead[1], Andrew Lewington[1], Clare Ecuyer[1], Richard Baker[1], Niaz Ahmad[1].
[1]Department of Transplantation, Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom.

Introduction: Kidney transplantation from donors less than two years of age have been rare in the United Kingdom (UK) at the rate of one transplant per year over a 15-year period[1]. A kidney transplant from a donor less than two-months of age was first performed in the UK in 2013. Until recently (2015), UK legislation did not permit the diagnosis of brain-stem death (BSD) in infants under two-months of age and only DCD donations have been possible. We describe our initial experience of kidney transplantation from donors less than two-months, including those from neonatal donors.
Methods: Kidney transplants performed at our centre from donors less than two-months of age were identified from a prospective database. All kidneys were retrieved and transplanted en bloc with abdominal aorta and inferior vena cava. Hypothermic machine perfusion was used in most cases. Recipients were young to middle-age adults with body mass index <30 and no cardiovascular risk factors. Donor & recipient characteristics as well as short-term graft & recipient outcomes are described.
Results: Seven En bloc Kidney Transplants (EKT) were performed from donors less than two-months of age from March 2013 to October 2015, six from DCD (86%) and one from DBD donor. Median follow up was 319 days (96-1,051). Median donor age and weight were 23days (range 0-58) & 3.4kg (1.9-5.0) respectively. Median recipient age and weight were 33yrs & 49.5kg, respectively. One primary non-function was observed and the recipient was excluded from subsequent analysis of graft function. The graft was from a 0day old 1.9kg DCD donor. Primary function was observed in 6 (86%) recipients with no early post-operative complications. Median GFR (Cockcroft-Gault, in ml/min/1.73m^2) at 1-month and 6-months post-transplant was 25 and 54 respectively. Graft function continues to improve over the first year with those completing one year (three) achieving a GFR>60.
Discussion: This is the first reported series of kidney transplants from donors less than two-months of age including neonatal donors in the UK. The recipient and graft outcomes are encouraging. Our study identifies small infants and neonates as a potential 'new' donor pool for kidney transplant. We suggest further consolidation of experience in this area in designated centres.

Organ donation after euthanasia leads to good transplant results

Jan Bollen[1,6], Tim van Smaalen[4], Wim de Jongh[4], Hanneke Hagenaars[5], Rankie ten Hoopen[6], Dirk Ysebaert[3], Ernst van Heurn[2], Walther van Mook[1].
[1]Intensive Care, Maastricht University Medical Center, Maastricht, Netherlands; [2]Pediatric Surgery, Academic Medical Center, Amsterdam, Netherlands; [3]Hepatobiliary, Transplant and Endocrine Surgery, University Hospital Antwerp, Antwerp, Belgium; [4]Transplant Coordination, Maastricht University Medical Center, Maastricht, Netherlands; [5]Transplant Coordination, Erasmus University Medical Hospital, Rotterdam, Netherlands; [6]Medical Law, Maastricht University, Maastricht, Netherlands.

Introduction: Organ donors after euthanasia are considered Maastricht category 3 donation after circulatory death (DCD) donors. From these donors, kidneys, lungs, liver and pancreas can be procured and transplanted. Because this combined procedure has only rarely been performed, it is currently unclear if transplantation of these organs may result in acceptable transplant outcome. In this abstract we present the outcome of kidneys transplantations for all 15 first organ donations after euthanasia in the Netherlands. In August, we aim to present outcome of all donations until 2015 for lung, liver, pancreas and kidney transplantation in both Belgium as the Netherlands (±n=40).
Methods: All cases of donation after euthanasia in the Netherlands until 2015 were studied. Donor, graft and recipient characteristics were anonymized and registered. Primary outcome parameter was short term graft function. For kidney transplantation, this was defined as immediate graft function, delayed graft function or primary non-function.
Results: Fifteen patients donated organs after euthanasia. One donor had already donated one kidney to a relative during life. 29 kidneys were eligible for donation, of which all were procured. Three kidneys were rejected by the transplantation team. 26 kidneys were successfully transplanted, of which 14 (53,8 %) had immediate graft function, 11 (42,3 %) had delayed graft function, and 1 (3,8 %) suffered from primary non-function. The mean donor age was 52,1 (SD ± 13,0) years and mean recipients age was 52,8 (SD ± 12,3) years.
Discussion: Donation after euthanasia has only been performed a dozen times in the Netherlands. These results show that the outcome of kidney transplantation, with a majority of immediate function, is at least equal to regular DCD-3 donors[1]. The good outcome may be explained by a multiple factors. Firstly, the process of death differs for donors after euthanasia compared to donors who normally sustained severe head injury after trauma or a cerebrovascular accident. Furthermore, the agonal phase during donation after euthanasia is mostly short and controlled by the short time to death by euthanasia. Euthanasia donors are also, on average, younger than 'regular' DCD-3 donors[2].
Conclusion: We conclude that donation after euthanasia leads to acceptable short-term transplant results. Organ donation after euthanasia may be a valuable way to increase the number of organs available for the limited donor pool. Further studies need to evaluate long term graft function and graft and patient survival.

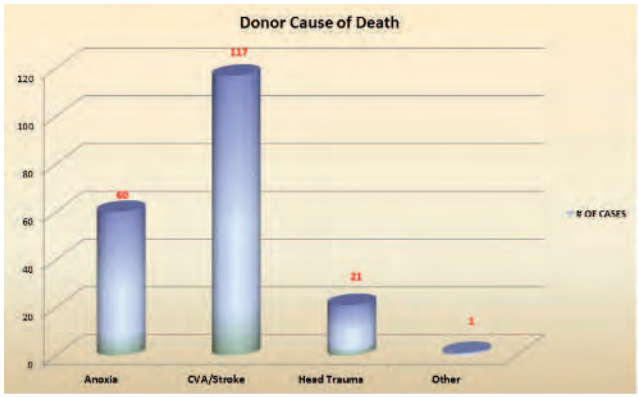
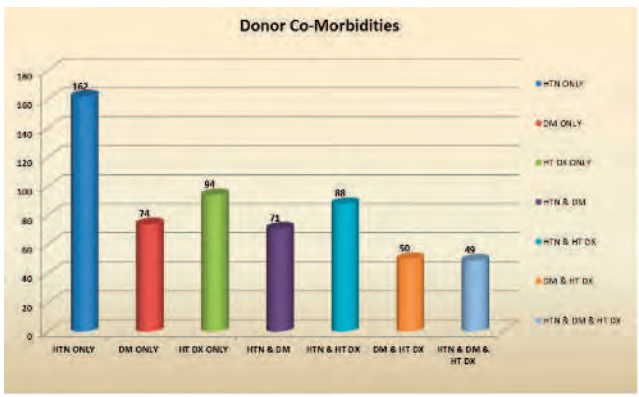
Saving lives one organ at a time: One OPO's experience in a service area with a high incidence of cerebrovascular accidents

Vernon Langley[1], Kathleen Lilly[1], Jean A.Davis[2], Bryan McDonald[3], Thomas Pearson[4], Nicole Turgeon[4], Marty Sellers[1].
[1]LifeLink of Georgia, LifeLink, Norcross, GA, United States; [2]Foundation, LifeLink, Tampa, FL, United States; [3]Accounting, LifeLink, Tampa, FL, United States; [4]Department of Surgery, Emory University, Decatur, GA, United States.

Introduction: From 2010-2014, LifeLink® of Georgia (GALL) noted a significant increase in single-organ donors (SODs). Review of national and Georgia-specific data[1] for age-adjusted mortality rates between 1994-2011 show our service area is higher for strokes (42.2 vs 38.9), diabetes (23.4 vs 20.9), and cardiovascular disease (242.5 vs 234.8) compared to the national average. GALL's donor service area, part of the "stroke belt" due to a high concentration of cerebrovascular accident (CVA) mortality rates in the southeastern United States, has large pockets of medically underserved areas, increasing the likelihood of undiagnosed diabetes and hypertension, which may lead to end-organ damage before death and donation. We hypothesize these factors contribute to our single organ yields.
Methods: Organ recovery data were reviewed for calendar years 2010-2014; donor demographics, cause of death, presence and duration of diabetes (DM), insulin therapy and hypertension (HTN) were recorded for SODs. These data were recorded for all donors from July 1, 2013 through December 31, 2014. Univariate and multivariate analyses (logistic regression) were performed.





Results: From 2010-2014 there were 1104 organ donors; causes of death were CVA/stroke (59%), anoxia (30%), and head trauma (11%). 199 (18%) were SODs; 196 (98.5%) were liver-only donors; 162 (81%) had hypertension; 74 (37%) had diabetes; 34 (17%) had chronic or end-stage renal disease. Single-organ donors increased from 27 (10%) in 2010 to 68 (25%) in 2014.

From July 2013-December 2014, there were 399 donors; 93 (23%) were SODs. CVA as the cause of death was more common in SODs (60.2 vs. 36.0%; $p<0.001$). DM was more prevalent in SODs (36.6% vs. 6.2%; $p<0.001$), as was HTN (85% vs. 29.7%; $p<0.001$). SODs were older (55.8 36.3
Conclusion: From 2010-2014 18% of our donors were SODs, and they have increased significantly during that time. Almost all SODs were liver-only donors. Independent predictors of SOD included DM, HTN and age. GALL positively impacted 199 recipients through aggressive donor evaluation protocols during the past 5 years. As a result of our review, we continue pursuing SODs to address the ever-increasing need for transplantable organs. We believe an OPO's responsibility is to pursue all potential organ donors and allow the transplant center to determine if an organ is suitable for one of their patients, regardless of performance measures (e.g., organs transplanted per donor) evaluated by various regulatory agencies.

Identifying neonatal potential for solid organ and tissue donation in the Newcastle upon Tyne Hospitals (UK)

Aranzazu Baglietto[1], Rashmi Kuttysankaran[2].
[1]ODT, NHSBT, Newcastle upon Tyne , United Kingdom; [2]GNCH, NUTH, Newcastle upon Tyne , United Kingdom.

Introduction: Organ donation has transformed the lives of many children. Unfortunately infants still die while awaiting transplant. The shortage of donor organs of suitable size is without question the major impediment to extending the lives of more patients awaiting solid organ transplantation. Currently organ donation is rarely considered in neonatal units; however there is increasing awareness about untapped potential of neonatal organ donation. Recently in the UK neonatal organ donation after circulatory determination of death has been facilitated. Since then guidelines have been published for diagnosis of death by neurological criteria (DNC) in infants from 37 weeks corrected gestation .Donation after neurological death is now possible in neonates. We studied the potential for solid organ and tissue donation in our Neonatal intensive care unit in the Newcastle upon Tyne Hospitals (NUTH) for last 6 years. The NUTH neonatal intensive care (NICU) is the centre of excellence for neonatal care in the North of England.
Methodology: *Design:* Retrospective review of the patient medical notes.
Setting: Neonatal Intensive Care Unit, NUTH.
Patients: Infants dying in NICU between 1st April 2010 and 31st December 2015 meeting the following criteria:
Potential tissue donation: Infants dying from 32 gestational age and over 2.5kg.
Potential Organ donation: Infants dying from 37 weeks gestational age.
Results: There were 44 deaths fulfilling the above criteria.
-19 (45%) infants died following an unplanned/uncontrolled death (UD).
-25 (55%) infants died following withdrawal of life sustaining treatment (WLST).
- 20 WLST (43%) infants were potential organ donors.
- 20 (15 UD + 5 WLST) (45%) infants had only tissue donation potential.
Donation type:
- 9 (45%) fulfil the criteria for donation after circulatory death (DCD).
- 11(55%) could theoretically fulfil the criteria for donation after brain stem death (DBD), however complete neurological assessment, including brain stem reflexes not documented. Evidence of brain stem death is documented in 4 infants.

Length of time from WLST to cardiorespiratory death is:
- Less than 3 hours in 18 (72%) infants.
- More than 3 hours in 6 (24%) infants.
- Not documented time of WLST in one patient.

Discussion: Excellent guidelines, standardised pathways and contemporary governance processes to structure organ donation in the Neonatal ICU are required.
Complete neurological assessment and detailed documentation is essential when assessing infants.
Changes in attitude and practice are necessary to include consideration for organ donation as part of the assessment once decisions of withhold or withdraw treatment have been made.
Meeting educational needs of the health care professionals regarding training in brain stem testing should be considered.
Determination of accurate time of cardiorespiratory death following WLST will be necessary where organ donation is offered.
Conclusion: The analysis of the data obtained from the audit confirms the significant potential for organ and tissue donation that the Neonatal population holds.

Evaluate quality of kidneys from DCD/ECD donors by parameters of machine perfusion

Guodong Chen, Chang Wang, Changxi Wang, Xiaopeng Yuan, Jiang Qiu, Lizhong Chen.
Organ Transplant Center, The First Affiliated Hospital of Sun Yat-sen University, Guangzhou, People's Republic of China.

Background: Donors from donation after cardiac death(DCD) and expanded criteria donors(ECD) have poorer outcomes compared to standard deceased donors(SCD). It is important to evaluate quality of kidney from DCD/ECD before transplantation. In this study, machine perfusion was used to preserve the DCD/ECD kidneys with the aim to investigating whether the parameters of machine perfusion could predict the quality of kidneys from DCD/ECD donors.
Methods: 72 kidneys from DCD/ECD donors were harvested in our hospital from July 2011 to August 2014. All kidneys were preserved with machine perfusion(Life Port), and parameters of machine perfusion were collected. All kidneys were biopsied before transplantation. The kidneys were discarded if histology results showed glomerulosclerosis or interstitial fibrosis were more than 20%. The primary endpoints were delayed graft function(DGF), graft loss and patient death. Postoperative complications and 1-year serum creatinine levels were also recorded.
Results: 14 kidneys(19.4%) were discarded before transplantation. During machine perfusion, resistant index(RI) were significantly higher and flow rate were significantly lower in discarded kidneys compared to the kidneys that were transplanted($p<0.05$). 58 recipients with kidneys transplanted were divided into two groups according to 1-hour RI of machine perfusion. 22 cases in high RI group (RI>0.4) and 36 cases in low RI group(RI $\leq$0.4). DGF rate was significantly higher in the high RI group(72.7% vs. 27.8%). 1-year serum creatinine levels were also significantly higher in the high RI group($p<0.05$). Acute rejection rate and 1-year graft survival were comparable between the two groups. Logistic multivariate regression showed that high RI was an independent risk factor for DGF after DCD/ECD kidney transplant(OR value=6.635, p=0.004).
Conclusion: Parameters of machine perfusion are good tools for evaluating quality of kidneys from DCD/ECD donors, and may predict DGF and 1-year graft function after transplantation.

353.1

Stem cell-mediated regeneration of ischemically damaged human renal allografts during ex vivo warm perfusion

Lauren Brasile[1], Nicholas Henry[1], Bart Stubenitsky[2].
[1]Research and Development, BREONICS Inc., Watervliet, NY, United States; [2]Plastic Surgery, University of Maastrict, Maastrict, Netherlands.

Introduction: Our goal is to address a large unmet medical need by providing more kidneys for transplantation. We evaluated if a mesenchymal stem cell (MSC) therapy could accelerate the repair of ischemically damaged human kidneys during 24 hours of ex vivo warm perfusion. We targeted the delivery of mesenchymal stem cells (MSC) directly to human kidneys to increase the intrarenal concentrations of paracrine/endocrine effects over what can be achieved with systemic administration of MSC. We hypothesized that by infusing MSC directly to the renal tissue during the ex vivo, warm perfusion, there would be an improved opportunity for repair relative to EMS perfusion alone.
Methods: An Exsanguinous Metabolic Support (EMS) perfusion technology (32°C), that supports ex vivo metabolism in isolated organs for several days, was used to evaluate the potential of repairing ischemically damaged renal allografts. Human MSC (1X108) were infused into the renal artery during the EMS perfusion at an individualized rate that did not adversely affect perfusion pressures and vascular flow rates. One kidney served as the control that was warm perfused, while the paired kidney was treated with MSC during the 24 hours of warm perfusion. Evaluation of the repair potential included: DNA synthesis, cytoskeletal regeneration, chemokine/cytokine synthesis, histologic evaluations and nuclear staining using Toluidine Blue.
Results: Treatment with MSC resulted in a significant reduction of inflammatory cytokines / chemokines synthesized by the kidneys (Figure 1).

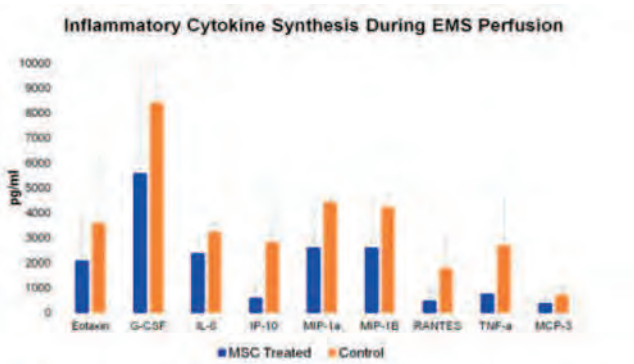

Figure 1: Human kidneys were EMS perfused with or without infusion of Mesenchymal Stem Cells (MSC). After 24 hours of EMS perfusion, perfusate samples were taken and analyzed on the Luminex Multiplex Platform.

MSC treatment lead to a significant increase in the synthesis of ATP and growth factors resulting in normalization of the cytoskeleton during 24 hours of perfusion. Toluidine Blue staining of MSC treated kidneys showed a significant increase in mitotic figures (23%) compared to EMS alone (Figure 2).
PCNA and Clusterin staining also detected the same positive MSC mediated effect.
Conclusions: Our work is the first to have achieved actual cellular regeneration while ischemically damaged human kidneys are perfused ex vivo for 24 hours. The observed regeneration entails: increased synthesis of ATP, a reduced inflammatory response, increased synthesis of growth factors, normalization of the cytoskeleton and mitosis. The ability to regenerate renal tissue ex vivo sufficiently enough to result in immediate function could revolutionize transplantation by solving the chronic organ shortage.

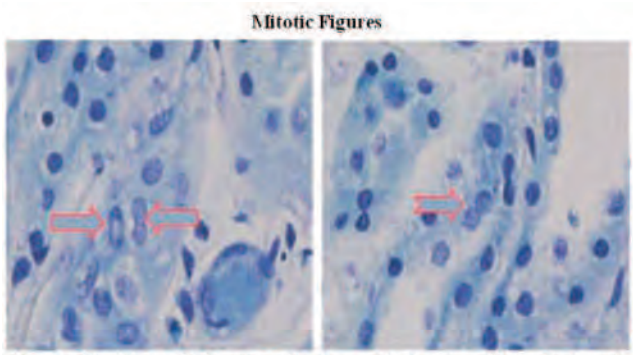

Figure 2: After 24 hours of EMS perfusion, biopsies were taken from stem cell infused and control kidneys, samples were processed and stained with a 1% Toluidine Blue solution. The left image represents an EMS perfused kidney w/ the addition of MSC. The right is the EMS control. The addition of MSC lead to a 23% increase in mitotic figures.

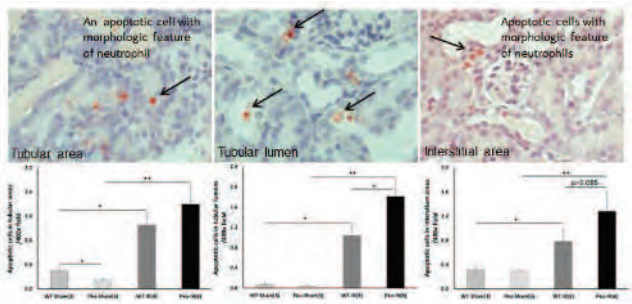
353.2

Properdin deficiency aggrevates the renal injury of ischemia reperfusion

Zinah D.Zwaini[1,3], Nigel J.Brunskill[1,2], Wilhelm Schwaeble[1], Cordula M. Stover[1], Bin Yang[1,2,4,5].
[1]Infection, Immunity and Inflammation, University of Leicester, Leicester, United Kingdom; [2]Renal Group, University Hospitals of Leicester, Leicester, United Kingdom; [3]College of Medicine, University of Kufa, Kufa, Iraq; [4]Nephrology, Affiliated Hospital of Nantong University, Nantong, People's Republic of China; [5]Basic Medical Research Centre, Medical School of Nantong University, Nantong, People's Republic of China.

Introduction: Ischemia reperfusion injury (IRI) is a major cause of acute renal injury, affecting native and transplant kidneys alike. Properdin stabilizes C3bBb/(C3b)nBb and positively regulates the alternative pathway (AP) of complement activation, which may play key roles in renal IRI. The aim of this work was to investigate the effect and mechanism of sole properdin knockout (PKO) on renal IRI.
Methods: Male C57/BL6 PKO (n=8) and their age and sex matched wild type (WT, n=9) mice were subjected to 30 min bilateral clamping of renal pedicles followed by 72 h reperfusion, in addition to their sham controls (n=3-5). The changes in renal function, histology, apoptosis, inflammation (HMGB1) and proliferation (PCNA), as well as complement activation, were measured.
Results: An IRI model was successfully established using serum creatinine (SCr), blood urea nitrogen (BUN) and tubulointerstitial damage (TID) as measurements, when compared to the respective sham groups. In PKO mice, IRI injury was clearly increased compared to the WT group on all levels showing SCr (1.78±0.29 vs. 1.19±0.18 mg/dl, P=0.046), BUN (481.59±109.92 vs. 258.42±51.38 mg/dl, P=0.034) and TID (2.67±0.26 vs. 1.94±0.22, P=0.025). Moreover, PKO presented with a higher number of apoptotic cells in the tubular lumen than the WT control (1.81±0.34 vs. 1.04±0.26, P=0.039). Likewise, the expression of inflammatory marker HMGB1 was significantly higher in Pko mice (1103000±316202 vs. 361636±134820, P=0.034) at time point 72 h after reperfusion. There was no statistically significant increase in caspase-3 activation, PCNA expression and mitosis (3.43±1.06 vs 1.72±0.69, P=0.18). There was also no significant change in the degree of complement C5 activation by measuring serum C5a (762.8±172.6 vs 850.8±170.5 ng/ml, P=0.7) and C5b-9 (2713±498.3 vs 2983±618.3 ng/ml, P=0.9) between two genotypic groups post IRI.



Conclusion: In PKO mice renal IRI was significantly aggregated, associated with increased apoptosis and inflammation compared to the WT control. This unexpected outcome is similar to that in mice with the deficiency of membrane bound negative regulators in complement activation, CD55 and CD59, and Crry. The underlying mechanisms are worthy to be further investigated.

353.3

Fractional excretion of NGAL instead of 99mTcMAG3 renography to monitor resolution of delayed graft function

J.R. Bank, M. E.J.Reinders, L. Noordermeer, M. J.K.Mallat, S. W.van der Kooij, C. van Kooten, J. W.de Fijter.
Nephrology, Leiden University Medical Center, Leiden, Netherlands.

Introduction: Kidneys transplanted from extended criteria donors have a higher prevalence of delayed graft function (DGF). Early identification of factors that prolong duration of DGF may improve clinical outcome and prevent invasive procedures. The current standard in our center to monitor resolution of DGF is a renography with ^{99m}Tc labelled mercaptoacetyltriglycine (MAG3). Since ischemia/reperfusion injury results in impaired extraction of ^{99m}TcMAG3 via the organic anion transporter, but also in impaired reabsorption of NGAL by proximal tubule epithelial cells (luminal side), we hypothesize that the fractional excretion of NGAL (FE-NGAL) can replace MAG3 scans to follow resolution of functionally defined DGF[1] (fDGF).
Methods: Ninety-two consecutive DCD transplant recipients were included, all received IL2-RB induction and maintenance therapy with steroids, MMF and delayed-CsA introduction at day 4. Before introduction of CsA on day-4 and at day-10, MAG3 scans were performed and tubular function slope (TFS) score[2] was calculated. Daily FE-NGAL was calculated using urinary and serum NGAL. Statistical analysis included positive and negative predictive values (PPV and NPV).
Results: In DCD recipients a day-4 TFS score >1.5 could distinguish patients with mild fDGF (≤7 days) from patients with moderate/severe fDGF (≥8 days), with PPV of 93.4% and NPV of 63.3%. Day-4 FE-NGAL <2.5% could even better distinguish patients with mild fDGF from those with moderate/severe fDGF (PPV=92.6%, NPV=100%). Also in patients with residual native kidney diuresis (>1L) FE-NGAL was highly distinctive (PPV=85.7%, NPV=100%). However, for the prediction of moderate (8-20 days) versus severe fDGF (≥21 days), both TFS and FE-NGAL had limited value (PPV=45.6% and 40.5%, NPV=100% and 87.5%, respectively). Furthermore, preliminary results suggest that sequential FE-NGAL may help to identify patients with additional CNI-toxicity and/or rejection.
Conclusion: In this cohort of DCD recipients FE-NGAL better distinguished patients with mild fDGF from those with moderate/severe fDGF compared to standard follow-up using ^{99m}TcMAG3 renography, also in patients with preserved residual diuresis. Sequential FE-NGAL may prove to be a useful non-invasive biomarker to guide optimal timing of a renal allograft biopsy in recipients with DGF and additional CNI toxicity and/or acute rejection.

Hypothermic pulsatile preservation of kidneys from uncontrolled deceased donors after cardial arrest

Palmina Petruzzo, Xavier Matillon, Ricardo Codas, Emmanuel Morelon, Lionel Badet.
Department of Transplantation, Edouard Herriot Hospital, Lyon, France.

Background: Kidneys from uncontrolled donors after cardiac arrest (uDCD) suffer from a period of warm ischemia between cardiac arrest and cold flushing. Aim of the study was to evaluate renal outcomes in pump-perfused uDCD kidneys and the influence of resistive index (RI) on graft function and survival.
Materials: Forty-four kidneys from uDCD were included. The potential donors (Maastricht category I and II) underwent cardiopulmonary resuscitation by assisted ventilation and chest compression; the organs were preserved with in situ cold perfusion (IGL-1 solution) using an aortic double-balloon triple-lumen catheter ("Gillot sonde") or a normothermic subdiaphragmatic extracorporeal membrane oxygenation. All the harvested kidneys were machine perfused using hypothermic (1-4°C) pulsatile perfusion (RM3, Waters Medical System). Kidneys with RI³0.5 mmHg/mL/min after 6 hours of perfusion were discarded.
Results: There was one PNF, while 37 recipients (84.1%) experienced DGF. Graft survival was 97.6% at 1 and 3 post-transplantation years. Renal function estimated by MDRD and inuline clearance at one year showed excellent results, remarking as the outcomes from uDCD are comparable to those of kidneys from controlled donors. Linear regression models showed that RI values at the end of perfusion were associated with MDRD variations at 3 and 6 months after transplantation (p=0.049 and p=0.010, respectively) and with inuline clearance at 1 year (p=0.030), and in a separate model, with renal fibrosis at 3 post-transplant months (p=0.022). RI at the beginning of perfusion was significantly influenced by the in situ cold perfusion procedure, donor smoking, warm ischemia time; at the end of the perfusion it was influenced by the in situ cold perfusion procedure, donor sex and donor serum creatinine values.
Conclusions: This study confirmed that good clinical outcomes could be obtained transplanting selected uDCD kidneys. The perfusion machine allowed to prevent the deleterious effects of warm ischemia in uDCD grafts and RI values were correlated to graft function.

353.5

Eculizumab for prevention and treatment of the kidney graft reperfusion injury

Michael Kaabak[1], Nadine Babenko[1], Allan Zokoyev[1], Stanislav Schekaturov[1], Valery Sandrikov[1], Alexander Kovaltchuk[2].
[1]Kidney Transplantation, Boris Petrovsky Scientific Center of Surgery, Moscow, Russian Federation; [2]Dialysis, Pediatric City Hospital #13, Moscow, Russian Federation.

Background: Ischemia-reperfusion injury (IRI) is unavoidable during clinical organ transplantation. Activation of terminal complement complex (C5b-9) was shown in IRI in clinical and experimental organ transplantation.
Eculizumab, a monoclonal antibody, blocks the terminal components of complement activation. We report preliminary results of RCT (ClinicalTrials.gov identifier NCT01756508) evaluating eculizumab influence on IRI.
Materials and Methods: Between September 2012 and October 2015, 46 patients (22 male, 7,7±4,1 y.o., 28/18 live/deceased donors) were randomized to receive or not (23/23) eculizumab prior to graft reperfusion. Immunosupression: two dose alemtuzumab followed by tacrolimus and MMF. Patients were followed 654±261 days, 77 surveillance and 14 indication biopsies were performed.
Results: One patient in each group (1.7 y.o. boy and 2.8 y.o. girl) died early post Tx because of cardiomyopathy. One late graft loss was observed in each group (Day 346 and Day 557). Three grafts were lost (boys 2, 3, and 6 y.o) in eculizumab group on day 26-60 as a consequence of flu-like syndrome. Other patients are alive with functioning graft. No difference in GFR at last follow up was found (91±25 ml/min), there were trend in eculizumab group to lower proteinuria (76±54 mg/day vs 108±91 mg/day) and statistically significant less chronic glomerulopathy (0.076±0,1 vs 0.123±0,2, p=0.046). Acute rejections observed in 5 eculizumab patients (including 3 subclinical), and in 7 control patients (including 3 subclinical).
Discussion: we found less signs of chronic/subclinical AMR in eculizumab group – less chronic glomerulopathy, and trend to lover proteinuria. However, our findings have a serious limitations – average time to biopsy since transplantation was lover in eculizumab patients (133±129 vs 235±204 days). Early graft losses in eculizumab patients make evident the need for effective vaccination before transplantation, not only against pneumococcal and meningococcal infections, but against influenza as well.
Conclusion: Combination of eculizumab and alemtuzumab leads to profound immunosuppression early post transplant, which can cause unusual course of flu-like infections when pretransplant vaccination was no complete. Continuation of the study is necessary to clarify potential clinical benefits.

353.6

Impact of pre-existing diabetes mellitus on the immunologic outcome after kidney transplantation

Oliver Staeck, Fabian Halleck, Anna Kleinsteuber, Lukas Lehner, Klemens Budde, Dmytro Khadzhynov.
Nephrology, Charite Universitaetsmedizin Berlin, Berlin, Germany.

Background: There is only limited data available on the immunologic outcomes of kidney transplant recipients (KTR) with pre-existing diabetes mellitus (preDM) at time of transplantation.
Methods: This long-term retrospective single center analysis included 839 deceased donor KTR transplanted 1999-2014. Prevalence and history of DM at time of transplantation were determined. Cox proportional hazard models were applied to examine the association of preDM and immunologic outcomes. Multivariate models were adjusted for recipient age, gender, time on dialysis, prior kidney transplantation, donor age, HLA-mismatches and cold ischemia time.
Results: Mean recipient age was 54±14 yrs, mean post-transplant follow-up was 5.9±3.7 yrs. 16% of all included KTR had preDM, while 9% of KTR had pre-existing diabetic end-organ damage (retinopathy, neuropathy or nephropathy). KTR with preDM had a significantly worse 7-year survival compared to recipients without DM (after 7 years 58.6% vs. 81.6%; p<0.001, respectively). However, preDM had no significant influence on a death censored graft survival in this analysis (p=0.128). Multivariate analysis adjusted for all relevant demographic factors identified DM as significant independent risk factors for death (HR 1.76, p=0.001).
Multivariate cox regression analysis revealed preDM as an independent risk factor for T-cell mediated rejections (HR 1.45, p=0.024). Independent association of preDM with antibody mediated rejections did not reach significance level (HR 2.08, p=0.064). Other significant independent risk factors were HLA mismatches and prior kidney transplantations. Pre-existing diabetes did not contribute independently as risk factor for de novo donor specific antibodies.

TABLE 1. Estimates of predictors for immunologic outcome (Cox proportional hazards models)

		Univariate analysis		Multivariate analysis*	
Outcomes	**Predictors**	**HR (95% CI)**	**P**	**HR (95% CI)**	**P**
TCMR	Recipient age, per year	1.01 (1.00-1.02)	0.076	0.99 (0.98-1.00)	0.018
	Donor age, per year	1.01 (1.01-1.02)	<0.001	1.01 (1.00-1.02)	0.087
	Male sex	1.14 (0.90-1.44)	0.279		
	Prior kidney transplantation	1.22 (0.91-1.63)	0.185	1.55 (1.12-2.14)	0.009
	Time on dialysis, per month	1.00 (1.00-1.01)	0.191		
	Cold ischemia time per hour	1.01 (0.99-1.03)	0.617		
	HLA-mismatches, per mismatch	1.26 (1.17-1.34)	<0.001	1.25 (1.15-1.36)	<0.001
	Diabetes	1.47 (1.09-1.99)	0.012	1.45 (1.05-2.00)	0.024
ABMR	Recipient age, per year	0.96 (0.95-0.98)	<0.001	0.94 (0.92-0.96)	<0.001
	Donor age, per year	0.99 (0.98-1.01)	0.467		
	Male sex	1.24 (0.70-2.17)	0.460		
	Prior kidney transplantation	1.92 (1.04-3.54)	0.037		
	Time on dialysis, per month	1.00 (1.00-1.01)	0.248		
	Cold ischemia time per hour	0.99 (0.94-1.04)	0.660		
	HLA-mismatches, per mismatch	1.26 (1.07-1.48)	0.006	1.52 (1.25-1.86)	<0.001
	Diabetes	1.45 (0.73-2.80)	0.288	2.08 (0.96-4.51)	0.064
de novo DSA	Recipient age, per year	1.00 (0.99-1.00)	0.239	0.98 (0.97-0.99)	0.003
	Donor age, per year	1.00 (1.00-1.014)	0.137		
	Male sex	1.08 (0.83-1.39)	0.570		
	Prior kidney transplantation	2.05 (1.53-2.69)	<0.001	1.78 (1.24-2.54)	0.002
	Time on dialysis, per month	1.00 (1.00-1.01)	0.297		
	Cold ischemia time per hour	0.99 (0.97-1.01)	0.286		
	HLA-mismatches, per mismatch	1.32 (1.22-1.42)	<0.001	1.44 (1.30-1.59)	<0.001
	Diabetes	0.89 (0.58-1.35)	0.571		

*multivariate analysis using stepwise backward elimination with inclusion of recipient age, donor age, prior kidney transplantation, HLA-mismatches, diabetes.

Conclusion: Pre-existing DM is not only associated with increased mortality but also a strong independent risk factor for T-cell-mediated rejections. This emphasizes the need for appropriate post-transplant management.

353.7

Is prolonged cold ischemia a contraindication to using kidneys from acute kidney injury donors?

Robert Stratta[1], Amber Carrier[1], Alan Farney[1], Jeffrey Rogers[1], Giuseppe Orlando[1], Muhammad Khan[1], Hany El-Hennawy[1], Amber Reeves-Daniel[2], Amudha Palanisamy[2].
[1]Surgery, Wake Forest, Winston-Salem, NC, United States; [2]Internal Medicine, Wake Forest, Winston-Salem, NC, United States.

Introduction: Elevated deceased donor (DD) serum creatinine (SCr) levels and prolonged cold ischemia time (CIT) are major independent reasons for kidney discard following organ recovery. Many kidneys are declined by local centers because of acute kidney injury (AKI), which results in delays and longer CIT as these kidneys are offered regionally and then nationally in the US. The study purpose was to analyze the combined effect of these 2 factors on kidney transplant (KT) outcomes.
Methods: We performed a single center retrospective analysis in adult DD KT patients (pts) receiving AKI donor kidneys. AKI was defined as a doubling in the DD admission SCr and a terminal SCr >2.0 mg/dl. Outcomes were stratified according to longer CIT categories. Delayed graft function (DGF) was defined as the need for dialysis for any reason in the 1st week post-KT. All pts received depleting antibody induction with tacrolimus/mycophenolate maintenance therapy ∓ steroids.
Results: Since 1/1/07, we performed 118 KTs from 89 AKI DDs. Mean DD age was 35 years; mean DD admission and terminal SCr levels were 1.2 mg/dl and 3.1 mg/dl, respectively. 27 KTs (23%) had CITs <20 hrs, 52 (44%) 20-<30 hrs, 30 (25%) 30-<40 hrs, and 9 (8%) ≥40 hrs. The proportion of imported kidneys (66% overall) increased with longer CIT category (30%, 67%, 90% and 89%, respectively, p<0.0001). Most kidneys (87%) were managed with both cold storage and machine perfusion (mean pump time 12.2 hours, mean total CIT 26.3 hours). The overall incidence of DGF was 41.5%; the DGF rate with longer CIT category was 30%, 48%, 33%, and 67%, respectively (p=NS). With a mean follow-up of 52 months, overall pt and kidney graft survival rates were 91% and 81%, respectively. Death-censored graft survival (DCGS) rates were 84% and 88% for pts with and without DGF (p=NS). DCGS rates were 92% in pts with CIT <20 hrs compared to 85% in those with CIT ≥20 hrs (p=NS). In the 9 pts with CITs ≥40 hrs, the 4-year DCGS rate was 100%.
Conclusions: These findings suggest that the presence of both AKI and prolonged CIT may not adversely influence intermediate-term outcomes, particularly when imported kidneys are placed on short-term machine preservation prior to KT. The presence of DGF likewise does not affect outcomes in this setting. Discard of AKI donor kidneys because of projected long CIT is not warranted. Consequently, use of these kidneys may be a safe and effective way to expand the donor pool and reduce the KT waiting list.

353.8

Retrospective study of post renal transplant delayed graft function - analysis of multiple definitions and respective prognostic capacity

Samantha Bateman[1], Theresa Nguyen[1], Shreeya Patel[1], Robyn Langham[1,2].
[1]Department of Nephrology, St Vincent's Hospital, Melbourne, Australia; [2]School of Rural Health, Monash University, Melbourne, Australia.

Introduction: Delayed graft function (DGF) is a term often used in describing an acute kidney injury from ischaemia-reperfusion in the post renal transplant (Tx) setting[1]. Though associated with an increase in morbidity, graft loss and increased hospital stay, consensus on the definition of DRG is lacking, with the term often misused and misunderstood. Currently, the reported incidence of DGF varies depending on definition used, with a range in the literature from five to 50 percent[2]. In order to progress meaningful intervention studies to improve the outcomes of DGF, there is a pressing need to develop a consensus on a unifying, clinically relevant and simple definition.
Materials and Methods: A retrospective single-centre analysis of 76 consecutive cadeveric renal transplants was undertaken. 18 published definitions of DGF were applied to the data set. Each definition was correlated to clinical outcome, hospital length of stay and mean serum creatinine (SCr) level at 1 year as a surrogate marker of graft function.
Results: Application of the 18 definitions of DGF to our cohort yielded a wide range in incidence from 10.8 to 68.9 percent. Only three of the 18 definitions predicted a clinically significant worse graft function at one year; 1. Urine output less than one litre and less than 25 percent fall in SCr from baseline in first 24 hours post Tx (incidence 52.7%; SCr 210mmol/L DGF vs 119mmol/L no DGF, p< 0.05); 2. SCr decrease less than 10% per day during the three consecutive days post Tx (incidence 43.3%; SCr 200mmol/L DGF vs 125mmol/L no DGF, p< 0.05) and 3. SCr reduction ratio of less than 25 percent and or need for dialysis (Dx) at 48 hours post Tx (incidence 48.65%; sCr 189mmol/L DGF vs 123mmol/L no DGF p<0.05). The only definition to associate with a significant difference in hospital length of stay was the clinical documentation of DGF (incidence 45.8%; LOS 13.5days DGF vs 10.7 days no DGF, p <0.05).
Discussion: Many definitions of DGF have been applied in the post renal transplant literature, creating confusion both academically and clinically. The inclusion of multiple clinical variables such as SCr, urine output and/or the need for Dx increases the likelihood of useful predictive validity of the definition. Excluding highly sensitive histopathological findings in renal biopsies increases the applicability of a definition. In determining the optimal definition that best predicts 1 year outcome, this study supports the use of a combination of SCr measures and the need for Dx in defining DGF.
Conclusion: Similar to the development of consensus definitions in AKI[3], determination of a consensus framework in defining DGF in renal Tx is needed in both research and clinical terms. Further interventional studies aimed at reducing the incidence and subsequent poorer outcomes of DGF require the development of a robust definition framework that is fit-for-purpose, with clarity and easy applicability.

Interim analysis to determine whether preoperative intravenous fluids result in a decrease in donor subclinical acute kidney injury

Ryan Ghita[1], Kieran Lafferty[2], Shona Mackinnon[2], Aitken Emma[1], Marc Clancy[1,2].
[1]Faculty of Medicine, University of Glasgow, Glasgow, United Kingdom; [2]Renal Transplant Department, Queen Elizabeth University Hospital Glasgow, Glasgow, United Kingdom.

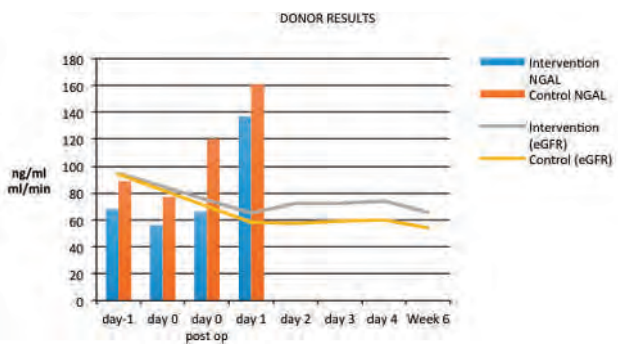
Introduction: Laparoscopic nephrectomy is considered the gold standard for living kidney donation, reducing post-operative pain and faster recovery[1]. Conversely, a pilot study (Aitken et al. 2014; unpublished) found laparoscopic nephrectomy exposes the kidneys to increased hemodynamic stresses due to extreme position and pneumoperitoneum leading to acute kidney injury (AKI). It is hypothesized that active hydration prior to donation counteract these stresses resulting in a reduced subclinical kidney injury and ultimately improving long-term renal function in both donor and recipient.
We are monitoring AKI using neutrophil gelatinase associated lipocalin (NGAL). It has been proven to be a more sensitive marker of AKI compared with creatinine or urine output[2].

Methods:

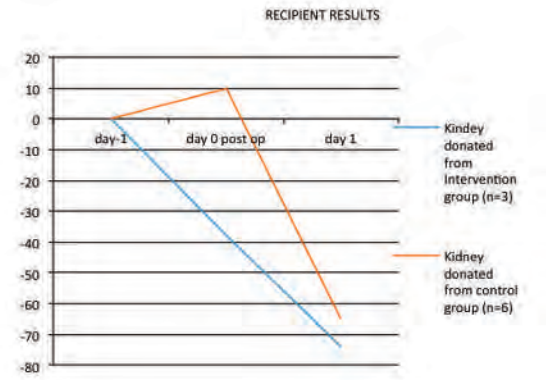
- A single center, single blinded randomized controlled trial
- The intervention cohort receives 3L of Harttmans solution overnight (00:00 to 08:00). The control group will be allowed clear oral fluids up to 06:00. Donor taken to theatre at 08:30
- Blood samples are taken from the donor day-1, day 0 (preop), day 0 (postop), day+1
- Blood samples are also taken from the transplant recipient at the same time points

Results:

- To date there are 8 patients in the control and 7 patients in the intervention
- Donor baseline NGAL dropped by 17% post intervention (p=0.197)
- Immediately post laparoscopic kidney donation NGAL was 66.86ng/ml in the Intervention (a rise of 18.4%(p=0.188)) and 120.38ng/ml in the control (a rise of 55.8% (p=0.003))
- Day 4 post laparoscopic kidney donation eGFR dropped by 21.8%(p=0.003) in the Intervention group compared to only 36.2%(p=<0.01) in the control group. By week 6 this trend had continued
- Recipient of a kidney from the control group has a post operative NGAL increase on average of 10%(p=0.128). Recipient of a kidney from the intervention group has a post operative NGAL decrease on average of 38%(p=0.136)



Recipients of kidneys donated from the control group have an immediate NGAL rise unlike the recipients of kidneys from the intervention group in which the NGAL begins to drop immediately post surgery. This may represent that kidneys donated from the control group are more susceptible to AKI associated with nephrectomy and then transplantation.



Preoperative IV hydration has shown to reduce any subclinical AKI in the donor prior to donation and reduces the degree of AKI associated with laparoscopic donor nephrectomy. There is also a consistent improvement in renal function in the intervention group at 6 weeks post surgery.

Conclusions: Preoperative Intravenous fluids may decrease the severity of AKI associated with laparoscopic donor nephrectomy with a subsequent increase in donor renal function 6 weeks post surgery. However further data is needed from completion of the Randomized Controlled trial to validate results and to see if this will have a longstanding impact on kidney function for both kidney donor and transplant recipient.

Extracorporeal membrane oxygenation practices changes as bridge to lung transplantation: An Institutional Experience and Literature Review

Daniel Absi, Margari Peradejordi Lastras, Juan Osses, Gustavo Parrilla, Mariano Candioti Lehmann, Roberto Favaloro, Alejandro Bertolotti.
Intrathoracic Transplant Department, Favaloro Foundation Universitary Hospital, Buenos Aires, Argentina.

Introduction: Respiratory failure patients requiring support with invasive mechanical ventilation while awaiting lung transplantation present a higher risk of death. Extracorporeal membrane oxygenation (ECMO) has been proposed as an alternative bridging mode to mechanical ventilation and this is an evolving management technique of rapidly progressive pulmonary disease. The aim of this study was to assess the current evidence regarding how the ECMO strategies have changed over the last years.
Methods: Retrospective review of a single-institution's experience placing patients (p) on ECMO in order to bridge them to lung transplant. From 2010 to 2015, we performed 62 ECMO Runnings in 58 p, of these, 25 p were bridge to lung transplant (BTT). We divided this cohort in two groups by era (Group 1: 2010-2012 and Group 2: 2013-2015). Categorical data were shown as frequencies/percentages and continuous data as means with standard deviation (SD). Fisher's exact test and the chi-square analysis were performed to compare continuous and categorical variables, respectively. Actuarial survival was estimated with the Kaplan–Meier method. End points, included successful bridging, duration of extracorporeal membrane oxygenation support and overall survival.
Results: Eight p were BTT in group 1 and 17 p in group 2. Overall median recipient age was 34,7±19,4 years. The etiologies were: cystic fibrosis (n=11), idiopathic pulmonary fibrosis (n=7), secondary pulmonary fibrosis (n=3), pulmonary arterial hypertension group 1 (n=3) and 1 p with pulmonary hypertension group 3. Veno-venous ECMO mode was used in 15 p (60%), veno-arterial in 5 p (20%), arterio-venous in 3 p (12%) and veno-arterio-venous in 2 p (8%). Thirteen p underwent sedated bridging, 7 p awake and 5 p ambulatory ECMO strategy. Eight p were declared futile. Support mean time was 9±6,8 days in group 1 and 19±12,6 days in group 2 ($p<0,05$). Overall successful bridging was 58,8% (20% vs 75% group 1 and 2 respectively, $p<0,05$). All p survive lung transplant except one. Survival rate at 1 year was 70%.
Discussion: Although the early experience and outcomes with ECMO as BTT were unconvincing, latest series demonstrate that better results can be achieved. The main contributors of poor early and late outcomes after transplant are: Pre-transplant deconditioning, prolonged immobilization and heavy sedation. Therefore, changes in ECMO strategies have shown to be an important goal that could improve these outcomes.
Conclusions: Early mobilization of patients on ECMO as BTT is an important goal because it facilitates participation in physical therapy and improves overall patient conditioning for lung transplantation. In carefully selected patients, ECMO is a safe and effective mean of bridging decompensated patients with end-stage lung disease to lung transplantation.

Donor CCR2+ cardiac macrophages mediate neutrophil extravasation after heart transplantation through MyD88-dependent production of chemoattractants

Wenjun Li[1], His-Min Hsiao[1], Ruyiji Higashikubo[1], Brian Saunders[2], Ankit Bharat[3], Daniel R.Goldstein[4], Alexander S. Krupnick[1,2], Andrew E.Gelman[1,2], Kory Lavine[5], Daniel Kreisel[1,2].

Introduction: Myocardial ischemia reperfusion injury contributes to morbidity and mortality in heart transplant patients. Neutrophilic infiltration into myocardial tissue plays a critical role in promoting damage and can also augment alloimmune responses. The goal of this study was to define cellular and molecular requirements for neutrophilic infiltration into ischemic myocardium.
Materials and Methods: Heart grafts from B6 wildtype (WT), B6 CCR2 DTR (after treatment with DT to deplete CCR2+ cells), B6 MyD88 flox x LysM-cre (MyD88 deletion in macrophages) and CXCL5-deficient mice were transplanted into the necks of congenic B6 CD45.1+ or syngeneic B6 neutrophil reporter LysM-GFP recipients. 2 hours after reperfusion we performed flow cytometric analysis or intravital two photon imaging of heart grafts. RNA expression levels of neutrophil chemoattractants were determined in flow cytometrically sorted cardiac macrophage populations.
Results: Flow cytometric analysis demonstrated donor-derived CD64+CD11b+CCR2- and CD64+CD11b+CCR2+ macrophages in heart grafts 2 hours after reperfusion. RNA expression levels of the neutrophil chemokines CXCL2 and CXCL5 were significantly higher in WT CCR2+ compared to CCR2- macrophages. Intravital two photon imaging revealed that, compared to WT conditions, extravasation of neutrophils into the graft tissue was markedly impaired when we transplanted hearts that lacked CCR2+ cells (extravasated cells: 12.2 ±5% (CCR2-DTR) vs 36.3±3.8% (WT), $p<0.05$). A similar neutrophil trafficking defect was observed when we transplanted hearts that lacked MyD88 selectively in macrophages (Lysozyme M+ cells) (extravasated cells: 1.2 ±1.2% (Myd88 flox x LysM-cre) vs 36.3±3.8% (WT), $p<0.01$). RNA expression levels of CXCL2 and CXCL5 were significantly decreased in MyD88-deficient compared to WT cardiac CCR2+ macrophages. Finally, neutrophils were unable to enter the myocardial tissue when we administered CXCL2-blocking antibody or transplanted CXCL5-deficient hearts (extravasated cells: 1.95 ±1.1% (CXCL2-blocking antibody), 12.7±2.6% (CXCL5-knockout heart), WT 36.3 ± 3.8%, $p < 0.05$ CXCL2-blocking antibody and CXCL5 knockout heart vs. WT).
Conclusion: Our work has identified novel mechanisms that regulate neutrophil trafficking into freshly reperfused cardiac grafts. We have shown that MyD88-mediated production of CXCL2 and CXCL5 by tissue-resident donor CCR2+ macrophages is critical to mediate extravasation of neutrophils into ischemic myocardial tissue. Our results provide the framework for the development of new therapeutic strategies for heart transplant recipients.

Tertiary lymphoid organs within pulmonary allografts promote tolerance

Wenjun Li[1], Hsi-Min Hsiao[1], Ryuji Higashikubo[1], Alexander S.Krupnick[1,2], Andrew E.Gelman[1,2], Daniel Kreisel[1,2].
[1]Surgery, Washington University School of Medicine, St. Louis, United States; [2]Pathology & Immunology, Washington University School of Medicine, St. Louis, United States.

Introduction: Immune responses after lung transplantation differ from those after transplantation of other organs. We have previously shown that tolerant lung grafts harbor tertiary lymphoid organs (inducible bronchus associated lymphoid tissue (iBALT)), which are rich in CD11c+ and Foxp3+ cells (Li W et al, Mucosal immunology. 2012). Here we explored whether lung grafts can induce systemic tolerance and whether the presence of iBALT is important to maintain lung allograft tolerance.
Materials and Methods: Balb/c lungs were transplanted into B6, B6 CD11c-EYFP/Foxp3-GFP and B6 CD11c-DTR recipients and treated with perioperative co-stimulatory blockade (MR1/CTLA4-Ig). At least 30 days after pulmonary transplantation recipients received Balb/c or CBA hearts. Tolerant lung allografts were removed 2 days before or 4 weeks after heart transplantation. Balb/c lungs were imaged by intravital two-photon microscopy > 30 days after transplantation into B6 CD11c-EYFP/Foxp3-GFP recipients. Tolerant Balb/c lungs were retransplanted into nonimmmunosuppressed B6 or B6 CD11c-DTR secondary recipients at least 30 days after their initial engraftment into immunosuppressed B6 hosts. Secondary hosts were treated with saline or diphtheria toxin (DT) at the time of retransplantation.
Results: Transplantation of donor-specific Balb/c hearts into tolerant B6 recipients of Balb/c lungs resulted in their long term survival with no evidence of allograft vasculopathy (>120 days, n=5). If we removed the tolerant lung graft 2 days before cardiac transplantation, Balb/c hearts were acutely rejected (18.5 days, n=4). If the tolerant pulmonary grafts were explanted 4 weeks after heart transplantation, the cardiac grafts rejected acutely or developed allograft vasculopathy (n=4). Retransplantation of tolerant Balb/c lungs into nonimmunosuppressed B6 recipients resulted in their long-term survival with maintenance of the iBALT within the pulmonary grafts (n=3). Selective depletion of CD11c+ cells from tolerant lungs at the time of retransplantation into nonimmunosuppressed B6 recipients resulted in structural disintegration of the iBALT and graft rejection (n=3). Intravital two photon imaging revealed interactions between CD11c+ and Foxp3+ cells in tolerant lung grafts.
Conclusion: The presence of iBALT in lung grafts is critical to maintain a tolerant state. Induction and maintenance of systemic tolerance after lung transplantation are dependent on the presence of the pulmonary graft. Developing strategies to induce tolerogenic tertiary lymphoid organs within allografts may provide a new therapy for transplant recipients.

Effects of brain death (BD) or cardiac death (DCD) on allogeneic lung graft survival in preclinical MHC-inbred CLAWN miniature swine

Yuichi Ariyoshi[1], Hisashi Sahara[1], Mitsuhiro Sekijima[1], Takahiro Murokawa[1], Takehiro Iwanaga[1], Yurika Ichinari[1], Akira Shimizu[2], Kazuhiko Yamada[1].
[1]Division of Organ Replacement and Xenotransplantation Surgery, Center for Advanced Biomedical Science and Swine Research, Kagoshima University, Kagoshima, Japan; [2]Department of Analytic Human Pathology, Nippon Medical School, Tokyo, Japan.

Introduction: We have extensively studied the mechanisms of pulmonary allograft rejection in MHC-inbred MGH miniature swine. To clarify that our newly developed Japanese line of MHC-inbred CLAWN miniature swine represent a highly-valuable preclinical model of transplantation, we established several models of orthotopic lung transplantation.
Methods: Five CLAWN miniature swine received fully MHC-mismatched lungs with 12-days continuous infusion of tacrolimus (constant blood levels 35-45 ng/ml) (Group 1). Additional four CLAWN miniature swine received MHC-matched, minor antigen-mismatched lungs under the same immunosuppressive protocol to investigate the influence of MHC disparity on allograft survival (Group 2). To investigate whether brain death (BD) or cardiac death (DCD) affects the graft survival, three recipients were transplanted with fully mismatched lung grafts from BD donors induced by subdural balloon and subsequently ventilated for 6 h before procurement (Group 3) and six recipients were transplanted with MHC-matched DCD lungs induced by venous injection of potassium chloride and allowed for 90 min before procurement (Group 4). Graft function was monitored by histology and chest X-rays.
Results: All MHC-mismatched grafts was rejected within 63 days with diffuse mononuclear infiltrates associated with intra-alveolar hemorrhage and capillary congestion, consistent with severe cellular and antibody-mediated rejection (Group 1). In contrast to Group 1, all MHC-matched lung in Group 2 was uniformly accepted over one year with occasional presence of minimum acute cellular rejection (the fourth animal is ongoing > 7 months). In Group 3, donor brain death accelerated pulmonary allograft rejection, and all three animals rejected the grafts within 35 days with accelerated development of anti-donor antibodies. In Group 4, three out of six animals eventually rejected the warm ischemic MHC-matched grafts at POD42, 56, 250, respectively.
Conclusions: By taking advantage of the controlled antigenicity of the MHC-inbred miniature swine, we created a reproducible large-animal model of lung transplantation similar to the clinical scenario. We anticipate that this preclinical model using MHC-inbred CLAWN miniature swine will facilitate further systematic study of the pathogenesis and therapy of lung graft rejection.

Intraoperative vasopressin use as a favorable prognostic factor for early survival after lung transplantation

Kyoung Shik Narm, Hee Suk Jung, Young Woo Do, Jin Gu Lee, Chang Young Lee, Anes Kim, Hyo Chae Paik.
Department of Thoracic and Cardiovascular Surgery, Yonsei University College of Medicine, Seoul, Korea.

Introduction: Lung transplantation has become the standard of care for end-stage pulmonary disease. Despite increasing experience in caring for these patients under extreme stress and improvement of immunosuppressant, the rate of perioperative mortality still remains high. In our institution, to maintain blood pressure during operation, norepinephrine was generally selected as a first drug. Vasopressin had been added to norepinephrine only if norepinephinre alone could not raise blood pressure effectively. Vasopressin was known as selective pulmonary vasodilator[1]. Therefore use of vasopressin might be beneficial to transplanted patient. The purpose of this study was to analyze the impact of intraoperative vasopressin use on early survival following lung transplantation.
Materials and Methods: Between March 2013 and November 2015, we retrospectively reviewed 48 consecutive patients who had undergone double-lung transplantation in Yonsei University College of Medicine. Patients who underwent single lung transplantation, multi-organ transplantation and who received ventilator care or extracorporeal membranous oxygenation(ECMO) support waiting transplantation and who died less than one month after transplantation were excluded. Donor organ procurement and transplantation were performed using standard methods. All operation was performed under ECMO support. All patients received triple drug regimen including tacrolimus (FK 506), mycophenolate mofetil (MMF; CellCept), and corticosteroid postoperatively. Patients were divided into two groups depending on intraoperative vasopressin use. Patients who received vasopressin infusion more than 30 minutes were included vasopressin group. Exact dose for each patient had not been recorded, but usual dose in our institution was 0.1~0.5 unit/min.
Results: 21(43.7%) patients received vasopressin during operation and 27(56.3%) patients did not. Patients characteristics including age, [illegible] preoperative NYHA classification

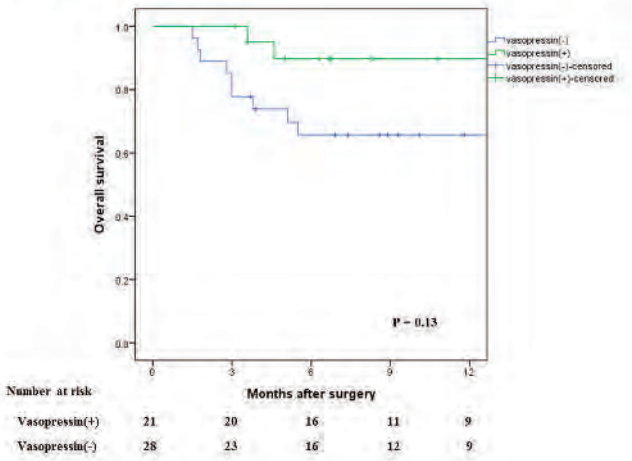
Table. Patients characteristics
ILD : interstitial lung disease, COPD: chronic obstructive pulmonary disease, NYHA: New York Heart Association

variables	Vasopressin use (n=21)	No vasopressin use (n=27)	P-value
Age (years)	48±16	50±11	0.58
Gender			0.26
male	9(42.9%)	16(59.3)	
female	12(57.1%)	11(40.7%)	
Preopetive diagnosis			0.10
Idiopathic pulmonary fibrosis	9(42.9%)	14(51.9%)	
Connective tissue-related ILD	4(19.0%)	7(25.9%)	
COPD	3(14.3%)	0(0.0%)	
Lymphangioleiomyomatosis	0(0.0%)	3(11.1%)	
Bronchiolitis obliterans	3(14.3%)	3(11.1%)	
Others	2(9.5%)	0(0.0%)	
NYHA class			0.87
III	5(23.8%)	7(25.9%)	
IV	16(76.2%)	20(74.1%)	
Operative time (min)	427±74	397±92	0.22
Blood loss during operation (cc)	1800(1150,4050)	1700(1050,3700)	0.92
Mortality	3(14.2%)	9(33.3%)	

Median follow-up period was 14.1 months (range of 1.5 to 32.7 months). Analyzed by Kaplan-Meier method, the 1- year overall survival rates in the vasopressin use group were 89.7% and those in the

no-vasopressin use group were 65.7%, respectively. Vasopressin use group showed tendency to better 1-year survival (p=0.13).

Figure. Overall survival



Conclusion: Our results showed that vasopressin use during operation might be associated with better early survival after lung transplantation. Given that pulmonary vasodilator effect of vasopressin, it could be considerable to use vasopressin earlier in managing blood pressure during operation. Further studies are needed.

The immunosuppressive effect via HGF-CMET pathway of autologous adipose tissue-derived mesenchymal stem cells in a rat lung transplantation model

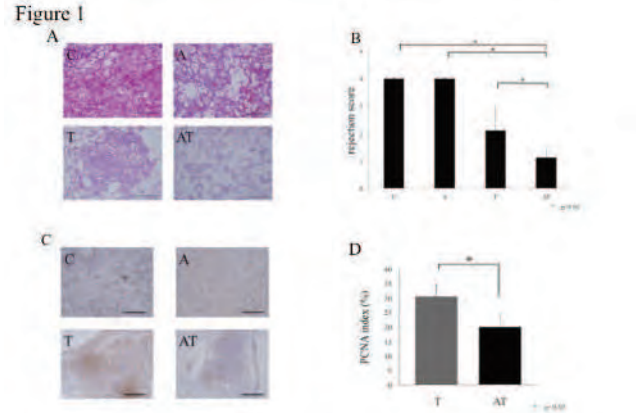
Hironosuke Watanabe[1], Tomoshi Tsuchiya[1], Naoya Yamasaki[1], Takuro Miyazaki[1], Keitaro Matsumoto[2], Hiroshi Yukawa[2], Yoshinobu Baba[1], Takeshi Nagayasu[1].
[1]Division of Surgical Oncology, Department of Translational Medical Sciences , Nagasaki University, Nagasaki, Japan; [2]Nagoya University's FIRST Center Innovative Nanobiodevices, Nagoya, Japan.

Purpose: Immunosuppressants are associated with various complications after lung transplantation, and thus less intense immunosuppression should be attempted. Adipose tissue-derived mesenchymal stem cells (ADMSCs) were recently found to have an immunomodulatory effect in various disease models through the secretion of hepatocyte growth factor (HGF). The purpose of this study was to investigate the effect of ADMSCs on immune response in a rat lung transplantation model.

Materials and Methods: Orthotopic left lung transplantation was performed in the rat using the cuff technique. Before transplantation, ADMSCs were gathered from the rats' abdominal subcutaneous adipose tissue and cultured. The experimental animals were then divided into the following four groups: a control group (C group), in which no treatment was administered after transplantation; an ADMSC group (AD group), in which rats were administered a single intravenous injection of ADMSCs (autologous 1 × 106 cells) after transplantation; a tacrolimus group (T group), in which rats were administered tacrolimus (0.5 mg/kg) every 24 hours after transplantation; and an ADMSC and tacrolimus group (AT group), in which rats were administered ADMSCs (autologous 1 × 106 cells) after transplantation in combination with tacrolimus (0.5 mg/kg) every 24 hours. Allografts were then assessed histologically and serum HGF levels measured.

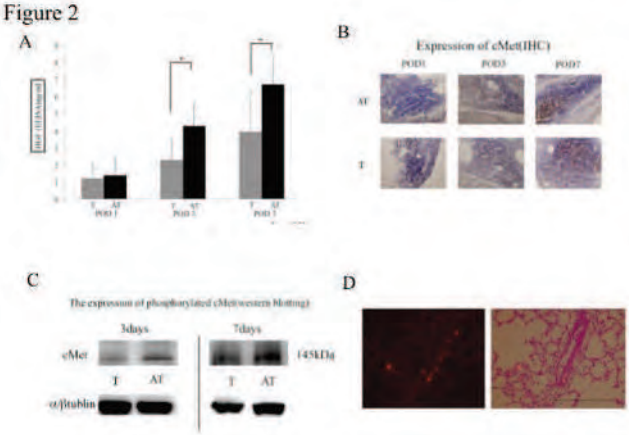
Results: Although no significant differences were found between the C and AD groups, the histologic rejection grade of the AT group was significantly lower than that of the other groups(Figure 1 A, B). The bronchus-associated lymphoid tissue cell proliferating cell nuclear antigen index of the AT group was significantly lower than that of the T group (19.88±4.67 vs. 30.5±3.92 Figure 1 C, D).

Figure 1



The serum HGF level of the AT group was significantly higher than that of the T group at postoperative days (POD) 3 and 7 (4.29±1.34 vs. 2.29±1.25 and 6.71±1.57 vs. 3.94±2.46 ng/mL, respectively (Figure 2 A). The expression of cMet, the tyrosine kinase receptor of HGF, increased with time in the AT group. Programmed death-ligand 1 expression in allografts of the AT group was significantly increased compared with that of the T group(Figure 2 B, C)The administered ADMSCs were detected in allografts at POD 7 using fluorescent quantum dots(Figure 2 D).

Figure 2



Conclusion: ADMSCs combined with tacrolimus reinforced immunosuppression, possibly due to the secretion of HGF.

354.7

Outcomes of acute kidney injury occurring immediately post lung transplantation: a retrospective single-centre audit

Khai Yang Ooi[1], Eldho Paul[2,3], Bronwyn Levvey[4], Greg Snell[4], Solomon Menahem[1,2].
[1]Department of Renal Medicine, Alfred Hospital, Melbourne, Australia; [2]Department of Epidemiology and Preventive Medicine, Monash University, Melbourne, Australia; [3]Clinical Haematology Department, Alfred Hospital, Melbourne, Australia; [4]Department of Allergy, Immunology and Respiratory Medicine, Alfred Hospital, Melbourne, Australia.

Background: Lung transplantation surgery is often complicated by acute kidney injury (AKI) requiring renal replacement therapy, adding to the peri-operative morbidity and mortality. We sought to characterise the risk factors for haemofiltration-dependent AKI occurring in the immediate post lung transplant period and evaluate its impact on survival and long term renal function.
Methods: We performed a retrospective review of all lung transplant recipients at our institution that required haemofiltration in the immediate period post lung transplantation surgery. Demographic, clinical and biochemical parameters were recorded. Kaplan-Meier curve was used to plot survival after transplant as a function of time and this was compared to survival data of all lung transplant recipients from the local Australian and New Zealand Cardiothoracic Organ Transplant Registry (ANZCOTR)[1]. Risk factors associated with mortality were assessed using Cox proportional hazards regression. Change in renal function over time was assessed using Wilcoxon signed rank test.
Results: Of 794 lung transplants performed between May 2000 and April 2015, 38 patients were identified to have developed haemofiltration-dependent AKI immediately post lung transplant. The 1-year survival was 76.1% (95% CI: 59.0-87.8%) and 5-year survival was 46.7% (95% CI: 28.3-63.0%), representing a 12.4% and 15.1% greater mortality risk respectively compared to ANZCOTR data. Cystic fibrosis (HR 4.48 [1.64-12.23], p = 0.003) and duration of inotropic support (HR 1.03 per day [1.003-1.05], p = 0.02) were significantly associated with increased risk of mortality whereas higher BMI (HR 0.88 [0.78-0.99], p = 0.03) was associated with reduced risk. There was no relationship with duration of renal replacement therapy and long term mortality. There was a median decline in renal function of 5.08mL/min/year (IQR -3.43 to 28.19, p = 0.02) in patients who became dialysis free.
Conclusion: This retrospective study demonstrates a greater mortality risk for those who develop haemofiltration-dependent AKI with the impact largely seen in the first year post transplant. It also demonstrates the significant impact AKI has on long term renal function.

Renal outcomes in lung transplant recipients treated with the mammalian target of rapamycin (mTOR) inhibitor everolimus

Timothy Coughlan[1], Steve Ivulich[2], Ryan Slack[1], Boyoun Choi[2], Eldho Paul[3], Greg Snell[2], Solomon Menahem[1].
[1]Department of Nephrology, Alfred Health, Melbourne, Australia; [2]Department of Allergy, Immunology and Respiratory Medicine, Alfred Health, Melbourne, Australia; [3]Department of Epidemiology and Preventative Medicine, Monash University, Melbourne, Australia.

Background: Lung transplantation is a treatment option for selected patients with progressive lung disease refractory to other treatment modalities[1]. The calcineurin inhibitors (CNIs) tacrolimus and cyclosporine A (CyA) are the mainstay of most immunosuppressive regimens but are associated with nephrotoxicity[2]. Studies have shown that the use of everolimus as a CNI sparing agent was associated with improvements in renal function, although these studies had relatively short follow-up periods and small numbers[3]-[6]. We sought to describe the renal outcomes of lung transplant patients switched to everolimus in a large single-centre cohort study with prolonged follow-up and determine whether there was an observable deleterious effect of everolimus on lung function.
Methods: We included all lung and heart-lung transplant recipients at the Alfred Hospital with no previous mTOR exposure who were converted to everolimus at any stage after transplantation. Recipients of simultaneous lung-kidney transplants were excluded . Patients who received at least three months exposure to everolimus and who were converted later than one month after transplantation were included for analysis. The study received ethics approval from the Alfred ethics committee.
Demographic and clinical data was collected at four time points: 1. Date of transplantation. 2. Date of conversion to everolimus. 3. 3 months after conversion to everolimus and 4. Date of everolimus cessation, death on everolimus, or last follow-up (end date).
Results: 110 lung allograft recipients at our institution were converted to everolimus of which 67 met the inclusion criteria for analysis. We observed a significant reduction in creatinine clearance between transplantation and conversion in this cohort. Use of everolimus was associated with a reduction or withdrawal of concurrent CNI use.
Following conversion to everolimus, we observed a significant improvement in creatinine clearance at both three months after conversion and at the end date (date of death on everolimus, everolimus cessation or last follow-up). The mean rate of change in creatinine clearance was +13.4 ml/min per year on everolimus, compared to -30.6 ml/min per year between transplantation and conversion (P<0.001).

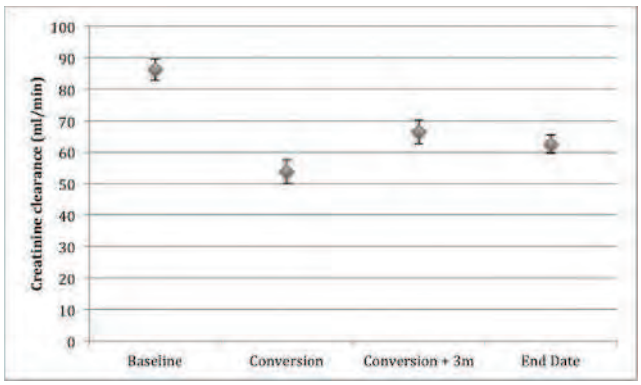

Figure 1: Mean creatinine clearance (+/-CI) by time point
There was no significant difference in FEV1 observed at baseline (first spirometry performed post-transplantation), at conversion to everolimus or at three months after conversion, but there was a significant decline at the end date. There was a mean rate of decline in FEV1 of 0.51L/year between conversion and the end date, compared to a mean rate of increase of 0.15L/year between baseline and conversion (P<0.001).

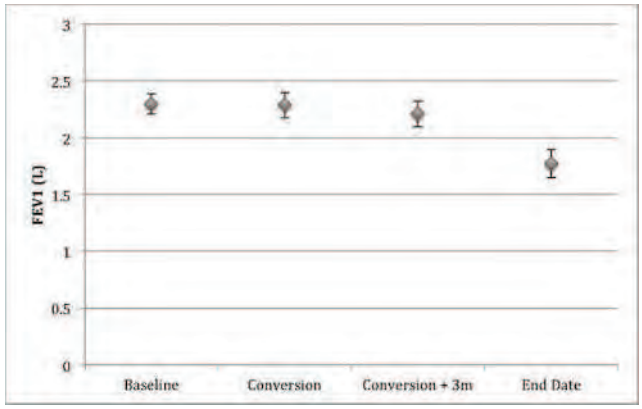

Figure 2: Mean FEV1 (+/-CI) by time point
Our observations are consistent with previous retrospective cohort studies suggesting that the use of everolimus to allow CNI minimization or withdrawal is associated with improved renal function in patients with renal impairment after lung transplantation. Randomised control trials are required to demonstrate whether everolimus is renoprotective when used in lung allograft recipients and whether there is a beneficial or deleterious effect on lung function and patient survival.

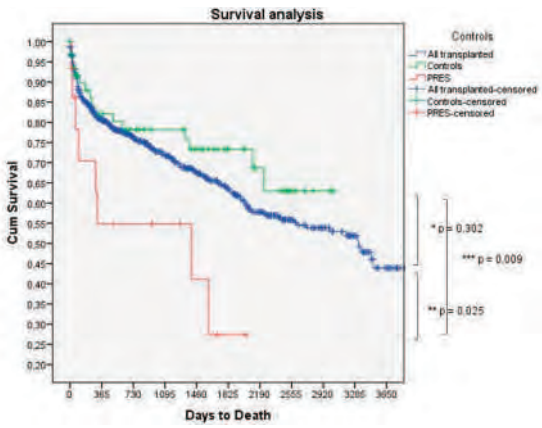
PRES after lung transplantation: A single centre experience

Alberto Benazzo[1], Stefan Schwarz[1], Sophie Bartsch[2], Gabriella Muraközy[1], György Lang[1], Walter Klepetko[1], Peter Jaksch[1].
[1]Department of Thoracic surgery, Medical University of Vienna, Vienna, Austria; [2]Department of Radiology, Medical University of Vienna, Vienna, Austria.

Posterior Reversible Encephalopathy Syndrome (PRES)[1],[2] is a rare but severe neuroradiological complication after solid organ transplantation (SOT). We describe the incidence, risk factors, clinical and radiological presentation and the survival of this syndrome after lung transplantation.
From 1029 patients we retrospectively evaluated 21 cases with a diagnosis of PRES. To chose our control group, 4 patients transplanted in the same period (max. ±50 days) were randomly chosen for each PRES patient (n=84). Two PRES Patients were eliminated for lack of data in matched control patients. All 19 patients received brain MRI and one patient was excluded because of an unclear radiological appearance. We collected demographic, medical, peri-operative and therapeutic data. Lab parameters were also collected at 7 time points: 1 wk, 3 d and 1 d before the PRES event, at the event and 1 d, 3 d and 1 wk after. The time period between surgery and the neurological event was applied to each of the matched 4 control patients to collect control lab values.
Incidence of PRES was 1,9%. Median PRES age was 26,8 yrs (7,4-65,6) and median control age was 47,4 yrs (14,4-66,1) ($p < 0,001$), indicating that young patients are more prone to develop PRES. Significant differences were found in pre-transplant intubation need (p=0,003) and pre- and post-operative ECMO support (p<0,001 and p=0,002), highlighting the more critical conditions in PRES group. Reintubation need (p=0,004) and tracheostomy need (p=0,013) were found significant as well as median ICU time and hospitalization time, respectively 32 d (8-69) vs 7 d (1-105) (p<0,001) and 44 d (20-90) vs 25 d (7-105) (p<0,001). These results, however, may be a consequence of PRES. No significant difference was found between median intubation time of PRES group (5 d, 1-21) vs control (2 d, 0-30) (p=0,81). Univariate conditional logistic regression for PRES within the first 2 months after Tx showed the following results: pre-tx intubation need (OR=7,93, p=0,003, CI=2,02-31,18), pre-operative ECMO need (OR=12, p=0.02, CI=2.42-59.54), post-operative ECMO need (OR=6.09, p=0,003, CI=1.83-20.23) and age<vs>20 (OR=4.069, p=0,022, CI=1,219-13,59). These results indicate that the factors analyzed represent risks for PRES onset. Survival analysis showed 1-year survival of 55% vs 80% and 5-year survival of 30% vs 60% compared to all transplanted patients (p=0,025). Radiologically, correlation was found between the number of affected regions and cytotoxic edema (p=0,03). Subcortical involvement, parietooccipital pattern and asymmetric extension were observed.



PRES is clearly predominant in young patients with severe pre-Tx conditions and complicated postoperative period. The critical conditions of the recipients and the circulatory support may induce a systemic inflammatory status[3] which activates cerebral endothelium and promotes blood extravasation and cerebral edema.

A Multicentre Randomised Controlled Trial to Compare the Efficacy of Normothermic Machine Perfusion with Static Cold Storage in Human Liver Transplantation: Early Outcomes

David Nasralla, The Consortium for Organ Preservation in Europe (COPE) Liver Research Group, Rutger Ploeg, Peter Friend. Nuffield Department of Surgical Sciences, University of Oxford, Oxford Transplant Centre, Oxford, United Kingdom.

Introduction: The international organ shortage has necessitated the use of sub-optimal organs, which are associated with inferior recipient outcomes. Normothermic machine perfusion (NMP) offers a potential solution to this problem; by perfusing the liver with oxygenated blood, medications and nutrients at 37C, the organ is preserved in a functioning, physiological state. Animal studies[1] suggest several benefits: (i) Repair of damage sustained during the retrieval process; (ii) Extended preservation times; (iii) Assessment of organ viability. If these were achieved in clinical practice, then organ utilisation could be greatly improved without compromise to safety or outcome. We present the first analysis of a randomised controlled trial (RCT) comparing NMP with static cold storage (SCS) in clinical liver transplantation.

Materials and Methods: Under the sponsorship of the University of Oxford, a European Union-funded multi-national RCT was commenced in June 2014 involving 7 transplant centres in England, Belgium, Germany and Spain. Livers from adult DBD and controlled DCD donors were eligible. Recipient eligibility criteria included adult recipients of liver-only transplants. Livers were randomised 1:1 to either NMP or SCS. The trial was powered to demonstrate a 33% drop in peak AST measured in the first week post-transplant, requiring a total of 220 transplanted livers (90% power). Secondary endpoints included: post-reperfusion syndrome; early allograft dysfunction; graft and patient survival; ischaemic cholangiopathy (6 month MRCP); health economic analysis. The flow of participants through the trial is illustrated in figure 1.

Results: No interim analysis is permitted in the design of this trial; preliminary data are therefore not available. However, at the current recruitment rate, enrolment will be complete by the end of February 2016. At TTS 2016, we will be able to present the early outcome data, including: (i) Peak AST (primary outcome); (ii) EAD rates; (iii) Length of ITU stay; (iv) 30-day graft and patient survival.

Conclusion: This is the first clinical study of NMP. If successful, this technology has the potential to greatly increase the pool of transplantable livers. A multi-centre RCT in the USA is scheduled to start in early 2016 as well as other NMP studies in Brazil, Spain and China.

DAMP-associated preservation injury and complications after liver transplantation: proof of concept

Denis Efimov[1], Alijaksei E.Shcherba[1], Olga A.Lebedz[1], Alla I.Kireeva[2], Sergey Korotkov[1], Alexander M.Dzyadzko[3], Oleg O.Rummo[1].
[1]Transplantation Department, RSP Center for Organ and Tissue Transplantation, Minsk, Belarus; [2]Institute of Genetics and Cytology National Academy of science, Minsk, Belarus; [3]Anesthesiology and ICU Division, RSP Center for Organ and Tissue Transplantation, Minsk, Belarus.

Introduction: There is no doubt that the activation of antigen-dependent immune response is the main pathogenetic pathway of immunological complications development following liver transplantation. Recently the attention to antigen-independent injury and subsequent inflammation as triggers of graft rejection was given[1]. High mobility group box 1 (HMGB1), the one of the most important damage associated molecular pattern (DAMP), was shown as an inflammatory trigger in organ transplantation and it was believed that HMGB1 inhibition reduced ischemic reperfusion injury (IRI)[2]-[4].
Aim: The aim of the study was to evaluate the relationship between the expression of HMGB-1 before and after reperfusion, severity of IRI, early allograft dysfunction (EAD) and acute rejection (AR) incidence after liver transplantation.
Materials and Methods: 68 consequent DBD adult liver transplants (LT) from standard criteria donors with static cold storage as conservation type were included in the prospective case-control study; study period: February 2013 – June 2014. Liver graft biopsies taken at procurement operation and 2h after portal reperfusion on LT were assessed: HMGB-1 and CD68+-cells expression, IRI severity, TLR-4 gene polymorphism. End points: early allograft dysfunction (EAD)[5], severe EAD (sEAD)[6], biopsy-proven acute rejection (BPAR) and graft survival were assessed according to standard criteria. Investigation was approved by local ethic committee.
Results and Discussion: Mean cold ischemia time was 441 min (370;510). The overall BPAR incidence was 19.1% (13/68), EAD incidence – 20.6% (14/68), sEAD – 10.3% (7/68). It was revealed that: more severe IRI (sever IRI vs moderate+mild IRI) was associated with larger increment of nuclear HMGB-1 expression (16% (1;24) vs 1% (-4;5), p=0.01) and with greater post reperfusion CD68+ infiltration (65 cell/mm2 (50;93) vs 42 (31;55); p=0.001). Furthermore, heterozygote in donor rs913930 TLR-4 gene (C/T vs CC+TT) were associated with bigger donor nuclear HMGB-1 expression (21% (17;29) vs 16% (10;19); p=0.018) and subsequently with higher sEAD incidence (21.4% (6/28) vs 2.5% (1/40); p=0.017). Alternatively the presence of cytoplasmic HMGB-1 expression (presence vs absence of cytoplasmic HMGB-1) in post reperfusion liver graft biopsy was marginally associated with smaller BPAR frequency (14.6% (7/48) vs 30% (6/20); p=0.1).
Conclusion: HMGB-1 – TLR-4 pathway is important pathogenic mechanism of liver graft injury during cold preservation and subsequent reperfusion. TLR-4 gene polymorphism is associated with sEAD incidence. More severe DAMP-associated preservation liver graft injury was associated with higher incidence of sEAD and lower incidence of BPAR by that proving the concept of antigen independent immune response in EAD and BPAR development after LT.

Biliary epithelial damage, regenerative capacity and local immune response after cold storage of DBD livers determine biliary complications after liver transplantation

Stefan Brunner, Henrik Junger, Hans J. Schlitt, Stefan Fichtner-Feigl.
Department of Surgery, University Medical Center Regensburg, Regensburg, Germany.

Background: The aim of this study was to examine molecular mechanisms of bile duct (BD) damage between organ retrieval and transplantation and its clinical relevance for patients.
Methods: BD samples after donor hepatectomy, cold storage and reperfusion were compared to healthy controls by H&E staining, immunohistochemistry (IH) for tight junctions (TJ), cytokeratin, e-cadherin, laminin, CD4, CD8 and CD14 and by global mRNA expression using Microarray technique. Bacterial infiltration was determined by FISH for bacterial antigens. Further, a BD damage score (BDDS) to quantify biliary epithelial injury was developed and correlated with recipient and donor data and patient outcome.
Results: Patients with major BD damage after cold storage, as quantified by the newly developed BDDS, had a significantly increased risk of biliary complications ($p<0.0001$) and graft loss ($p=0.0004$). After cold storage ($p=0.0119$) and even more after reperfusion ($P=0.0002$), epithelial damage categorized by the BDDS and by TJ architecture was markedly increased. mRNA levels of adherens-junctions ($q=0.003$) and focal-adhesion-molecules ($q=0.04$) in damaged BDs without compared to damaged BDs with biliary complications were increased reflecting enhanced regenerative capacity of the biliary epithelium in the first group. Consecutively, IH showed significantly increased cytokeratin, e-cadherin and laminin expression in this group. FISH analysis demonstrated equal distribution of bacterial infiltration of BDs, however, mRNA analysis detected induced antibacterial immune response ($q=0.00084$) and phagocytosis ($q=0.04$) in BDs with enhanced epithelial regenerative capacity corroborating with significantly increased $CD4^+$ and $CD8^+$ cell-mediated adaptive immune response.
Conclusions: In many cases, the common BD epithelium shows considerable damage after cold ischemia with further damage occurring after reperfusion. The extent of epithelial damage can be quantified by our newly developed BDDS and is a prognostic parameter for biliary complications and graft loss. Following BD damage during cold storage, functional regenerative capacity of the biliary epithelium and enhanced local adaptive antibacterial immune response are able to rescue BDs and prevent biliary complications after liver transplantation.

355.4

Importance of DNA methylation patterns and association with graft injury severity after liver transplantation

Daniel G. Maluf, Ricardo Gehrau, Valeria Mas .
Surgery, UVA, Charlottesville, VA, United States.

Background: Epigenetics modifications in the graft may impact on severity of injury and function post liver transplantation (LT). This study aimed to interrogate the effect of different graft DNA methylation patterns on gene expression profiles that associate with graft injury after LT.
Patients and Methods: The study included 22 deceased donor LT patients with severe (SI, n=11; AST>500 IU/L) and mild (MI, n=11; AST<500 IU/L) early graft injury at 1-day post-LT. Tissue biopsies were collected at pre-implantation (L1) and at post-reperfusion (L2). Genomic DNA was extracted from pre implantation biopsies; bisulfite converted and used in Infinium 450K methylation arrays. Raw data was normalized by SWAN method and analyzed with R bioconductor. Beta scores were converted to M-values. F-test was fit for significant demethylated CpG sites ($q<0.05$). Total RNA was isolated from all biopsies, labeled and used in gene expression microarrays. Probeset summaries were obtained using RMA algorithm. Unpaired ANOVA was fit for deregulated probesets ($p<0.001$, FDR <5%). Molecular pathways were evaluated by IPA tool. CpGs (Methylight) and genes (RT-PCR) were validated.
Results: There was not difference between groups in demographics, graft preservation type, and cold- and warm-ischemia times. In total, 3663 CpG sites (2574 hypomethylated; 1089 hypermethylated) were significantly demethylated and mapping within genic regions. Interestingly, 2251 CpGs (92% hypomethylated, $p<0.0001$) mapped within GC-islands located at promoter regions (1971 genes) in SI grafts. Molecular pathway analysis based on CpGs methylation identified apoptosis activation signaling (TP53, BIM, BAD, BAX, DIABLO, APAF1, CAD, FADD, CASP2, CASP3), ubiquitin protein degradation, and cell cycle regulation (Rb, p27KIP, p18INK4C, CDK, CHK1) ($p<0.0001$). Genes with multiple hypomethylated CpGs anticipated increases in liver cell death (BCL2L11, HSPD1, APP, INHA, TRIM27, BAD) and G1/S cell cycle check-point (SKP2, CDC25A, SIN3A, PA2G4). No genes were differentially expressed at pre-implantation. A unique significantly deregulated molecular signature (94 genes) correlating with CpG demethylation coincided with liver damage (KRT18), apoptosis and cell cycle regulation (PAWR, KRAS, DUSP4, PTPR3) at post-reperfusion in SI grafts. Genes were validated by RT-qPCR.
Conclusion: Hypomethylation of specific genes involved in the regulation of cell death pathways may induce increases in graft injury post-LT.

355.5

Exogenous melatonin promotes graft regeneration in small-for-size liver transplantation

Zhuolun Song, Eleonora Maurizio, Bostjan Humar, Rolf Graf, Pierre AlainClavien, Yinghua Tian.
Department of Visceral and Transplantation Surgery, University Hospital Zurich, Zurich, Switzerland.

Introduction: Live donor liver transplantation increases the liver donor pool, but it is impeded by small-for-size syndrome. Melatonin (MLT) is an endogenous hormone regulating circadian rhythm, which is a strong antioxidant in a pharmacological dose. The aim of the study is to investigate whether MLT enhances liver graft regeneration and prevents small-for-size liver graft failure in model of mouse partial liver transplantation.
Materials and Methods: Male C57BL6 mice were divided into 3 groups: (I) I/R+PH group: 60 min liver ischemia plus 2/3 hepatectomy; (II) I/R+exPH group: 60 min liver ischemia plus extended (86%) hepatectomy; (III) POLT group: arterialized 30% liver transplantation. Each group was subdivided into MLT treated and control groups. Hepatic injury was determined by AST, ALT and histology. The cytokines and histological evidence of liver regeneration were examined by PCR and immunostaining. Serum HMGB1 was measured by ELISA. Survival rate was monitored in I/R+exPH and POLT groups. In mouse primary hepatocytes culture model, hepatocytes were subjected to 4h hypoxia followed by 2h reoxygenation, AST and ALT from the supernatant as well as cytokines from hepatocytes mRNA were measured.
Results and Discussion: The group I disclosed less hepatic injury, improved hepatocyte regeneration and promoted regenerating cytokine release in MLT treated group than controls. HMGB1 was reduced significantly in mice treated by MLT. In group II, 7 day's survival rate was 0% in control mice in comparison with 50% in MLT treated mice. In POLT group, the treatment of MLT increased the survival rate of recipient mice from 0% to 57%. In vitro experiment demonstrated less injury and lower level of pro-inflammatory cytokines in MLT treated hepatocytes. The data indicated that MLT reduces liver ischemia injury and enhances graft regeneration in the setting of mouse partial liver transplantation.
Conclusion: MLT rescues small for size liver graft failure by reducing graft ischemic reperfusion injury and promoting liver regeneration. The enhanced liver graft regeneration is through up-regulated IL-6 and TNF-α by MLT.

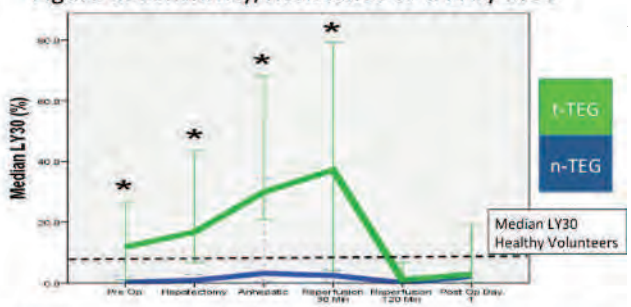
355.6

Reperfusion fibrinolysis shutdown after liver transplantation: Rationale for permissive hypocoagulability in the post-operative setting

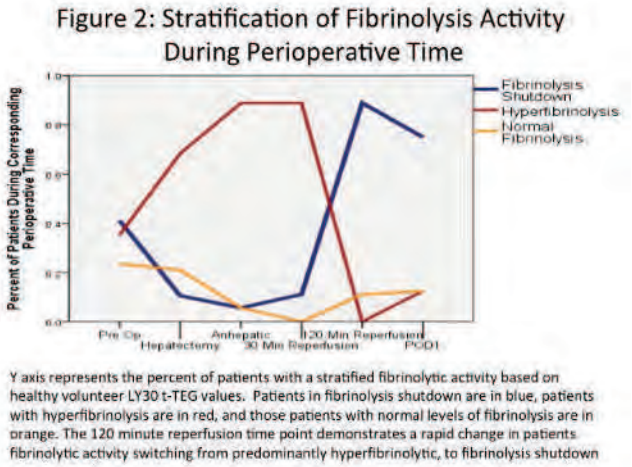
Hunter Moore, Ernest E.Moore, Michael Wachs, Igal Kam, Peter J.Lawson, Benjamin R.Huebner, Thomas Bak, Kendra Conzen, Anirban Banerjee, Christopher C.Silliman, Trevor L.Nydam.
Surgery / Transplant, University of Colorado, Aurora, United States.

Introduction: The mechanisms of post-operative thrombotic events after liver transplant remain poorly understood. Recently it has been appreciated that hypotensive trauma patients develop resistance to clot degradation (fibrinolysis shutdown) within 2 hours of resuscitation. The duration that these patients remain in fibrinolysis shutdown has been associated with thrombosis and other complications. We hypothesize that liver transplant recipients will also transition to a state of fibrinolysis resistance shortly after graft reperfusion.
Methods: Liver transplant recipients had serial blood samples analyzed with citrated native thrombelastography (n-TEG) and a modified TEG assay using tPA (t-TEG). The t-TEG was used to quantify the patient's sensitivity/resistance to fibrinolysis using the lysis at 30 minutes (LY30). Based on the LY30 distribution of 160 volunteers with t-TEG (median LY30 8.2; 25th percentile 4.8; 75th percentile 14.9) fibrinolysis activity was categorized as: fibrinolysis shutdown (<25 %), normal fibrinolysis (25%-75%), and hyperfibrinolysis (>75%). Transplant n-TEG variables were also contrasted to healthy volunteers (R time, angle, MA, LY30). Endogenous tPA levels and its inhibitor [plasminogen activator inhibitor -1 (PAI-1)] levels were measured using ELISA in stored paired patient plasma.
Results: Nineteen patients were enrolled in this study with a median MELD of 30, 37% required >10 units RBC during surgery, and the mortality rate was 5%. When contrasting paired n-TEG vs t-TEG values, the t-TEG LY30 were significantly higher from pre op until 30 minutes of graft reperfusion (all p<0.001). However, at 120 minutes post reperfusion (p=0.212) and post-operative day 1 (POD1 p=0.184), no significant differences were observed (figure 1). Fibrinolysis activity markedly changed during the perioperative period with 70% of patients remaining in fibrinolysis shutdown on POD1 (p<0.001 figure 2). POD1 platelet counts were significantly decreased compared to pre op values (60K vs 75K p=0.04) However, INR and TEG parameters (R, Angle, MA) were not significantly different (although median values pre and POD1 were all abnormal compared to healthy volunteers). Endogenous tPA levels quadrupled from pre op to anheptatic phase of surgery (2.5 to 19 ng/ml p=0.001) and returned to similar pre op levels by 120 minutes post reperfusion (3.6). Free PAI-1 activity levels tripled from pre op to POD1 (5.7 to 16.2 ng/ml P<0.001). Patients who remained in fibrinolysis shutdown on POD1 had longer post-operative

Figure 1: Sensitivity/Resistance to tPA by LY30



Y Axis represents the median LY30 and X axis represents time points during the perioperative period. The dotted line represents the median LY30 of healthy volunteers t-TEG. The green bar represents paired patients samples analyzed with the t-TEG versus n-TEG (blue). LY30 from t-TEGs were significant higher compared to n-TEG until 120 minutes post reperfusion and remained similar on POD1.



Y axis represents the percent of patients with a stratified fibrinolytic activity based on healthy volunteer LY30 t-TEG values. Patients in fibrinolysis shutdown are in blue, patients with hyperfibrinolysis are in red, and those patients with normal levels of fibrinolysis are in orange. The 120 minute reperfusion time point demonstrates a rapid change in patients fibrinolytic activity switching from predominantly hyperfibrinolytic, to fibrinolysis shutdown

Conclusion: Reperfusion fibrinolysis shutdown occurs in the majority of liver transplant patients within 2 hours of graft reperfusion and associated with high levels of PAI-1. Patients who remain in shutdown appear to be at a higher risk of post-operative complications. Resuscitating these patients to a permissive hypocoagulability state post operatively is logical, as over correction to hypercoagulability can result in intravascular thromboses, and the majority of these patients lack the endogenous capacity to clear these clots.

The effect of nafamostat mesilate to minimize ischemic-reperfusion injury of the liver following liver transplantation : a single arm pilot study

Young-Dong Yu, Dong-Sik Kim, Sung-Won Jung, Jae-Hyun Han. Department of Surgery, Division of HBP Surgery and Liver Transplantation, Korea University Medical College, Seoul, Korea.

Background: Ischemia-reperfusion injury in the liver, a major complication of hemorrhagic shock, resection and transplantation, is a dynamic process that involves the two interrelated phases of local ischemic insult and inflammation-mediated reperfusion injury. Nafamostat mesilate inhibits various serine proteases generated during inflammation, coagulation and fibrinolysis cascades and is used for the treatment of pancreatitis and disseminated intravascular coagulation. Although its role in attenuating ischemic reperfusion injury has been studied in animal models, there are few reports regarding its effect on ischemic-reperfusion injury in human liver transplantation. The aim of this study was to examine the effect of nafamostat mesilate to minimize ischemic-reperfusion injury of the liver following liver transplantation.

Methods: Patients that were enrolled in this study underwent additional rinsing with a solution consisting of Nafamostat mesilate following graft perfusion using standard HTK solution. Blood samples were taken from the recipient just before portal vein transection during recipient hepatectomy and 1 hour, 24 hours after reperfusion. Samples were also taken on third and seventh postoperative day. Liver function tests of the study group was compared to a control group match-paired for sex, age, type of transplantation and fatty change of the graft. The levels of TNF, IL-6 and IL-1 were also examined in the study group.

Results: Ten patients were enrolled in this study. The male to female ratio was 7 to 3. The mean age was 55 years. The average MELD score of the recipient was 20.9. The most common indication for transplantation was hepatocellular carcinoma and liver cirrhosis due to hepatitis B. Most patients received emergency deceased donor liver transplantation. The mean cold and warm ischemic time was 373 and 35 minutes, respectively. Although not statistically significant, the mean aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels on the first and third postoperative day were lower in the study group. In addition the mean peak AST and ALT levels were lower in the study group. There were no significant differences in serum bilirubin or prothrombin time.

Conclusion: Although further studies are needed, Nafamostat mesilate showed promise in decreasing ischemic-reperfusion injury and might be useful when using marginal grafts for liver transplantation.

355.8

Impact of a newly developed solution containing artificial oxygen carrier hemoglobin vesicles under subnormothermic conditions with machine perfusion preservation for DCD liver grafts in pigs

Naoto Matsuno[1], Lingtong Meng[1], Tomohiro Suzuki[2], Jo Yamamoto[2], Hiroshi Azuma[3], Yuji Nishikawa[4], Hiromizu Sakai[5], Hiromichi Obara[6], Hiroyuki Furukawa[1].
[1]Surgery and Transplantation, Asahikawa Medical University, Asahikawa, Japan; [2]Pharmacy, Asahikawa Medical University, Asahikawa, Japan; [3]Pediatrics, Asahikawa Medical University, Asahikawa, Japan; [4]Division of Tumor Pathology, Department of Pathology, Asahikawa Medical University, Asahikawa, Japan; [5]Biochemistry, Nara Medical University, Nara, Japan; [6]Mechanical Engineering, Tokyo Metropolitan University , Tokyo, Japan.

Utilization of grafts from donors after cardiac death (DCD) would greatly contribute to the expansion of the donor organ pool. However, the implementation of such a strategy requires the development of novel preservation methods to recover from changes due to warm ischemia. To assess the effects of cell-free oxygen carrier under subnormothermic conditions for porcine livers procured after 60 minutes of warm ischemic time (WIT) were perfused and preserved.
Materials and Methods: Porcine livers were perfused with MP system developed by our group. Liver was perfused with modify UW-gluconate(UW-G) in Group 1 and UW-G containing with artificial oxygen carriers andamino solution(JPS) as in Group 2. All liver grafts were perfused under subnormothermic condition for 4 hours.
Results: A hepatic artery pressure during perfusion was smoothly came down in Group2 rather than in Group1. Lactate level in perfusate was maintained in low level (<3.0mnol/L)I in Group 2. No decrease of PH and no increase of wet tissue weight were seen in Group 2. The AST and LDH levels in perfusate were significantly higher in Group 1. .Histologically, enlarged Disses space was seen in Group 1.
Conclusion: Our perfusion solution containing with artificial oxygen carrying hemoglobin vesicles is expected to facilitate the recovery and resuscitating the function of DCD liver grafts.

355.9

The comparison with donation after cardiac death liver grafts by oxygenated subnormothermic with rewarming machine perfusion in pigs

Lingtong Meng[1], Naoto Matsuno[1], Mariko Furukori[1], Hiroyuki Takahashi[1], Masahiro Hagiwara[1], Tatsuya Shonaka[1], Koji Imai[1], Noriyuki Morito[2], Masamichi Obara[2], Yuji Nishikawa[3], Hiroyuki Furukawa[1].
[1]Surgery and Transplantation, Asahikawa Medical University, Asahikawa, Japan; [2]Mechanical Engineering, Tokyo Metropolitan University , Tokyo, Japan; [3]Division of Tumor Pathology, Department of Pathology, Asahikawa Medical University, Asahikawa, Japan.

Background: The shortage of donor organs would be improved through the use of grafts from donors after cardiac death (DCD). However, the implementation of such a strategy requires the development of novel preservation methods to recover from changes due to warm ischemia. The aim of this study was to evaluate the effectiveness of subnormothermic machine perfusion preservation with rewarming for porcine DCD liver grafts for transplantation.
Methods: Porcine livers were perfused with newly developed machine perfusion (MP) system. The livers were perfused for 4 hours with modified UW-gluconate solution. Group 1: Grafts were preserved with WIT 0 min and simple cold storage (CS). Group 2: Grafts were preserved with WIT 0 min and hypothermic MP (HMP). Group 3: Grafts were preserved with WIT 60 min and CS. Group 4: Grafts were preserved with WIT 60 min and HMP. Group 5: Grafts were preserved with WIT 60 min and rewarming up to 25˚C by MP (RMP). Each graft was preserved for 4 hours. Modified UW-gluconate solution was used.
Results: The aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) in the effluent maintained at lower level in Group 5 compared to Group 4. However, tissue ATP levels maintained in low in Group 3, Group 4 and Group 5. Portal vein pressure during perfusion was lower in Group 4, compared to Group 5. Histologically, the steatotic change and enlarged Disse's space was seen in group 4. Tissue cytokine mRNA level IL-1β, IFN-γ, iNos, and IL-4 were significantly lower in group 5 than group 4.
Conclusion: Potentially, subnormothermic preservation with rewarming is expected to help the recovery of function for DCD liver grafts.

Donor DCs in chimeric vascularized thymic grafts, but not antigen-presenting host DCs, play an essential role in the induction of tolerance of solid organs in a preclinical large animal model

Kazuhiko Yamada[1,2], Tatsu Tanabe[1,2], Mitsuhiro Sekijima[2,3], Akihiro Kawai[2,3], Vincenzo Villani[2], Masayuki Tasaki[2,3], Akira Shimizu[2,3], David Sachs[1,2].
[1]Columbia Center for Translational Research/Surgery, Columbia University Medical Center, New York, United States;
[2]Transplantation Biology Research Center/Center for Transplantation Science, Massachusetts General Hospital, Boston, United States;
[3]Center for Advanced Biomedical Science and Swine Research , Kagoshima University, Kagoshima, Japan.

Background and Aim of the Study: We have demonstrated that host thymus plays an important role in transplantation tolerance. Euthymic animals accepted a class I mismatched kidney with 12 days of CyA while thymectomized hosts did not in an MHC inbred miniature swine model. Furthermore, we have established technique of isolated vascularized thymic lobe transplantation (VTL) that allows us to study thymic dependent tolerance without changes in thymic structure due to ischemia following thymic transplantation. Utilizing this novel technique, we have reported VTL induced transplant tolerance across allogeneic barriers in miniature swine. In this study, we investigated the mechanisms of thymic dependent tolerance utilizing the VTL technique.
Materials and Methods: MHC-inbred swine were used and allogeneic tolerance was assessed across a class I mismatched barrier using (1) donor-antigen presenting thymi (Donor Ag-VTL) and (2) chimeric thymi containing donor-type dendritic cells (Donor DC-VTL). Donor Ag-VTLs were exposed to donor antigens in long-term tolerant recipients of class I mismatched kidneys. Donor DC-VTLs were prepared by thymic graft parking such that the VTL contained donor DCs at the corticomedular junction but all of the epithelial cells remained recipient-type. Donor Ag-VTLs (Group 1. n=3) or Donor DC-VTLs (Group 2. n=5) were transplanted across class I mismatched barriers with 28 days of FK506. Donor Ag or DCs SLA matched kidneys were transplanted 2 months later without immunosuppression to assess the induction of tolerance.
Results: All eight recipients in both Groups 1 and 2 had donor specific unresponsiveness by in vitro CML assay. However, striking difference was seen following donor-type kidney transplantation without immunosuppression. All recipients of Donor Ag-VTLs rejected donor MHC matched kidneys at day 7, 8 or 9. In contrast, four of five recipients of DC-VTL subsequently accepted the DC matched kidneys without immunosuppression until the termination of the experiment (POD 287, 223, 215 and 187, respectively). One animal lost renal function on POD92, however did not show evidence of donor responsiveness in vitro by CML or development of anti-donor antibodies by FACS. In addition, the results of CD25 depleted CML assays suggested that CD8 T cells were being deleted by donor thymic DCs.
Conclusions: The presence of donor DCs plays an essential role in the induction of tolerance in this model. To our knowledge, this is the first report to indicate that donor DCs induced tolerance of kidneys without immunosuppression in a large animal model.

356.2

The combined effect of stem cell factor and granulocyte macrophage colony-stimulating factor administration after 90% partial hepatectomy in rats

Seung Duk Lee, Yoon Sung Suh, Hyerim Byeon.
Center for Liver Cancer, National Cancer Center, Republic of Korea, Goyang-si, Korea.

Background: After major hepatectomy or liver transplantation, the ability of the liver to regenerate has been used to prevent postoperative hepatic failure. Stem cell factor (SCF) and granulocyte macrophage colony-stimulating factor (GM-CSF) are known to play important roles in liver regeneration with synergistic effects in a previous in vitro study. The purpose of this study was to identify the impact of exogenous SCF and GM-CSF administration after 90% major hepatectomy in rats.
Methods: Sprague Dawley rats underwent 90% major hepatectomy using a bile duct-sparing portal pedicle ligation technique under microscopy. The rats were divided into two groups: group 1 (phosphate-buffered saline) and group 2 (SCF+GM-CSF treatment, each 25 mcg/kg). Treatment was administrated immediately after operation through the inferior vena cava. Liver regeneration capacity and expression of cytokines and their downstream signaling molecules were evaluated at postoperative day 1, 2, 4, and 7.

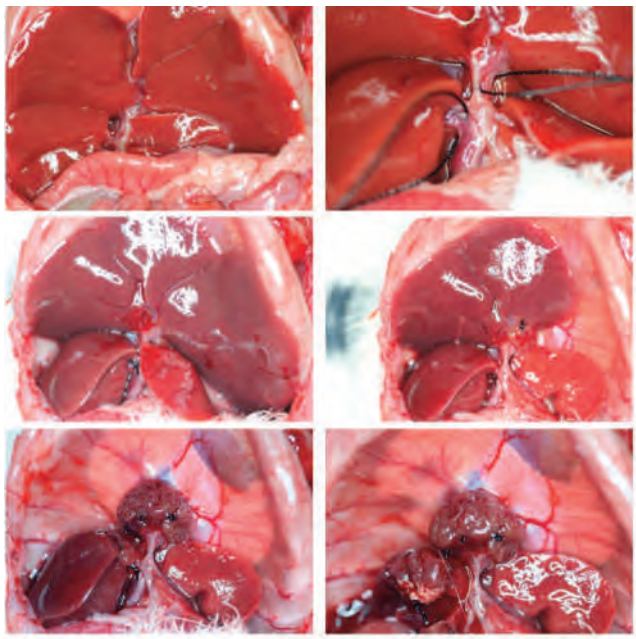

Fig. 1. Surgical technique of 90% partial hepatectomy (PH)
The 90% PH was performed to dissect hilum under microscopy and divide bile duct and portal vein/hepatic artery pedicle entering median/left lateral lobe and right lateral lobe. The pedicles of the lobes were divided into two to three parts and ligated by piercing before the lobes were resected.

Results: The survival rate after 90% hepatectomy in rats using this technique were increased to 95% compared with 55% with conventional parenchymal ligation technique ($p = 0.004$). The combination effect of SCF and GM-CSF was evaluated in in vitro study. Group 2 exhibited a significantly increased liver regeneration index at early period after hepatectomy compared to group 1 (day 2: 287.5 ± 19.6 vs. 513.9 ± 67.1, $p = 0.025$ and day 4: 647.6 ± 108.8 vs. 941.7 ± 53.9, $p = 0.046$). Furthermore, serum liver enzyme levels including total bilirubin, aspartate aminotransferase, and alanine aminotransferase, were significantly lower in group 2 than in group 1 on postoperative days. The expression of Ki-67 and cyclin D1 were significantly higher

in group 2 than in group 1 on postoperative days. Group 2 displayed significant increases of interleukin (IL)-6 and transforming growth factor (TGF)-β expression within 24 h after hepatectomy. Especially, C-X-C motif chemokine 12 (CXCL12)/C-X-C chemokine receptor type 4 (CXCR4) and matrix metalloproteinases 2 and 9 levels in the liver tissue of group 2 were also significantly upregulated according to quantitative polymerase chain reaction on postoperative days.
Conclusions: Our data suggest that the administration of SCF+GM-CSF after major hepatectomy can enhance liver regeneration by liver cell proliferation and mobilization of stem cell modulating IL-6/TGF-β and CXCL12/CXCR4 pathway as well as by matrix remodeling. These findings suggest the possibility of therapeutic treatment using a combination of SCF and GM-CSF in the clinical setting to promote liver regeneration after extreme hepatectomy.

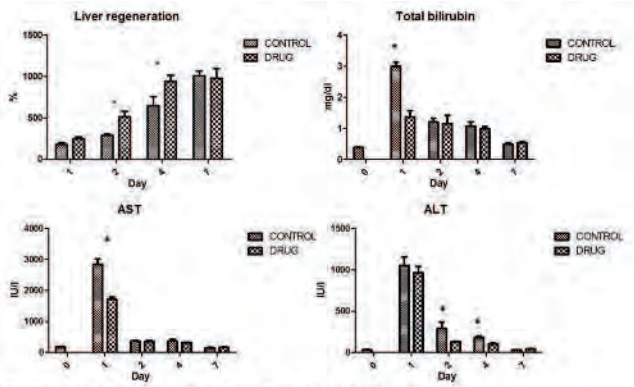

Fig. 3. The results of liver regeneration index and liver function tests between two groups.
The liver regeneration index was statistically significantly increased in SCF+GM-CSF group at postoperative days 2 and 4 (day 2: 287.5 ± 19.6 vs. 513.9 ± 67.1, $p = 0.025$; day 4: 647.6 ± 108.8 vs. 941.7 ± 53.9, $p = 0.046$). Liver enzyme levels including total bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) at baseline and on postoperative days 1, 2, 4, and 7 between control and SCF+GM-CSF group (*: $p < 0.05$).

Interleukin-34 is a Treg-specific cytokine and mediates transplant tolerance

Séverine Bézie, Antoine Freuchet, Véronique Daguin, Claire Usal, Ignacio Anegon, Carole Guillonneau.
ITUN, INSERM UMR1064, Nantes , France.

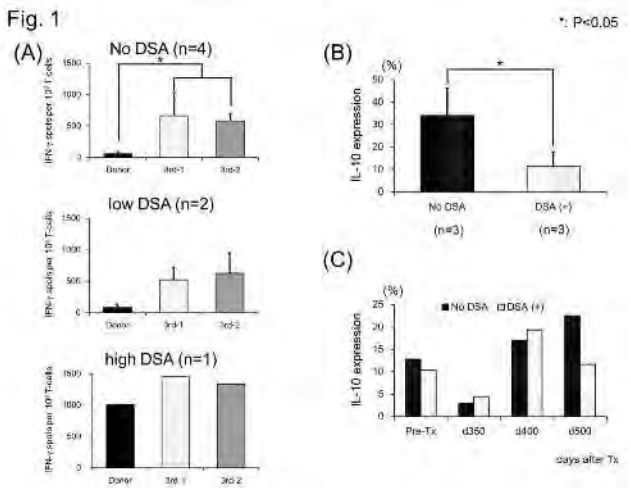
Introduction: Cytokines are powerful tools to regulate immune responses. In transplantation, it is still important to identify new specific and powerful mediators of immune tolerance. Interleukin-34 (IL-34) is a cytokine that binds to CSF1R (the MCSF receptor) and PTPz, and involved in differentiation and survival of myeloid cells. The recent correlation of IL-34 expression level with metastasis development and viral infection permission suggests immunoregulatory properties, but no link with T cell biology nor transplantation has ever been reported.
Materials and Methods: Lew-1A rats were treated with $1x10^{12}$ vg AAVIL-34, 30 days later they were grafted with an allogeneic Lew-1W heart and treated with 0.4mg/day/kg of rapamycin for 10 days. Recipients to cardiac allograft were irradiated at 4.5 Gy for adoptive cell transfers. PBMCs were obtained from blood of healthy volunteers. Monocytes were sorted on CD14/CD16 expression by FACS Aria, cultured for 6 days with 50ng/ml IL-34, and then cultured 14 days with Tregs. NSG mice were infused with human PBMCs and treated with 0.4mg/kg/2days human IL-34 protein or co-infused with expanded Tregs for xenogeneic GVH reaction studies.
Results: We showed that the cytokine IL-34 was expressed by rodent $CD8^+CD45RC^{low}$Tregs and human $FOXP3^+CD45RC^{low}CD8^+$ and $CD4^+$ Tregs. Furthermore, we observed a correlation of IL-34 expression level with the suppressive activity of Tregs and the tolerant status of rat cardiac allograft recipients. Indeed, IL-34 was involved in the suppressive function of both $CD8^+$ and $CD4^+$Tregs and markedly inhibited alloreactive immune responses. In addition, by using a rat IL-34 recombinant AAV vector, we demonstrated that rat IL-34 overexpression associated with a suboptimal dose of rapamycin potently induced tolerance to cardiac allograft in rat with a total inhibition of alloantibody production. In this model, IL-34 promoted allograft tolerance through induction of $CD8^+$ and $CD4^+$ Tregs. Moreover, these Tregs were capable of serial tolerance induction through modulation of macrophages that migrate early into the graft. Translationally, we demonstrated that human IL-34 protein administration into NSG mice infused with human PBMCs efficiently delayed the xenogeneic GVH development. In vitro, we showed that human macrophages cultured in the presence of IL-34 more efficiently expanded $CD8^+$ and $CD4^+$ $FOXP3^+$ Tregs compared to allogeneic APCs or anti-CD3/CD28, with a potentiation of suppressive activity since lower ratios of IL-34-expanded Tregs were sufficient to delay GVH development in humanized mice compared to polyclonally expanded Tregs.
Conclusions: We revealed that IL-34 is a suppressive Treg–specific cytokine that could be considered as a biomarker of immune status of patients. Moreover, we demonstrated the clinical relevance of IL-34 in transplantation as a potent tolerance inducer and as a promising candidate for cell therapy through efficient expansion and potentiation of Tregs.

356.4

IL-10 expression of in vitro activated B cells as a biomarker for B cell tolerance

Tetsu Oura, Kiyohiko Hotta, Benedict A Cosimi, Tatsuo Kawai.
Deaprtment of Surgery, Center for Transplantation Sciences, Massachusetts General Hospital, Boston, MA, United States.

Background: A significant role for regulatory B cell has been suggested in kidney transplant recipients who achieved operational tolerance while receiving conventional immunosuppression. We studied T and B cell responses in recipients in whom tolerance induction was attempted via HLA-mismatched combined kidney and bone marrow transplantation (CKBMT).
Materials and Methods: Five CKBMT recipients who achieved long-term immunosuppression-free survival (>5 years) were retrospectively studied. Two recent CKBMT recipients were also prospectively studied. T cell responses were determined by IFN-g ELIspot assay using irradiated PBMCs (direct) or lysates (indirect). B cell responses were evaluated by IL-10 expression of naïve B cells after stimulation with CD40L/IL-2/CpG/F(ab)'.
Results: Donor specific antibodies (DSA) were never detected in four recipients but three developed low (n=2) or high titer (n=1) DSA. Nevertheless, except for the recipient with high DSA titers, all recipients showed donor-specific hyporesponsiveness in direct IFN-g ELIspot (Fig. 1A). No anti-donor responses were detected by indirect IFN-g ELIspot. In contrast, significantly higher IL-10 expression was observed on in vitro activated B-cells obtained from long-term recipients with no DSA than from recipients with DSA (Fig. 1B). Similar observations were made in the two prospectively followed recipients, one of whom achieved tolerance without DSA while the other developed subclinical rejection and low titer DSA, first detected on day 518, during weaning of his immunosuppression. Although both recipients showed donor-specific hyporesponsiveness on direct IFN-g ELIspot assay, IL-10 expression of in vitro activated B-cells was noted to fall in the rejecting recipient. In contrast, IL-10 expression remained high in recipient who achieved tolerance (Fig. 1C).
Conclusion: Although T cell response assay failed to differentiate "Tolerant" from "non-Tolerant" recipients, IL-10 expression of in vitro activated B-cells appear to be a useful biomarker for B cell tolerance. Studies to identify the B cell specific subsets responsible for the higher IL-10 expression are currently underway.

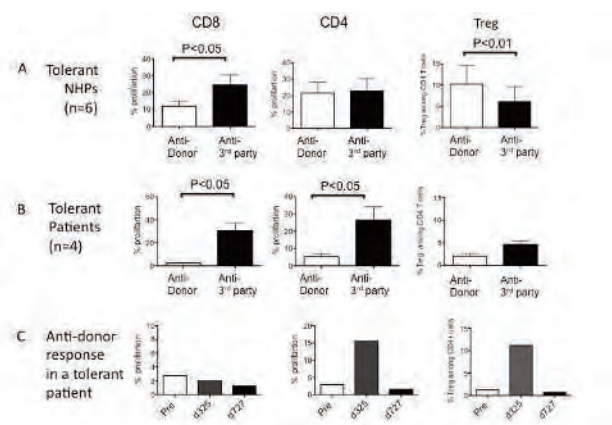


356.5

Immune tolerance monitoring in renal allograft tolerance induced by transient mixed chimerism in nonhuman primates and humans

Kiyohiko Hotta, Tetsu Oura, Kerry A.Crisalli, David H.Sachs, Benedict Cosimi, Tatsuo Kawai.
Center for Transplantation Science, Massachusetts General Hospital, Boston, United States.

Background: Successful induction of allograft tolerance in MHC-mismatched kidney transplantation has been achieved after induction of transient chimerism in both nonhuman primates (NHP) and humans. However, development of a reliable assay to monitor tolerance is critically important to safely taper immunosuppression.
Method: Six NHP and four human recipients of combined kidney and bone marrow transplantation (CKBMT) who achieved long-term renal allograft survival without immunosuppression were studied. Differential T-cell responses were evaluated by CFSE-MLR co-stained with for CD4, CD8 and Foxp3.
Results: NHP tolerant recipients evaluated at 2.1±0.9 years after transplantation showed donor- specific CD8+ T cell hypo-responsiveness but displayed vigorous anti-donor CD4+ T cell proliferation. Interestingly, among these proliferated CD4+ cells, significantly higher Foxp3+ cell proliferation was observed against donor, compareding with the third party stimulators (Fig. A). In contrast, consistently high anti-donor CD8+ and CD4+ T cell responses with limited Treg expansion were observed in rejectors (data not shown). In humans, although assays were performed at significantly markedly later time points (4.7±1.8 years), tolerant patients displayed more significant much greater loss of anti-donor CD8+ and CD4+ T cells responses. However, unlike NHPs, Treg expansion was not significant ands entire CD4+ T cell responses were limited (Fig. B). Finally, we prospectively monitored T cell responses in one recent human CKBMT recipient who achieved renal allograft tolerance. Although anti-donor CD8+ T cell responses gradually disappeared, significant CD4+ responses and Treg expansion were observed at day 325 as observed in most NHP recipients. However, anti-donor Treg responses eventually disappeared by day 727, as observed in other human tolerant recipients (Fig. C).
Conclusion: Regulatory mechanisms were suggested in NHPs at 2 years. Although tested at significantly later time point, mMore robust loss of anti-donor T cell responses werase observed in human tolerant recipients, although these recipients were tested at later time points than the NHP.



356.6

Recently alloactivated CD4+CD8-CD25+Treg express CD8 and are the antigen-specific Treg

Bruce M. Hall[1], Catherine M. Robinson[1], Paul Wilcox[3], Nirupama D.Verma[1], Giang T. Tran[1], Nicole Carter[1], Rochelle A. Boyd[1], Suzanne J. Hodgkinson[1,2].
[1]Immune Tolerance Group, UNSW Australia, Sydney, Australia; [2]Neurology, Liverpool Hospital, Sydney, Australia; [3]Medicine, University of Sydney, Sydney, Australia.

Aim: Transplant tolerance induction requires CD4+CD25+FOXP3+Treg known as thymic Treg (tTreg). Expanding non antigen-specific tTreg for therapy requires impossibly large numbers to induce tolerance. Naïve tTreg with specific TCR for donor can be induced and expanded in vitro, into more potent antigen-specific Treg that could effect tolerance with smaller numbers of cells. After culture of naïve tTreg with alloantigen and IL-2, there is induction of the IFN-gamma receptor (IFNGR) and IL-12 receptor beta2. We called these T suppressor 1 (Ts1) cells. We propose that in the cultures with IL-2 and alloantigen, there are two processes for expansion of tTreg. One, there is polyclonal expansion of tTreg induced by IL-2 that increases the number of tTreg. Second, the small proportion of tTreg with receptor for the specific alloantigens are activated through TCR and expand the antigen-specific activated Treg. In this study we examined if there were phenotypic changes that may identify the antigen-specific Treg.
Methods: Naïve CD4+CD25+Treg from DA rats were cultured with stimulator cells from PVG rats and IL-2 for 3-4 days to induce Ts1 cells. 10-30% of cultured cells expressed CD8, whereas starting population had <1% CD8+ cells. We compared the function of the CD4+CD8+CD25+T cells to the CD4+CD8-CD25-T cells in vitro and in vivo.
Results: Using RT-PCR we examined for differences in the CD8+ and CD8- subpopulation. The increase in IFNGR and IL-12Rb2 that characterizes Ts1 cells was mainly in the CD8+fraction. Further the CD8+ fraction had a marked increase in IRF4, a transcription factor induced by TCR activation. This suggested the antigen specific Treg were induced to express CD8.
The CD8+ fraction had increased suppression in MLC to PVG at 1:1012, and to Lewis at 1:32. The CD4+CD8-FOXP3+T cells had no enhanced suppression to PVG. The unfractionated population suppresses in MLC at 1:32-1:64. In our adoptive transfer assay, IL-2 and alloantigen activated Treg suppress rejection and induce tolerance at 1:10, whereas removal of the CD8+ cells removes their capacity to induce tolerance, suggesting the tolerance is mediated by the CD8+ fraction.
To examine if CD4+CD8+CD25+T cells are induced in vivo, DA rats rejecting PVG grafts or treated to induce tolerance were examined. In these animals 10 days after transplantation, 12-18% of CD4+CD25+T cells expressed CD8, whereas in naïve rats <5% express CD8. These CD25+T cells from both rejecting and tolerance induced rats suppressed MLC to PVG at 1:256-1:512, and to Lewis at 1:16-1:32, showing specific suppression. The enriched CD4+CD8+CD25+T cell suppressed to PVG at 1:1000 in MLC but did not suppress responses to third party Lewis. The CD8- fraction did not suppress.
Conclusion: Expression of CD8 on CD4+CD8-CD25+FOXP3+T cells is a marker of Treg that have been activated by specific antigen. This marker early after tTreg activation may be used to identify and further expand antigen-specific Treg. This de-differentiation to a dual expressing CD4+CD8+T cell may facilitate selection of Treg with TCR that recognize antigen expressed by either class I or class II MHC. Such dual expressing CD4+CD8+ T cells have been observed in man after culture with IL-2.

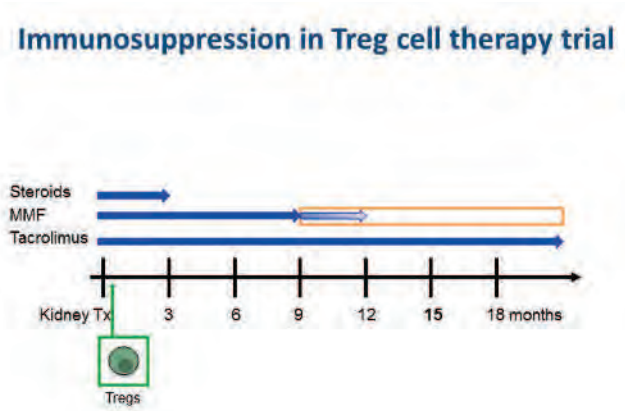
The UK ONE Study trial: safety and feasibility of regulatory T (Treg) cell therapy in renal transplantation

Andrew R. Bushell[1], Jeroen van der Net[1,2], David S. Game[3], Rachel Hilton[3], Sarah J.Thirkell[4], Joanna Hester[1], Katie Lowe[4], Laura Fry[4], Peter J. Friend[2], Edward Geissler[5], Kathryn J. Wood[1], Paul N. Harden[2], Giovanna Lombardi[4].
[1]Transplantation Research Immunology Group, Nuffield Department of Surgical Sciences, University of Oxford, Oxford, United Kingdom; [2]Oxford Transplant Centre, Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom; [3]Nephrology and Transplantation, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; [4]Immunoregulation Laboratory, MRC Centre for Transplantation, King's College London, Guy's Hospital, London, United Kingdom; [5]Department of Surgery, University Hospital Regensburg, University of Regensburg, Regensburg, Germany.

Introduction: The UK ONE Study trial investigates the safety and feasibility of regulatory T (Treg) cell therapy in renal transplantation.
Materials and Methods: Eleven (9m;2f) living donor renal transplant recipients (RTR), median age 42 (28-71) years, were enrolled and received Treg cell infusions. 350 ml whole blood or 55 ml of leukapheresis product was obtained 6-10 weeks before transplant. Treg were enriched by CD25 positive selection combined with CD8 negative selection and then expanded by stimulation with CD3/CD28 beads + IL-2 in the presence of Rapamycin at the GMP facility GMP facility at Guy's Hospital, London. Final cell products were cryopreserved at the specified dose and delivered to either the Oxford Transplant Centre in a dry shipper (-190ºC) or to The Clinical Research Facility at Guy's Hospital. 5 days after transplantation; 2 ml cell product was thawed, suspended in 5% HSA, and administered over 30 minutes as an IV infusion. A dose-escalation of three participants at each of 1x10E6, 3x10E6, 6x10E6 and 10x10E6 cells/kg was performed. Immunosuppression comprised Mycophenolate Mofetil, Tacrolimus and Prednisolone. No induction therapy was given (Figure 1).



Results and Discussion: No cell-infusion-related adverse events were noted. During a median follow-up of 10 (1-15) months, no biopsy-proven rejection episodes were observed. All patients have stable transplant function (median latest serum creatinine of 128 (90-176) µmol/l).
Conclusion: This study reports the outcome of the first eleven RTR to receive expanded Treg in the UK. The data confirm the feasibility and safety of Treg infusion in RTR to a dose of 10x10E6 cells per kg. These results demonstrate the feasibility of Treg therapy in solid organ transplantation, and establish the need for future trials investigating the efficacy of Treg therapy in renal transplantation.

Combination of veto cell transfer and iNKT cell therapy establishes complete hematopoietic chimerism in non-myeloablative BMT recipients

Toshihito Hirai[1], Rumi Ishii[1], Yusuyukiu Ishii[2], Masayoshi Okumi[1], Kazunari Tanabe[1].
[1]Department of Urology, Tokyo Women's Medical University, Tokyo, Japan; [2]Laboratory for Vaccine Design, RIKEN IMS-RCAI, Yokohama, Japan.

Hematopoietic chimerism after non-myeloablative bone marrow transplantation (nmBMT) has been found beneficial for establishment of transplant tolerance. Since bone marrow cells (BMCs) are endowed with "veto" activity, reduction in the number of transferred BMCs usually results in engraftment failure in nmBMT. We previously reported that BM engraftment could be promoted by (1) enhancing Treg activity via iNKT cell stimulation with a liposomal α-galactosylceramide (lipo-aGC), and (2) inducing donor-specific peripheral deletion with CD40/CD40L blockade (MR1). Here, we implemented a 3rd strategy: additional transfer of donor-derived T cells as veto cells to facilitate BM engraftment. 3 Gy-irradiated BALB/c ($H2^d$) recipient mice were administered B6 ($H2^b$) BMCs (5×10^6) followed by lipo-aGC plus MR1. On the following day, skin grafts from B6 and C3H ($H2^k$) mice were simultaneously transplanted on the recipient mice. When this clinically practical number of BMCs was used, all mice rejected both B6 and C3H grafts. However, when 5×10^5 splenic T cells obtained from an $H2^{b+}$GFP-Tg donor were additionally administered, complete chimerism was established in the mice (fig 1) and they accepted the skin allograft permanently in an $H2^b$-specific manner. Only $H2^{b+}CD8^+$T cells showed this veto effect, whereas transfer of $H2^{b+}CD4^+$T cells or 3rd party T cells did not facilitate BM engraftment. Concordantly, early expansion of $GFP^+CD44^{hi}CD62L^{lo}$effector $CD8^+$T cells was observed in many lymphoid organs, including the BM and thymus. BM-derived $H2b^+GFP^-$T cells immediately regenerated thereafter and had completely replaced GFP^+T cells until day 60. Therefore, complete chimeric mice did not show GvHD physically and pathologically. Lack of host reactivity was also confirmed in an in vitro proliferation assay. The mice treated with lipo-aGC or MR1 alone rejected BM and skin grafts despite T cell transfer (fig 2), suggesting that Treg cells, peripheral deletion, and veto T cells act in concert for establishing tolerance in nmBMT recipients.

Natural Killer cells demonstrate functional and receptor diversity in response to alloantigen

Olivia Hatton[2,3], Todd Shawler[2], Catherine Blish[1,3], Olivia M. Martinez[2,3], Sheri M. Krams[2,3].
[1]Department of Medicine, Stanford University School of Medicine, Stanford, CA, United States; [2]Department of Surgery, Division of Abdominal Transplantation, Stanford University School of Medicine, Stanford, CA, United States; [3]Stanford Immunology, Stanford University School of Medicine, Stanford, CA, United States.

Natural killer (NK) cells play an important role in the first-line defense against tumor and virus-infected cells. Although "missing-self" suggests NK cells would target foreign organ allografts, the prevailing dogma has been that NK cells are not important in the rejection of solid organ allografts. However, studies now suggest NK cells participate in both acute and chronic rejection while paradoxically also facilitating tolerance to an allograft. In clinical studies, however, a clear relationship between predicted NK cell alloreactivity and graft survival was not observed suggesting NK cell function in response to alloantigen is complex. NK cell activity is tightly regulated by a repertoire of inhibitory and activating receptors. The goal of this study were: 1) to determine if NK cells recognize and respond to allogeneic targets, and 2) establish the diversity of NK receptors utilized in the alloimmune response.

To assess the ability of NK cells to recognize and respond to allogeneic targets, we generated B lymphoblastoid cell lines (LCL), from a cohort (n=10) of healthy donors. Primary human NK cells ($CD3^-CD14^-CD19^-CD56^+$) from the same cohort, were isolated by negative selection, and co-cultured with autologous (control) or allogeneic LCLs. NK cells were then assayed by flow cytometry for the degranulation protein CD107a, the NK cell maturation marker CD57, the NK cell receptors NKG2A, NKG2C, NKG2D, 2B4, and CD16, and the cytokine IFNγ.

NK cells from nine of 10 donors specifically recognized and responded to the panel of allogeneic LCLs and this was not specifically correlated to HLA and/or KIR ligand mismatches. NK cells from seven donors showed both cytolytic and IFNγ responses whereas the other 2 donors had either a cytolytic or IFNγ response. Visualization of the frequencies of 64 different NK receptor combinations on NK cells co-cultured with allogeneic LCL from each of the 10 donors indicate that 2B4 and NKG2D were highly expressed (>90%) on NK cells that produced IFNγ, CD107a or were polyfunctional ($IFN\text{-}\gamma^+$, $CD107a^+$) whereas expression of the activating receptor, NKG2C was generally absent. Variable expression of CD16, CD57, and the inhibitory receptor, NKG2A was observed on alloresponsive NK cells.

Our study, using a multi-parameter approach to examine NK cells suggests diversity in the NK receptors responding to alloantigen. These findings may provide insight into the varied role of NK cells in alloimmunity and will lead to novel strategies to prevent graft rejection and promote tolerance to an allograft.

357.1

Cell-free mitochondrial DNA activates DCs in an age-dependent fashion and compromises the survival of older grafts

Midas Seyda[1,2], Hong M.Li[1], Guangxiang Liu[1], Markus Quante[1], Hirofumi Uehara[1], Jeroen M.Schuitenmaker[1], Abdala Elkhal[1], Stefan G.Tullius[1].
[1]Division of Transplant Surgery and Transplant Surgery Research Laboratory, Brigham and Women's Hospital/Harvard Medical School, Boston, MA, United States; [2]Institute of Transplant Immunology, IFB-Tx, Hannover Medical School, Hannover, Germany.

The world population is aging at a dramatic pace and the need for organ transplantation has, at least in part, been compensated by the utilization of older donor organs. We submit that age-dependent immunogenicity in addition to injury and repair will impact alloimmunity and transplant outcomes. Following ischemia and reperfusion injury (IRI), cell-free DNA is shed into the circulation potentially impacting pro-inflammatory responses via toll-like receptors (TLRs) of primarily dendritic cells (DCs) and macrophages. While cell-free DNA has very recently been implicated as an emerging biomarker in transplantation, we tested the impact of cell-free mitochondrial DNA (mtDNA) in DC activation and graft rejection in an age-dependent fashion.
Circulating mtDNA levels were tested by quantitative PCR in old and young mice. In addition, DC activation was characterized by flow cytometry. IRI was performed by bilateral clamping of the renal pedicles for 23 minutes. Sorted old or young CD11b+ CD11c+ DCs were adoptively transferred into young DBA/2J cardiac allograft recipients to determine in-vivo consequences and subsequently received young or old cardiac allografts.
DC activation was associated with highly elevated levels of circulating cell-free mtDNA in naïve old mice. In sharp contrast, young animals had no detectable mtDNA levels. Strikingly, following renal IRI the circulating mtDNA proportion of total cell-free DNA was similarly elevated in old mice. In vitro, DCs demonstrated an upregulation of CD40 and CD80, two costimulatory surface molecules involved in T cell activation when co-cultured with cell-free plasma DNA of old animals. Moreover, DCs cultured in presence of isolated mtDNA were characterized by an upregulation of CD40 that was dose dependent. Notably, the addition of a TLR9 antagonist abrogated the upregulation of co-stimulatory molecules on DCs. While we showed that naïve old DCs expressed augmented levels of costimulatory molecules, they furthermore promoted pro-inflammatory IFN-γ and IL-17 responses of allogeneic T cells in vitro. Finally, we demonstrated the relevance of our findings in a cardiac transplant model by showing that the adoptive transfer of old DCs but not young DCs prior to heart transplantation reduced graft survival significantly. This effect was associated with an increased capacity of old DCs to stimulate proliferative responses of alloreactive T cells in vitro. Collectively these results suggest that aging increases cell-free mtDNA, thereby favoring DCs activation that in turn can orchestrate pro-inflammatory T cell responses and consequently reduces the survival of older grafts.

Donor brain death influences early NK cell migration in murine heart and kidney transplantation

Paul Ritschl[1], Muhammad Ashraf[1], Rupert Oberhuber[2], Vanessa Mellitzer[2], Cornelia Fabritius[2], Thomas Resch[2], Susanne Ebner[2], Martina Sauter[3], Karin Klingel[3], Johann Pratschke[1], Katja Kotsch[1].
[1]Department of General, Visceral and Transplantation Surgery, Charité – Universitaetsmedizin Berlin, Berlin, Germany; [2]Center for Operative Medicine, Department of Visceral, Transplant and Thoracic Surgery, Medical University of Innsbruck, Austria, Innsbruck, Austria; [3]Department of Molecular Pathology, University Hospital Tübingen, Tübingen, Germany.

The majority of organs used for solid organ transplantation (SOT) is retrieved from brain dead (BD) donors. Donor BD has been defined as irreversible loss of brain and brain stem function resulting in a number of pathophysiological changes suggesting an impaired graft outcome in the long-term. However, detailed information regarding the influence of BD in combination with ischemia reperfusion injury (IRI) on various immune cell subsets within solid organs and their comparative immunological profile is still missing. We therefore characterized the BD-related impact on distinct inflammatory expression patterns and passenger leukocyte composition in solid organs applying a murine model of BD. Following 4 hours of BD investigated organs were characterized by a defined inflammatory profile. For instance, after onset of BD lipocalin 2 (LCN2), a marker described for acute kidney injury was exclusively induced in the liver and not in the kidney. Moreover, BD livers were characterized by a significant decrease of CD3+CD4+ and CD3+CD8+ T cells ($p<0.01$) as well as NK cells compared with sham controls ($p<0.05$). BD derived hearts showed the highest MCP-1 and P-selectin expression compared with BD kidneys and livers, whereas both, BD hearts and kidneys showed significant lower numbers of CD11c+MHC class II+ dendritic cells ($p<0.05$, $p<0.01$). This yet unknown organ specific effect of BD on lymphocytes was further investigated in a murine kidney (KTx) and heart (HTx) transplantation model. Interestingly, 20 hours post reperfusion transplanted BD hearts were characterized by significant lower NK cell frequencies compared with sham derived hearts whereas BD kidneys illustrated significant higher levels of NK cells ($p<0.01$, respectively, Figure 1). Contrarily, T cells or dendritic cells were not affected and no histological differences between BD or sham derived organs in both models were noted. We therefore hypothesize that NK cells present a possible target of future therapy approaches in order to alleviate BD-related organ damage in SOT.
In conclusion, our data illustrate the varying impact of donor BD on solid organs underlining the necessity of organ-specific treatment schemes to improve donor organ quality to close the existing gap between organ demand and available organs.

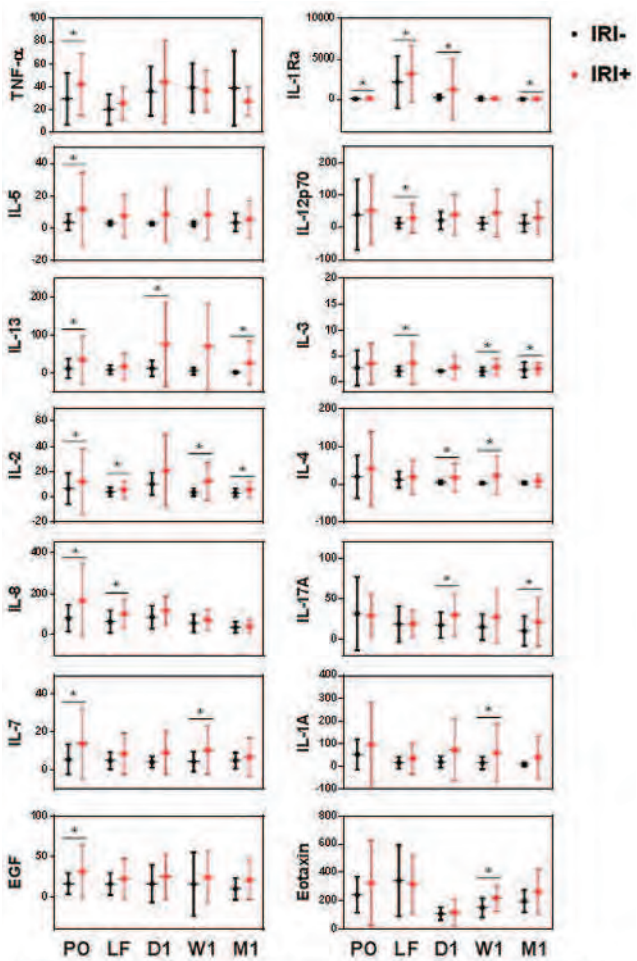
Evolution of innate and adaptive cytokine responses in ischemia reperfusion injury in orthotopic liver transplantation

Ali Zarrinpar[1], Rebecca Sosa[2], Ping Rao[2], Charles Lassman[2], Ronald Busuttil[1], Yuan Zhai[1], Ying Zhang[2], David Gjertson[2], Jerzy Kupiec-Weglinski[1], Elaine Reed[2].
[1]Surgery, UCLA, Los Angeles, CA, United States; [2]Pathology and Lab Medicine, UCLA, Los Angeles, CA, United States.

Background: Ischemia reperfusion injury (IRI) in orthotopic liver transplantation (OLT) can lead to primary graft non-function, re-transplantation or recipient death. Data from experimental models indicate that OLT-IRI is mediated by complex interactions between the innate and adaptive arms of the immune system. This study aims to determine the evolution of cytokine response over time following OLT-IRI.



Measured Analytes: VEGF, sCD40L, EGF, Eotaxin, FGF-2, Flt-3 ligand, Fractalkine, G-CSF, GM-CSF, GRO, IFN-α2, IFN-γ, IL-1α, IL-1ß, IL-1RA, IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-8, IL-9, IL-10, IL-12p40, IL-12p70, IL-13, IL-15, IL-17A, IP-10, MCP-1, MCP-3, MDC, MIP-1α, MIP-1ß, TGF-α, TNF-α, TNF-ß;
PO=pre-operative, LF=liver flush, D1=day 1, W1=week 1, M1=month 1;
*indicates p≤0.05 by Wilcoxon Nonparametric Rank-Sum Test

Methods: Blood samples from 53 adult OLT recipients were collected pre-operative, intraoperative (blood liver flush, LF) and post-transplant on day 1, weekly for 1 month, and bi-monthly for 3 months. Graft biopsies were collected pre-transplant and 2 hours after reperfusion. LF and plasma were analyzed using Luminex 38-plex cytokine/chemokine arrays (Millipore). H&E stained slides of liver biopsies were graded for IRI (0=none, 1=minimal, 2=mild, 3=moderate, 4=severe) based on the following parameters: necrosis, inflammatory infiltrates, large droplet macrovesicular steatosis, congestion, and ballooning. IRI scores and cytokine levels were analysis to detect significant associations.
Results: 47% of transplant recipients (25/53) were IRI+ (score ≥2). Pre-operative blood from IRI+ patients showed increased expression of the pro-inflammatory cytokines TNFa, IL-2, IL-8, IL-7, EGF. The intraoperative liver flush from IRI+ patients showed increases in innate immune cytokines IL-2, IL-8, IL-12p70 and IL-3. Early post transplantation (day1) adaptive cytokines/chemokines IL-13 and IL17a were significantly higher in IRI+ patients compared to IRI-. Late after IRI (week 1 and week 4 post-transplantation), adaptive cytokines/chemokines dominate the immune response in IRI+ recipients showing significant increases in IL-17A, IL-2, IL-4, IL-7, IL-3 and eotaxin. Persistent IL-1Ra was found in IRI+ recipients across most time-points tested. Notably, IRI+ patients exhibited increased IL-1a expression at week 1 post transplant that was accompanied by a significant decrease in IL1-Ra implying a resurgence of an acute inflammatory response.
Conclusion: Activation of innate immunity during human OLT-IRI triggers adaptive immunity and correlates with the degree of IRI injury.

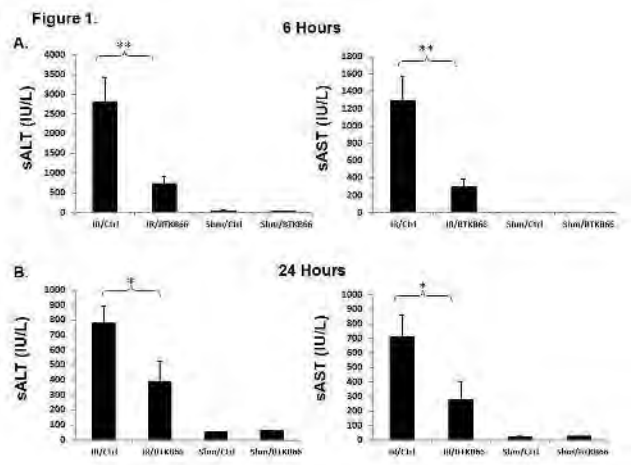
Bruton's tyrosine kinase inhibition attenuates mouse liver damage due to ischemia and reperfusion

Tiziana Palumbo[1], Kojiro Nakamura[1], Charles Lassman[2], Ronald Busuttil[1], Jerzy Kupiec-Weglinski[1], Ali Zarrinpar[1].
[1]Surgery, UCLA, Los Angeles, CA, United States; [2]Pathology and Lab Medicine, UCLA, Los Angeles, CA, United States.

Introduction: Bruton's tyrosine kinase (Btk) is a central player in multiple signaling pathways in lymphoid and myeloid cells, including neutrophils. Neutrophils are crucial effectors in the pathophysiology of organ ischemia/reperfusion injury (IRI). BTKB66 is a highly selective, irreversible inhibitor of Btk. In this study, we tested this small molecule in in vitro and in vivo assays of neutrophil activation and hypothesized that it would reduce warm hepatic ischemia-reperfusion injury (IRI).
Materials and Methods: BTKB66 was tested in an in vitro model of LPS-mediated neutrophil activation. To further assess its efficacy in vivo, BTKB66 was administered for seven days to mice in their drinking water prior to subjecting them to 90 minutes of warm hepatic ischemia followed by 6 or 24 hours of reperfusion. Clinical and pathologic features of these mice were examined following IRI, including AST, ALT, and a panel of cytokines and chemokines.
Results: BTKB66 potently inhibited LPS-mediated activation of bone-marrow derived neutrophils at 1 μM. It also reduced the amount of IRI as determined by AST and ALT levels, as well as in immunohistochemical analyses, at a dose of ~60 mg/kg/day. There were significant decreases in markers of inflammation in the liver, such as CXCL1, CXCL2, and CXCL10. There were also significant decreases in serum markers of the activation of myeloid cells, such as CCL5, CCL11, and CXCL5.



Conclusions: BTKB66 is effective in inhibiting warm hepatic IRI. These finding confirm that neutrophil recruitment and activation plays a large role in injury during IRI and that targeting Btk activity could provide a useful approach for preventing liver IRI and improving overall outcomes in liver transplantation.

Pre-treatment of heart allografts with the cytotopic anti-thrombin inhibitor Thrombalexin prolongs transplant survival and augments the therapeutic efficacy of adoptively transferred regulatory T cells

Qi Peng, Anna Nowocin, Lesley Smyth, Richard A.Smith, Anthony Dorling, Robert Lechler, Giovanna Lombardi.
MRC Centre for Transplantation, King's College London, London, United Kingdom.

Cardiac transplantation is the treatment of choice for end-stage heart failure. Its efficacy is limited by the occurrence of ischemia-reperfusion (IR) injury as well as the development of cardiac allograft vasculopathy. IR of transplanted organs triggers the activation of innate components of the immune system such as complement and coagulation pathways, which are key contributors to early graft injury, local inflammation and graft dysfunction. Limiting the effects of IR injury and preserving heart function by inhibiting the aforementioned is therefore of primary importance.
In this study, we developed a novel therapeutic strategy of a cytotopic anti-thrombin inhibitor (Thrombalexin) targeting thrombin, a major molecule involved in the coagulation pathway and also interacts with the complement system. Thrombalexin contains a Hirulog-like sequence and a membrane-interacting component with specific inhibition of thrombin activity. We then tested the efficacy of this drug using a murine heart allograft transplant model with the perfusion of the heart allografts with Thrombalexin prior to transplantation. Furthermore, the impact of Thrombalexin on the therapeutic efficacy of adoptive regulatory T (Treg) cell therapy was also assessed. Perfusion of the BALB/c heart grafts with Thrombalexin for 15min before transplantation significantly reduces graft injury and prolongs graft survival in C57BL/6 recipient mice (n=8, MST=15 days) as compared to untreated hearts (n=8, MST=11.5 days). This protection was associated with a significantly reduced macrophage and T cell infiltration. To shed some light on the effects observed in vivo, murine heart endothelial cells (EC) were incubated in vitro with Thrombalexin. The pre-treatment of EC with Thrombalexin resulted in down-regulation of TNFα-induced expression of adhesion molecules such as ICAM-1. Finally, this pre-treatment with Thrombalexin significantly augmented the effect of adoptively transferred Treg cells in allograft survival.
In conclusion, coagulation mediated allograft heart IR injury and graft rejection may be prevented/delayed by pre-treatment of the grafts with the anti-thrombin drug Thrombalexin prior to transplantation. The results from our study suggest that localized anti-thrombin inhibition is effective in reducing early local inflammation and provides a window of opportunity to combine Thrombalexin-treatment with adoptive Treg cell therapy to induce transplantation tolerance.

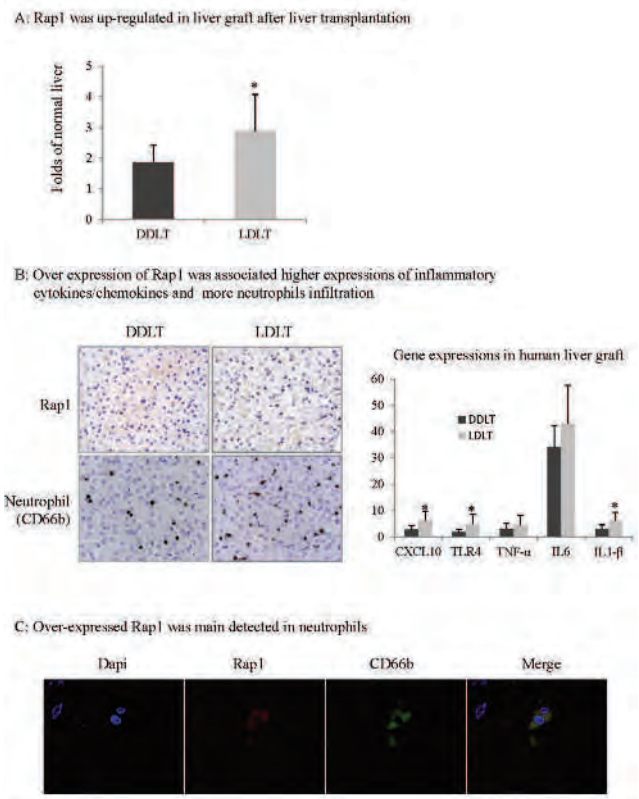
Repressor and activator protein accelerates hepatic ischemia reperfusion injury by promoting neutrophil inflammatory response

Chang Xian LI[1], Chung Mau Lo[1], Kevin Tak Pan Ng[1], Xiao Bing Liu[1], Xiang Qi[1], Yuen Yuen Ma[1], Qi Zhou Lian[2], Kwan Man[1].
[1]Surgery, The University of Hong Kong, Hong Kong, People's Republic of China; [2]Medicine, The University of Hong Kong, Hong Kong, People's Republic of China.

Background: Increasing evidence showed that hepatic ischemia reperfusion injury (IRI) is a typical inflammatory response involving a complex web of interactions between various cellular and molecular signals. Repressor and activator protein (Rap1) directly regulates nuclear factor-κB (NF-κB) dependent signaling, which is the key player for inflammatory response. Therefore, Rap1 may potentially play an important role in hepatic IRI. We here intended to investigate the effect of Rap1 in hepatic IRI and to explore the underlying mechanisms.

Figure 1



Methods: The association of Rap1 expression with hepatic inflammatory response were investigated both in human and rat liver transplantation. The direct role of Rap1 in regulating hepatic IRI was studied in Rap1 knockout mice IRI model in vivo and primary cells in vitro.

Results: In clinical samples, Rap1 was over-expressed in liver graft and mainly detected in neutrophils after transplantation (Fiugre 1A and C). Over expression of Rap1 was associated with severe histological damage, hepatic apoptosis, higher expressions of inflammatory cytokines/chemokines, more infiltrations of macrophages and neutrophils (Figure 1B). The results were also validated in rat liver transplantation. In mouse hepatic IRI model, the knockout of Rap1 reduced hepatic histological damage, apoptosis and decreased the levels of AST and ALT after liver IRI. Furthermore, the knockout of Rap1 also attenuated hepatic inflammatory response by decreasing the expressions of pro-inflammatory cytokines/chemokines and neutrophil chemoattractants, neutrophil infiltration, and suppressing the activations of inflammation-associated NF-κB and MAPK pathway (Figure 2A and B). In vitro functional study, the knockout of Rap1 suppressed primary neutrophil migration activity and adhesion in response to liver sinusoidal endothelial cells through down-regulating neutrophil F-Actin expression and CXCL2/CXCR2 pathway (Figure 2C). In addition, the knockout of Rap1 also decreased production of pro-inflammatory cytokines/chemokines in primary neutrophils and neutrophil-induced hepatocyte damage.

Conclusions: Rap1 may induce hepatic IRI through promoting neutrophil inflammatory response. Rap1 may be the potential therapeutic target of attenuating hepatic IRI.

Expression of human CD55 and CD59 reduces complement deposition and preserves renal function in a mouse model of renal ischemia reperfusion injury

David Bo Lu[1], Anjan Bongoni[1], Veena Roberts[1,2], Doreen Fang[1,2], Siddharth V.Rajakumar[1,2], Karen M.Dwyer[1,2], Peter J.Cowan[1,2].
[1]Immunology Research Centre, Vincent's Hospital, Melbourne, Fitzroy, Australia; [2]Department of Medicine, The University of Melbourne, Fitzroy, Australia.

Background: Complement activation plays a key role in antibody-mediated rejection and ischemia reperfusion injury (IRI). We have shown that kidneys from transgenic pigs expressing the human (h) complement regulators CD55 and CD59 are protected from hyperacute rejection in a preclinical baboon model. However, it is not known whether these transgenes have additional benefit by reducing renal IRI. We have addressed this question in a mouse model and shown that transgenic hCD55±hCD59 expression or treatment of wild type (WT) mice with recombinant human CD55 (rhCD55) protects against renal IRI (unpublished). To investigate the mechanism of protection, we examined kidney sections from these mice for deposition of complement.
Aim: To determine whether hCD55-mediated protection from renal IRI correlates with a reduction in complement deposition.
Methods: Transgenic mice expressing hCD55±hCD59 from the broadly active H2Kb promoter were used, with littermate controls. The right kidney was removed from 10-12 week old male mice and the left renal pedicle was clamped for 18 min (mild IRI) or 22 min (moderate IRI). Mice were sacrificed 24 hrs after reperfusion, and samples were collected to assess (i) renal function (serum creatinine), (ii) histological injury score (HIS) on a scale of 0 (no injury) to 4 (severe injury), and (iii) C3b/c and C5 deposition by immunofluorescence staining/confocal microscopy, with quantification as Raw Integrated Density (RawIntDen) using Image J. In a separate study using the moderate IRI model, WT C57BL/6 mice were injected i.v. with 2µg rhCD55 or vehicle immediately after reperfusion.
Results: hCD55 mice were protected from mild IRI (creatinine, $p<0.05$ vs. littermates) but not moderate IRI ($p=0.36$) (see Table). hCD55+hCD59 mice were protected in both models ($p<0.05$). rhCD55 treatment protected WT mice from moderate IRI ($p<0.05$ vs. vehicle). The level of complement deposition correlated well to the degree of injury. In the mild IRI model, C3b/c was lower in hCD55 and hCD55+hCD59 kidneys (both $p<0.05$ vs. littermates), and C5 deposition was lower in the latter ($p<0.05$). In the moderate IRI model, C3b/c and C5 were lower in hCD55+hCD59 kidneys ($p<0.05$, $p<0.01$), and in kidneys from rhCD55-treated mice ($p<0.01$, $p<0.05$ vs. vehicle).
Conclusions: Protection of hCD55 transgenic mice against mild renal IRI is associated with a reduction in C3b/c deposition, consistent with CD55's mid-level regulation of the complement pathway. The additional expression of hCD59, which regulates the terminal stage of the pathway, reduced both C3b/c and C5 deposition and provided further protection. This suggests that activation of the terminal pathway can still occur in IRI even in the context of elevated CD55 expression, possibly by C3-independent mechanisms such as thrombin-mediated cleavage of C5. Our studies further indicate that systemic treatment with soluble rhCD55 is more protective than transgenic expression of the membrane-bound native form.

Mice	Ischemia	n	Mice	HIS	C3b/c (RawIntDen)	C5 (RawIntDen)

357.8

AMP-activated protein kinase attenuated marginal liver graft injury via promoting mitochondrial biogenesis and respiratory function

Jiang Liu, Kwan Man, Hui Liu, XIANG QI, Xiaobing Liu, Chang Xian LI, Yuen Yuen Ma, See Ching Chan, Chung-Mau Lo.
Surgery, The University of Hong Kong, Hong Kong, Hong Kong.

Introduction and Objective: AMP-activated protein kinase (AMPK) is an energy sensor to AMP/ATP ratio in cells, and its activation can transit cellular anabolism to catabolism to generate more ATP[1]. AMPK was reported to regulate mitochondrial biogenesis of metabolism related enzymes after exercise and training to conquer cell aging. In this study, we aimed to investigate the role of AMPK pathway in marginal graft injury after liver transplantation, and to further explore the underlying mechanism.
Materials and Methods: The expression levels of AMPK, PGC-1α and mitochondrial election transition chain (ETC) components together with liver function were explored in clinical samples from recipients after liver transplantation. Further, a rat orthotopic liver transplantation model with small-for-size fatty liver graft was established to investigate mitochondrial function and correlation with AMPK and PGC-1α expression. The functional role of AMPK in regulating graft injury, mitochondrial biogenesis and respiratory status was studied in AMPKα1 knock-in (AMPKα1+/-) mice underwent partial hepatic I/R injury and semi-hepatectomy.

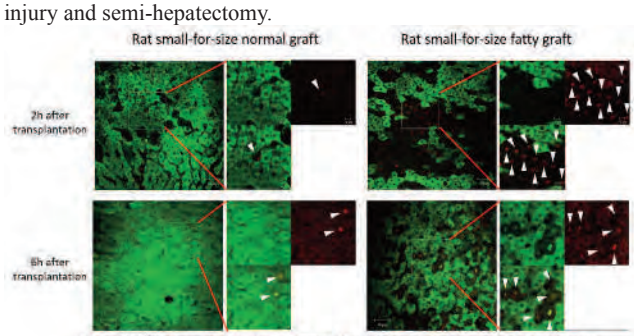

Figure 1. Mitochondrial membranaceous depolarization and hepatocyte necrosis are more severe in fatty graft compared to normal graft after small-for-size liver transplantation in rats.

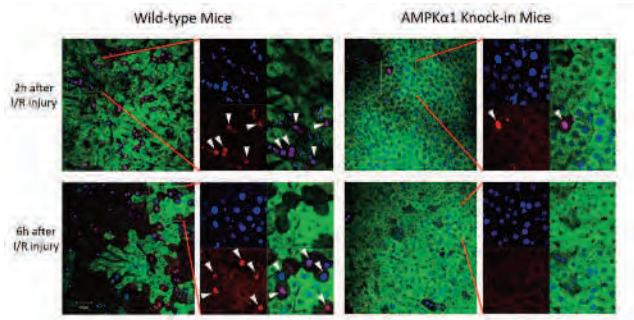

Figure 2. Mitochondrial membranaceous depolarization and hepatocyte necrosis are ameliorated in AMPKα1 knock-in mice compared to wild-type mice during I/R injury.

Results and Discussion: Down-regulation of AMPK and PGC-1α was found in clinical recipients with fatty liver grafts compared to normal grafts, and was correlated with poor acute phase liver function (ALT: 476 vs 346IU/L, AST: 362 vs 275IU/L, TBIL: 193 vs 163mg/dL, LDH: 852 vs 626U/L, $p<0.01$) after liver transplantation. Also, expression of ETC components was suppressed in recipients with fatty liver grafts compared to normal grafts. Consistently, in rats liver transplantation models using small-for-size fatty grafts, lower expression levels of AMPK and PGC-1α were also correlated with more severe mitochondrial membranaceous depolarization, larger proportion of

nonviable cells indicated by intravital imaging analyses (Figure 1), and suppressed function of ETC evidenced by lower ATP level and decreased succinate dehydrogenase (SDH, complex II of ETC) activity than that in normal grafts. In AMPK knock-in mice, there were less nonviable cells, attenuated depolarization of mitochondria (Figure 2), restored expression status of ETC components than in wild type mice. Furthermore, PGC-1α signaling was also maintained in AMPK knock-in mice than in wild type mice.

Conclusion: The AMP-activated protein kinase attenuated fatty graft injury by promoting mitochondrial biogenesis and respiratory function via PGC-1α pathway activation during liver transplantation.

Changes in activin levels and the impact of follistatin treatment in renal ischemia-reperfusion injury in mice

Doreen Fang[1,2], Bo Lu[1], Susan Hayward[4], David de Kretser[3,4], Peter Cowan[1,2], Karen Dwyer[2].

[1]Immunology Research Centre, St. Vincent's Hospital, Melbourne, Australia; [2]Department of Medicine, The University of Melbourne, Melbourne, Australia; [3]Faculty of Medicine, Monash University, Melbourne, Australia; [4]Centre for Reproductive Health, Hudson Institute of Medical Research, Melbourne, Australia.

Introduction: Activins, members of the TGF-β superfamily, are key drivers of inflammation and hence are thought to play a significant role in ischemia-reperfusion injury (IRI), an inherent process in renal transplantation that negatively impacts early and late allograft function. Activin A is a homodimer of the β_A-subunits of the gonadal hormone, inhibin A. Activin B is a homodimer of the β_B-subunits of inhibin B, which has 65% sequence homology with the β_A-subunit. Follistatin (FS) is an activin-binding protein that inhibits its activity. This study examined the changes in activin A and B levels, and the effect of exogenous FS using a mouse model of renal IRI.

Materials and Methods: Mice were treated with intravenous recombinant FS (0.4 μg/g) or vehicle before renal IRI surgery (right nephrectomy and left renal pedicle was clamped for 20 min). Sham mice underwent right nephrectomy only. Serum and kidney activin A, activin B and FS levels, and renal injury parameters, were measured at 3, 6 and 24 h after reperfusion.

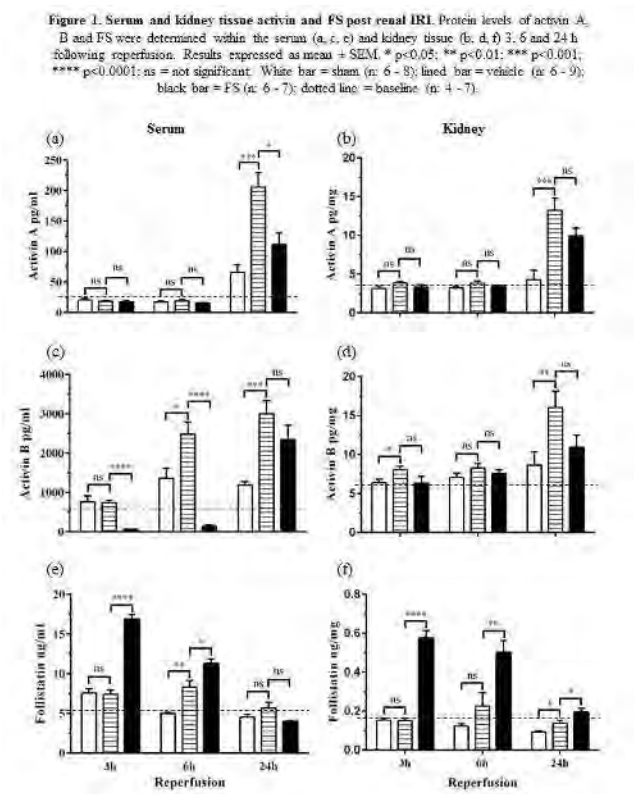

Figure 1. Serum and kidney tissue activin and FS post renal IRI. Protein levels of activin A, B and FS were determined within the serum (a, c, e) and kidney tissue (b, d, f) 3, 6 and 24 h following reperfusion. Results expressed as mean + SEM. * p<0.05; ** p<0.01; *** p<0.001; **** p<0.0001; ns = not significant. White bar = sham (n: 6 - 8); lined bar = vehicle (n: 6 - 9); black bar = FS (n: 6 - 7); dotted line = baseline (n: 4 - 7).

Results and Discussion: Serum and kidney activin B levels were increased within 6 h post renal IRI preceding that of activin A (Figure 1a-d). The increase in activin B was accompanied by renal injury illustrated as a 3-fold increase in serum creatinine ($p<0.0001$), and increased mRNA expression of kidney injury molecule-1 (KIM-1) ($p<0.01$) and neutrophil gelatinase-associated lipocalin (NGAL) ($p<0.001$). E-selectin mRNA, a marker of endothelial activation, was

also increased ($p<0.01$). FS treatment blocked the rise in serum activin B (Figure 1c) and reduced the mRNA expression of KIM-1 ($p<0.05$), NGAL ($p<0.05$) and E-selectin ($p<0.01$) but had no effect on serum creatinine. Serum and kidney activin A increased later between 6 and 24 h post renal IRI (Figure 1a-b), with a further increase in creatinine to 5-fold ($p<0.0001$) and in KIM-1 ($p<0.01$) and NGAL ($p<0.05$) mRNA. FS treatment blunted the increase in serum activin A (Figure 1a) and late injury to the kidney, attenuating the increase in creatinine ($p<0.01$), KIM-1 and NGAL mRNA ($p<0.05$), renal tubular injury score ($p<0.05$), and renal cell apoptosis ($p<0.001$). Serum levels of the pro-inflammatory proteins IL-6 and MCP-1 were also decreased by FS treatment. Interestingly, FS treatment had no impact on activin levels in the kidney despite the demonstrable protective renal effect (Figure 1b and 1d).

Conclusion: We propose that activin B initiates and activin A potentiates renal IRI. The renal protection conferred by treatment with FS may be due to dampening of the systemic inflammatory response consequent to reduced serum activin B and A. This suggests a potential clinical application of FS treatment in renal transplantation to improve graft function and survival.

Time-series variations in calculated panel reactive antibody among kidney transplant candidates

Yoshitsugu Obi[1,2], Akihiro Shimomura[3], Reza FAlizadeh[3], Shiri Li[3], Uttam G Reddy[1,2], Kamyar Kalantar-Zadeh[1,2], Clarence E. Foster[3], Hirohito Ichii[3].
[1]Harold Simmons Center for Kidney Disease Research and Epidemiology, University of California Irvine, Orange, CA, United States; [2]Division of Nephrology & Hypertension, University of California Irvine, Orange, CA, United States; [3]Division of Transplantation, University of California Irvine, Orange, CA, United States.

Background: The Calculated Panel Reactive Antibody (cPRA) calculator has been used to evaluate kidney transplant candidates. However, the time-series variations in cPRA levels and the optimal cPRA evaluation interval remain unclear, potentially resulting in unnecessary tests and increased medical cost.

Method: We retrospectively examined the trajectory of cPRA among 118 end-stage renal disease (ESRD) patients wait-listed for kidney transplantation at our department between January 2011 and December 2014. We measured cPRA levels every 3 months. CPRA levels were then categorized into 0–19%, 20–79%, 80–97%, and 98–100%. Increase or decrease in cPRA levels >10% was used as the primary outcome.

Results: Among 118 wait-listed patients, 50, 28, 19, and 21 patients were categorized as 0–19%, 20–79%, 80–97%, and 98–100%, respectively. One patient with 0% baseline cPRA experienced an increase cPRA levels to 36% at Month 6 but then spontaneously returned to 0% at Month 9. Another patient decreased cPRA from 17% at baseline to 0% at Month 36. Among the other 48 patients in the 0-19% cPRA category, cPRA changes were within 10%. Similarly, cPRA did not change more than 10% among patients in the 98-100% category with an exception of one patient who decreased cPRA from 98% at baseline to 54% at Month 33. Variations in cPRA >10% were observed among 16 (57%) and 9 (47%) patients in the 20–79% and 80-97% category, respectively. Decrease in cPRA was more frequent than increase in cPRA in these middle categories. In particular about half of those with cRPA>80% showed a decline over time without any intervention.

Conclusion: Many wait-listed kidney transplant candidates show a large fluctuation in cPRA over time, while high cRPA tend to decline over time. Further studies are needed to identify predicting factors against cPRA changes and to determine the optimal cPRA evaluation interval that reduces costs and improve efficiency of limited medical resources.

Early de novo DSA with T cell mediated rejection (TCMR) is associated with allograft dysfunction with chronic injury

Aravind Cherukuri, Rajil Mehta, Puneet Sood, John Lunz, Sundaram Hariharan, David Rothstein.
Thomas E. Starzl Transplantation Institute, University of Pittsburgh, Pittsburgh, PA, United States.

Introduction: De novo anti-donor HLA-specific antibody (DSA) detected post-renal transplantation is associated with adverse outcomes. However, the relationship between early de novo DSA and subsequent T cell-mediated rejection (TCMR) and its impact on allograft survival, remain unknown. In this prospective longitudinal study, DSA was measured longitudinally post-transplantation, and compared to the development of TCMR and subsequent allograft outcomes.
Methods: HLA specific antibodies were analysed longitudinally at 0,1,3,6,9,12 and 18 months post-transplant. Patients had protocol biopsies at 3 and 12months in addition to for-cause biopsies, and the development of rejection was examined in relation to DSA. In a subset of 26 patients where PBMCs were available, B cell subsets and cytokines were examined at 3 months.
Results: 53 (18%) of 299 patients transplanted between dates 1/13 and 7/14, developed de novo DSA (IS: Thymo, MPA+TAC & rapid steroid withdrawal). In 48/53 (90%) of these patients, DSA developed early (<6m). 51.2% of patients who developed DSA had rejection versus 29% of patients without DSA (OR 2.54, p=0.002). Of the patients with DSA and rejection, 74% had DSA at or before the diagnosis of rejection while 15% developed DSA after a rejection episode. Only 3 patients (11%) developed ABMR and were excluded. Patients with de novo DSA had significantly worse renal function at 12 and 18m than those without DSA. Importantly, patients with DSA+TCMR had worse Scr than patients with either DSA or TCMR alone (table 1A). Moreover, patients with DSA had significantly worse chronicity (IFTA & IF+i) scores than those without DSA, predominantly due to patients in the DSA+TCMR sub-group, who had markedly worse chronicity scores than patients with either DSA or TCMR alone (Fig 1).

A

Allograft dysfunction	DSA	No DSA	P-value
Creatinine-12m	1.81 (0.2)	1.46 (0.03)	0.0006
Creatinine-18m	2.04 (0.3)	1.51 (0.06)	0.005
IFTA score (ct+ci)	1.99 (0.16)	1.6 (0.07)	0.05
Interstitial fibrosis and inflammation (IF+i)	55%	39%	0.02

Allograft dysfunction	DSA	DSA+TCMR	P-value
Creatinine-12m	1.42 (0.16)	2.34 (0.2)	0.01
Creatinine-18m	1.48 (0.18)	3.05 (0.5)	0.01
IFTA score (ct+ci)	1.29 (0.2)	2.29 (0.2)	0.001
Interstitial fibrosis and inflammation (IF+i)	7%	89%	<0.0001

B

B cell parameter	DSA	DSA+TCMR	P-value
B cell-IL-10/TNF	**0.73**	**0.26**	**0.02**
T1-IL-10/TNF	**5.9**	**0.9**	**0.0001**
TrB-IL-10/TNF	**2.14**	**0.56**	**0.002**
Naïve B-IL-10/TNF	0.64	0.29	0.2
Memory B-IL-10/TNF	0.33	0.28	Ns

Patients with DSA+TCMR were younger (43 vs. 55yrs, p=0.02) and had a higher incidence of DGF (35% vs. 14.8%, p=0.001) when compared to those with DSA alone and both were independent risk factors (recipient age OR 0.95, p<0.05; DGF OR 6.9, p=0.02). Cumulative MFI levels for the DSA were significantly higher in the DSA+TCMR sub-group (7106 vs. 3212, p=0.03).

Thus, DSA+TCMR identifies patients at high risk for poor graft outcomes. Early diagnosis and treatment could improve outcomes. In this regard, in patients with DSA+TCMR, 50% of the rejections were subclinical (diagnosed on the 3 month protocol biopsy), and 19% presented with late rejection despite a normal 3-month biopsy. We found that transitional B cell (TrB) IL-10/TNFa ratio is a measure of Breg activity and predicts rejection. Patients with DSA+TCMR (16/26) had significantly lower TrB and other B-subset cytokine ratios at 3 months than those with DSA alone (10/26) (Table-1B). Moreover, in patients with DSA, a low TrB cytokine ratio is a strong predictor for presence of concomitant or subsequent TCMR (AUC 0.90, p=0.003; specificity 100%; sensitivity 78%).
Conclusion: de novo DSA with TCMR is associated significantly worse renal function and chronic allograft injury than DSA alone, suggesting that DSA is a marker for a heightened cellular alloresponse. In patients with DSA, TrB cytokine ratios may help identify those at high risk of TCMR allowing early intervention.

The new OPTN kidney allocation system: A look at the one year transplant trend in the highly sensitized patient cohort

Taba Kheradmand, Chak-Sum (Sam) Ho.
Histocompatibility and Immunogenetics Laboratory, Gift of Life Michigan, Ann Arbor, MI, United States.

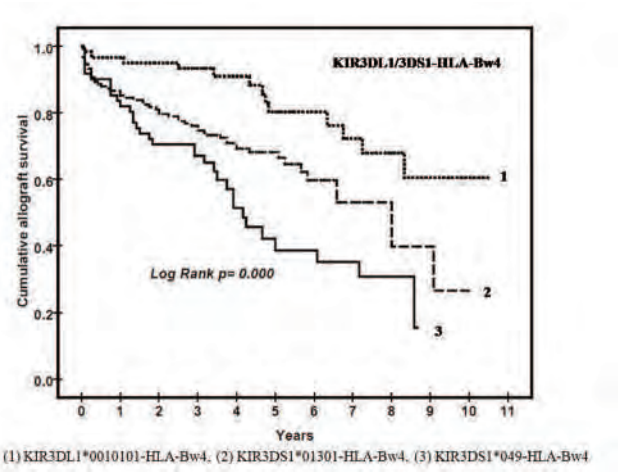
Aim: The new OPTN Kidney Allocation System (KAS) was implemented on Dec 4, 2014, in the U.S. with the primary goals to 1) reduce kidney discards, 2) better match for longevity, and 3) increase transplant opportunities for difficult-to-match recipient candidates, particularly the highly sensitized patient cohort (with 99 and 100% cPRA). Michigan kidney recipient candidates comprise approximately 3% of the United Network for Organ Sharing (UNOS) waiting list, with 9% being highly sensitized. Herein, we evaluated the impact of the new KAS on kidney allocation and transplantation trend in Michigan within the first year after its implementation.
Methods: Data was collected from the 8 Michigan renal transplant centers on recipient candidates with cPRA ≥99%, between Dec 4, 2014 and Dec 3, 2015, and the same time period of the previous three years. In this patient cohort, we investigated: 1) number of kidney offers, 2) transplant rate, 3) number of out-of-state kidney offers, and 4) incompatible positive crossmatch rate (number of positive crossmatch/total number crossmatch performed).
Results: Since the inception of KAS, while the number of kidney offers to recipients with cPRA ≥99% has somewhat increased by 30%, from 6 offers/month pre-KAS, to 9 offers/month post-KAS, the transplant rate in this patient cohort has significantly increased by nearly 8 fold to 45% (47 transplanted out of 105 offers) in comparison to an average of 6% (5 transplanted out of 79 offers) in the past 3 years. Overall our data showed that since the new KAS, 18% of the highly sensitized candidates in Michigan were being transplanted, in comparison to 13% nationally. As a consequence with the new KAS which mandated national/regional sharing for highly sensitized recipient candidates, the majority of the kidney transplant were from out-of-state donors (68%, or 32/47), which demonstrated a 3.5-fold increased compared to the previous 3 years. There did not appear to be a noticeable bias among the transplanted patients with regards to age, sex, race, or their donors' kidney donor profile index (KDPI). Finally, as expected, incompatible positive crossmatch rate was much higher in the highly sensitized patient cohort at 28-48% in the past 4 years, compared to that in all other patients at 21-25%. This could be attributed in part to the high prevalence of HLA antibodies to DP and DQA1 in the highly sensitized patients which were not being accounted for during the kidney allocation process by UNOS.
Conclusions: To date, our data suggested that, despite the higher incidence of incompatible positive crossmatch, the new KAS has greatly enhanced the number of kidney offers for the highly sensitized patient cohort, which led to a significantly higher transplant rate in these difficult-to-match patients.

358.4

Association of KIR3DL1/3DS1 alleles with renal allograft rejection

Raj Kumar Sharma[1], Swayam Prakash[1], Suraksha Agrawal[2].
[1]Nephrology , Sanjay Gandhi Post Graduate Medical Institution, Lucknow, India; [2]Medical Genetics, Sanjay Gandhi Post Graduate Medical Institution, Lucknow, India.

Introduction: Functioning of NK cell is regulated by KIR like inhibitory and activating cell surface receptors. Highly polymorphic KIR3DL1/3DS1 genes affect their corresponding HLA-Bw4 ligand binding affinities. This causes variation in NK cell inhibition and may have an impact on the long term renal allograft survival. Present study evaluated allelic diversity of KIR3DL1/3DS1 and importance of its corresponding HLA-Bw4 ligand affinity with renal transplant cases.
Materials and Methods: KIR3DL1/3DS1 allelic diversity was examined in 100 renal transplant cases and 100 normal controls. All samples were positive for KIR3DL1 or/and KIR3DS1 and possessed HLA-Bw4 ligand. PCR-SSP was used to determine incidence of KIR3DL1/3DS1 genes and sequence based typing method evaluated the pattern of KIR3DL1/3DS1 allele distribution. HLA class-I genotyping was performed using PCR-SSP kits. Relative quantification of KIR3DL1/3DS1 mRNA expression was done by 2-ΔΔCt algorithm with GAPDH as the housekeeping gene.



(1) KIR3DL1*0010101-HLA-Bw4, (2) KIR3DS1*01301-HLA-Bw4, (3) KIR3DS1*049-HLA-Bw4

Results and Discussion: We observed presence of 84 KIR3DL1/3DS1 alleles in the studied north Indian cases and controls. However, only 6 inhibitory KIR3DL1 alleles and 4 activating KIR3DS1 alleles with incidence > 1% were noted. For KIR3DL1*0010101, no-risk (OR=0.37, p=0.0072) association was observed with increased mRNA expression among antibody mediated graft rejection (Fold change=1.48±0.32, p=0.031), and antibody mediated chronic rejection (Fold change=1.12±0.15, p=0.042) cases. Risk was found for KIR3DS1*049N (OR=5.16, $p \leq 0.0001$) and KIR3DS1*01301 (OR=4.27, $p \leq 0.0001$). Both KIR3DS1*049N and KIR3DS1*01301 showed a decreased mRNA level. Looking at the ligand affinity, 3DS1*01301/HLA-Bw4+ (OR=2.12, p=0.0120) and 3DS1*049N/HLA-Bw4+ (OR=3.42, p=0.0051) combinations showed susceptibility. Kaplan-Meier survival analysis performed on a 15 year follow-up data revealed highest overall survival for KIR3DL1*0010101-HLA-Bw4 (cumulative survival=63% at 11 years). Less prolonged survival of was noted for 3DS1*01301/HLA-Bw4+ (cumulative survival=36% at 10 years) and least survival for 3DS1*049N/HLA-Bw4+ (cumulative survival=18% at 8 years).
Inhibitory signal transmitted by KIR3DL1 induces the ITIM motifs giving rise to an inhibitory signaling in KIR positive cells. Inhibition leads to higher T cell response due to protection of T cell from activation induced cell death. During the disease phase, inhibitory

signal loss and resultant activation causes NK cell lysis. This is in contrast to renal allograft donors who lack the KIR3DL1-HLA-Bw4 interaction. Donors carrying this combination posses a functional NK cell subset that induces NK cell inhibition leading to better allograft survival.

Conclusion: These findings highlight the evidence that prolonged survival of the renal allograft depends on presence of inhibitory KIR receptors. Importantly suppressing KIR3DS1 like activating NK cell surface receptors may improve the survival of HLA compatible kidney grafts.

C1q-fixing antibodies against denatured HLA and MICA antigens are associated with antibody mediated rejection

Junchao Cai[1], Paul I.Terasaki[1], Dong Zhu[2], Nils Lachmann[3], Constanze Schönemann[3], Matthew Everly[1], Xin Qing[4].
[1]Research, Terasaki Foundation Laboratory, Los Angeles, CA, United States; [2]Urology, Zhongshan Hospital, Fudan University, Shanghai, People's Republic of China; [3]Center for Tumor Medicine, Charité-Universitätsmedizin Berlin, Berlin, Germany; [4]Pathology, Harbor-UCLA Medical Center, Torrance, CA, United States.

Background: We have found antibodies against denatured HLA class I antigens in the serum of allograft recipients which were not significantly associated with graft failure. It is unknown whether transplant recipients also have denatured HLA class II and MICA antibodies. The effects of denatured HLA class I, class II, and MICA antibodies on long-term graft outcome were further investigated based on their ability to fix complement c1q.

Materials and Methods: In this 4-year retrospective cohort study, post-transplant sera from 975 kidney transplant recipients were tested for antibodies against denatured HLA/MICA antigens and these antibodies were further classified based on their ability to fix c1q.

Results: Thirty percent of patients had antibodies against denatured HLA class I, II, or MICA antigens. Among them, 8.5% and 21.5% of all patients had c1q-fixing and non c1q-fixing antibodies respectively. There was no significant difference on graft survival between patients with or without antibodies against denatured HLA/MICA. However, when these antibodies were further classified according to their ability to fix c1q, patients with c1q-fixing antibodies had a significantly lower graft survival rate than patients without antibodies or patients with non c1q-fixing antibodies ($p=0.008$). In 169 patients who lost renal grafts, 44% of them had c1q-fixing antibodies against denatured HLA/MICA antigens, which was significantly higher than that in patients with functioning renal transplants (25%, $p<0.0001$). C1q-fixing antibodies were more significantly associated with graft failure caused by AMR (72.73%) or mixed AMR/CMR (61.9%) as compared to failure due to CMR (35.3%) or other causes (39.2%) ($p=0.026$).

Conclusions: Transplant recipients had antibodies against denatured HLA class I, II, and MICA antigens. However, only c1q-fixing antibodies were associated with graft failure which was related to antibody mediated rejection.

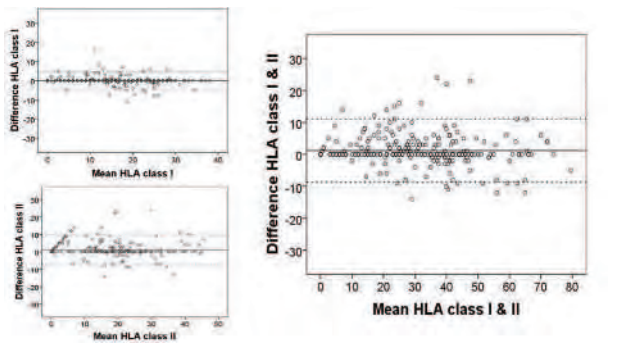
Agreement between number of donor / recipient eplet mismatches calculated using two-digit serological versus four-digit molecular Human Leucocyte Antigen (HLA)-typing

Samantha Fidler[1], Wai Lim[2], Joshua Lewis[2], Germaine Wong[3]. [1]School of Pathology and Laboratory medicine, University of Western Australia, Perth, Australia; [2]School of Medicine and Pharmacology, University of Western Australia, Perth, Australia; [3]School of Public Health, University of Sydney, Sydney, Australia.

Aim: We aimed to assess the agreement of the number of eplet mismatches at the HLA-A, -B, -C, -DQ and -DR loci determined by 2-digit serological and 4-digit molecular typing. Methods: We included patients who received live or deceased-donor kidney transplants between 2003 and 2007. Donor and recipient serological typing was determined using complement-dependent cytotoxicity, and molecular 4-digit typing determined using sequence based typing (Sanger). The number of eplet mismatches was calculated by converting the 2 and 4-digit HLA-typing using HLAMatchmaker. Correlation and agreement of HLA-A, -B, -C, -DP and -DR mismatches between the two methods was analysed using Spearman rank correlation and Bland Altman plots respectively. HLA-DP can only be determined using 4-digit typing and therefore not included in this study.
Results: Of 264 kidney transplant recipients, 86 (33%) were females. The correlation between class I (HLA-A, -B, -C) and class II (HLA-DQ, -DR) between 2 and 4-digit converted eplet mismatches were 0.966 and 0.931 respectively. Bland-Altman's limits of agreement between class I, class II and combined class I and II eplet mismatches using 2 and 4-digit typing is shown below (figure 1). The number of class I and II eplet mismatches determined by 4-digit conversion exceeded that of 2-digit conversion in 37% of recipients, with 10% exceeding 7 eplet mismatches. One hundred and sixteen (44%) recipients had identical number of class I and II eplet mismatches as determined by 2 and 4-digit typing. Of the 21 "outliers" for both class I and II eplet mismatches, 5 (24%) of patients were females and 8 (38%) of either patients or donors were non-Caucasians. A further 4 (19%) had unusual (non-Caucasian) HLA alleles.



Intraclass correlation coefficients* for consistency and absolute agreement (n=264)

	Consistency	Absolute agreement
2 Digit	4 Digit (95% CI)	4 Digit (95% CI)
HLA-A	0.995 (0.994-0.996)	0.995 (0.994-0.996)
HLA-B	0.983 (0.978-0.987)	0.982 (0.977-0.986)
HLA-C	0.875 (0.843-0.900)	0.875 (0.843-0.900)
Class I	0.969 (0.960-0.975)	0.969 (0.960-0.975)
HLA-DR	0.987 (0.984-0.990)	0.987 (0.983-0.992)
HLA-DQ	0.810 (0.764-0.848)	0.802 (0.748-0.845)
Class II†	0.935 (0.918-0.949)	0.931 (0.908-0.948)

*Two-way fixed intraclass correlation coefficients. †Excluding HLA-DP.

Conclusions: It appears that there is good correlation and agreement between 2 and 4 digit typing for total eplet mismatches at the HLA-A, -B, -C, -DQ and -DR loci. Future research should focus on exploring the clinical significance of total eplet mismatches determined by the two different methods.

Careful deselection of low risk unacceptable antigens can facilitate renal transplantation in highly sensitised patients with excessive time on the waiting list

Stuart Falconer[1], Ann-Margaret Little[2], Graeme Pang[3], Colin Geddes[1], Marc Clancy[1].
[1]Renal Transplant Unit, Queen Elizabeth University Hospital, Glasgow, United Kingdom; [2]Histocompatibility and Immunogenetics, Gartnavel General Hospital, Glasgow, United Kingdom; [3]University of Glasgow Medical School, University of Glasgow, Glasgow, United Kingdom.

Highly sensitised patients wait considerably longer for deceased donor transplantation. Modern histocompatibility testing techniques make it possible to monitor the HLA antibody profile of highly sensitised patients. This creates the opportunity to attempt transplantation against previously sensitising mismatched HLA antigens with a low risk of early, severe rejection. We report our early experience of deselecting low risk unacceptable antigens in highly sensitised patients.
Of 294 patients on the local waiting list, 68 had a calculated reaction frequency (cRF) >95% and 18 had been waiting > 6 years. 17 patients were identified in whom it was possible to de-list previously declared unacceptable antigens by the consultant clinical scientist who carefully reviewed each patient and where antigens were felt to be low risk such as historic weakly positive, or a low mean fluorescence intensity (MFI) <3000 by Luminex, these were deselected as 'unacceptable' for transplantation from the Organ Donation and Transplantation database. All patients who then went on to be transplanted had clinical data such as donor/recipient demographics, renal function, rejection and transplant and patient survival recorded.
There were 11 female and 6 male patients in whom it was possible to deselect unacceptable antigens and 10 patients (76.9%) had a reduction in their CRF as a result. 13 of the cohort subsequently received a transplant between 03 Sep 14 and 19 Oct 2015. Of those receiving a transplant, mean age was 52±11.93 years, 8 had received ≥1 transplant previously and mean waiting list time for this transplant was 10.4±5.4 years. There were 10 DBD, 2 DCD and one live non-directed donor with a mean donor age of 49.92±13.94 years. The HLA mismatch levels were 1 at level 1 (000); 4 at level 2 (0DR and 0/1B) and 8 at level 3 (0DR and 2B) or (1DR and 0/1B). All patients had a negative T and B cell complement dependent cytotoxic crossmatch though 2 patients had positive flow cytometry T cell and B cell crossmatch. 7 patients received a transplant as a result of antibody deselection, transplanted against previously unacceptable antigens, and for 6 deselection made no difference in their offer. Mean cold ischaemia time was 17:09h. All but 2 patients were given rabbit anti-thymocyte globulin induction and all patients received prednisolone, tacrolimus and mycophenolate mofetil maintenance immunosuppression. Of the patients who have not received a transplant yet, 2 have been suspended from the list temporarily and 2 patients are still awaiting transplant. 6 patients (46.2%) had delayed graft function. 3 patients (23.1%) had acute rejection following transplantation, one cell mediated and 2 antibody mediated. One patient died of unrelated causes and maintained transplant function. No transplants have failed. Serum creatinines at day 7, 14, 1 month, 2 months, 3 months and 6 months were 301±229.37, 156±298.84, 145.5±219.46, 162±55.81, 143±45.91, 125±53.25 mg/L respectively.
Highly sensitised patients can benefit from deselection of low risk unacceptable antigens to reduce the cRF and facilitate a transplant. This small study has found such patients to have good early transplant function with a low risk of acute rejection. Longer follow up is required to determine if these higher immunological risk transplants will continue to have adequate function and transplant survival.

C1q/C3d single antigen bead assay only detects high titer/avidity class-I anti-HLA antibodies detected by single antigen beads

Manish Gandhi[1], Nicole Henderson[1], Steven DeGoey[1], Justin Kreuter[1], Ripudamanjit Singh[2], Laurie Wakefield[1].
[1]Division of Transfusion Medicine, Mayo Clinic, Rochester, MN, United States; [2]Mayo Clinic, Rochester, MN, United States.

Introduction: Detection of donor-specific anti-HLA antibodies (DSA) by solid phase assay (SpA) has enhanced donor selection by allowing prediction of the actual crossmatch (xM), a process which is referred to as a virtual crossmatch (VxM). At our center we find good correlation (R2=0.85) between flow xM (FxM) and VxM using single antigen bead (SAB) assay to identify DSA. In addition, we and others have demonstrated better post-transplant outcomes in patients that are transplanted with negative xM. The SAB assay is considered a sensitive SpA; however, a concern is that clinically insignificant anti-HLA antibodies may be detected and preclude the recipient from receiving a transplant. The complement fixing (C1q/C3d) SAB assay's has been proposed as a way to minimize the detection of clinically insignificant anti-HLA antibodies. We present a summary of our evaluation of this assay.
Materials and Methods: 20 positive sera, previously used for serological typing, were tested with SAB, at 1:8 dilution with SAB and by C1q and C3d SAB method as per the manufacturer's protocol. Serological anti-HLA specificities were compared with those that were obtained by SAB, C1q SAB and C3d SAB. For the SAB SpA, specificities >5000 MFI were considered as positive, while specificities >500 MFI were considered positive for C1q/C3d assay. In our center SAB >5000 MFI correlates with a positive flow cytometric xM (FxM) and >10000 MFI correlates with cytotoxicity xM.
Results: In total there were 25 anti-HLA antibody specificities as defined by serology, 354 as defined by SAB, 151 as defined by C1q (figure 1)and 60 as defined by C3d. SAB identified all 25 specificities as defined by serology; C1q identified 22/25 and C3d 15/25 (figure 2). SAB specificities not identified by C1q/C3d had MFI between 5000-10,000. C3d SAB MFI were significantly lower as compared to the C1q MFI
Conclusions: For Class I anti-HLA antibodies, C1q/C3d assay only identify high titer/avidity antibodies as defined by SAB. C1q assay identified more specifcities as compared to C3d assay. As DSA with SAB MFI: 5000-10000 can result in a positive FxM, additional investigation is warranted to determine the clinical significance of these anti-HLA antibodies.

Method	Total Specificities
Serological	25
SAB	354
C1q SAB	151

Regulation of microRNA hsa-mir-663a by HLA class I antibodies in endothelial cells

Omar Moussa[1], Kathryn Twombley[2], Satish Nadig[3], Medhat Askar[4], Titi Srinivas[2], Prabhakar Baliga[3].
[1]Pathology and Labratory Medicine, Medical University of South Carolina, Charleston, United States; [2]Medicine, Medical University of South Carolina, Charleston, United States; [3]Surgery, Medical University of South Carolina, Charleston, United States; [4]Pathology, Baylor University Medical Center, Dallas, United States.

Introduction and Aim: The role of HLA antibodies in endothelial cells signal transduction and transplant vasculopathy is well documented by numerous studies. In the current study, we describe a novel mechanism for HLA class I antibodies in endothelial cell signaling by up-regulating microRNA 663a.
Methods: Cultured human umbilical vein endothelial cells (HUVEC) were grown to 80% confluency in EGM media. Following overnight incubation with growth factor free media, cells were treated with humanized monoclonal antibodies (mAbs) directed to a general epitope of HLA class I antigens (invivogen). Following RNA extraction, samples were subjected to global microRNA analysis utilizing Illumina RNASeq platform. MicroRNA 663a expression levels were validated by Taqman real-time PCR (Applied Biosystems). Expression levels were calculated relative to U6 levels. To determine the serum microRNA 663a levels in patients, total microRNA were extracted from patients with antibody mediated rejection (AMR) and evidence of class I donor specific antibodies (DSA) (n=8) and non-AMR controls (n=6) using miRNeasy Serum/Plasma Kit (Qiagen) followed by Taqman real-time PCR assay.
Results: Treatment of cultured HUVECs with class I HLA antibodies resulted in a 3.6 ± 0.7 fold increase in microRNA 663a compared to control cells. Sera from patients with AMR showed increased relative microRNA 663a levels (45.6±13.1) compared to non-ABMR (20.5±3.4) ($P<0.05$). To further understand the functional role of mir-663a in AMR and endothelial cell signaling, we investigated its potential targets using microRNA databases. The heparin sulfate proteoglycan 2 (HSPG2) which also called Perlecan is known to inhibit smooth muscle cell proliferation and play a role in maintaining vascular homeostasis was found to be a direct target for mir-663a. HSGP2 mRNA levels measured by real-time PCR were found to be down-regulated in endothelial cells treated with HLA antibodies.
Conclusion: The current study describes a novel role played by HLA antibodies in modulating endothelial cell signaling by modulating mir-663a and its target HSPG2. Higher serum microRNA 663a in patients with ABMR could be linked to endothelial cell activation following HLA antibody coupling and could be studied as a mechanistic biomarker in future studies.

Mass cytometry reveals NK cell and T cell subsets in pediatric liver transplant patients with acute rejection

Audrey Lau[1,2], Kelly Haas[1], Todd Shawler[2], Carlos O. Esquivel[2], Olivia M. Martinez[2], Ricardo O. Castillo[1], Sheri M. Krams[2].
[1]Pediatrics, Division of Gastroenterology, Hepatology, and Nutrition, Lucile Packard Children's Hospital/Stanford University, Palo Alto, CA, United States; [2]Surgery, Division of Abdominal Transplantation, Stanford University, Palo Alto, CA, United States.

Introduction: Proper evaluation of the immune status of liver transplant recipients is crucial for appropriate post-transplant management. Current monitoring of graft function relies mainly on non-specific liver enzyme tests and immunosuppressive drug levels without proper assessment of the immune system. Alterations in hepatic enzyme levels can occur for a variety of reasons including acute rejection (AR). Currently the gold standard for diagnosing patients with AR and ruling out other causes of graft dysfunction is liver biopsy. Identifying an immune signature that differentiates patients with AR through a minimally invasive blood test would be preferable.
Materials and Methods: To define an immune signature of AR, we utilized cytometry by time-of-flight (CyTOF, mass cytometry) to comprehensively characterize the peripheral blood mononuclear cells (PBMC) from pediatric recipients of liver allografts (n=11) on conventional immunosuppression (single agent tacrolimus monotherapy). PBMC from patients with biopsy-proven AR prior to treatment (3.8±5.9 years post-transplant, mean age 9.6±8.0 y) were compared to stable pediatric liver recipients (13.0±1.5 years post-transplant, mean age 15.2±4.9 y).
Results and Discussion: Correlation analyses from mass cytometry data was performed using Citrus, a method for unsupervised identification of significant cellular populations, with cell subsets identified using hierarchical clustering of live cells using R. Cells were clustered on the basis of the expression of 22 markers. Significant changes in cell frequency were inferred using the "glmnet" package in R. When the two patient populations were compared, two clusters of significance, a $CD4^+CD5^+CD25^+CD27^+CD44^+$ T cell population and a $CD56^+CD16^+$ NK cell population, were significantly increased in the AR patients as compared to the stable group. Manual gating of the data revealed that $CD3^-CD19^-CD20^-CD8\alpha^+CD16^+CD56^+$ NK cells were significantly increased in the AR group ($p\leq0.05$) and that the NK:$CD3^+$ T cell ratio as well as the NK:$CD4^+CD5^+CD25^+CD27^+$ T cell ratio were significantly increased in the AR group compared to stable patient group ($p\leq0.01$ for both).
Conclusion: Additional studies to further define the phenotype and function of these NK and T populations are necessary. In summary, using mass cytometry, a highly parameterized single cell platform, we have identified that NK cells and a specific T cell subset are significantly increased during AR in pediatric transplant recipients. These results demonstrate the power of mass cytometry to discover significant immune cell populations that may have diagnostic potential.

Pediatric liver transplantation using segmental grafts in Japan: A single-center experience with 270 patients

Koichi Mizuta[1], Taizen Urahashi[1], Yoshiyuki Ihara[1], Yukihiro Sanada[1], Noriki Okada[1], Naoya Yamada[1], Yuta Hirata[1], Takumi Katano[1], Kentaro Ushijima[2], Shinya Otomo[3].
[1]Department of Transplant Surgery, Jichi Medical University, Tochigi, Japan; [2]Department of Clinical Pharmacology, Jichi Medical University, Tochigi, Japan; [3]Department of Pharmacy, Jichi Medical University Hospital, Tochigi, Japan.

Objectives: This retrospective study evaluated the outcome of pediatric liver transplantation (PLT) using segmental grafts at a single high-volume PLT center in Japan.
Patients and Methods: Two hundred and seventy patients (105 males and 165 females, mean age 3.2 years) who received segmental grafts from living donors or split grafts from deceased donors were retrospectively evaluated between May 2001 and January 2016. The causes of liver disease were biliary atresia (n=195), ornithine transcarbamylase deficiency (n=18), Alagille syndrome (n=11), graft failure (n=11), neonatal hemochromatosis (n=6), and others (n=36). The segmental graft type of living donor liver transplantation (LDLT) was determined according to the recipient's body weight and the donor's preoperative CT volumetry. A summary of the surgical technique for LDLT is described as follows: donor graft hepatectomy was routinely performed with intraoperative ultrasonographic guidance without the Pringle maneuver during the parenchymal transection. The graft biliary duct was resected using intraoperative repeated real-time cholangiography. Recipient hepatic vein anastomosis was performed with 5-0 monofilament sutures to completely clamp the suprahepatic and infrahepatic IVC. The portal vein was reconstructed using 6-0 absorbable sutures by adjusting the alignment of the donor and recipient portal veins. Hepatic artery anastomosis was performed using the microvascular technique with 9-0 Nylon sutures. Biliary reconstruction was performed by hepaticojejunostomy using external biliary drainage with 6-0 absorbable sutures.
Results: The recipients received a total of 276 segmental transplants; 275 were LDLT: left lateral segments (S2,3) in 196 (71%), left lobes (S1,2,3,4 or S2,3,4) in 66 (24%), monosegments (S2 or S3) in 13 (5%), and right posterior segment (S6,7) in 1. The patients' parents comprised 96% of the living donors. One donor encountered re-operation due to postoperative abdominal bleeding, and there was no mortality in any of the living donors. Only one patient received deceased donor split liver transplantation with the left lateral segment. The postoperative surgical complications experienced by the recipients were hepatic arterial complications (HAC; 6%), portal vein stenosis (PVS; 12%), hepatic vein stenosis (HVS; 6%), and biliary stricture (BS; 16%). Regarding the graft type, the incidence of HAC (23%) in the monosegment group, the incidence of HVS (9%) in the left lateral segment group, and the incidence of BS (26%) in the left lobe group were significantly greater than those in the other groups. The graft and patient survivals were 93% and 95%, respectively.
Conclusions: LDLT is an effective and irreplaceable treatment for pediatric end-stage liver disease in Japan. However, the surgical complications may differ according to the graft type.

Single kidney transplantation from pediatric donors younger than 3 years to adult recipients

Lan Zhu, Gang Chen, Jipin Jiang, Zhishui Chen.
Institute of Organ Transplantation, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, People's Republic of China.

Background: Traditionally, the criteria of splitting pediatric en bloc kidneys for transplantation into two adults includes: donor age > 3 years, donor weight > 12kg, or kidney length > 6cm. To expand the donor pool, we investigated the feasibility and safety of the single kidney transplantation from pediatric donors younger than 3 years to adult recipients.
Methods: From 2014.9 to 2015.9, a total of 21 single kidney transplants from pediatric DCD (donation after citizen death) donors younger than 3 years (8-26 months) were performed in our center. Almost all recipients were adult patients except 2 children. Here we summarized the outcome of these small single kidney allografts in 19 adult recipients.
Results: The average donor age was younger than 2 years (18.0±6.1m), with 4 donors younger than 1 year. The youngest donor was only 8 months. The average donor weight was less than 12kg (11.6±5.2kg), and the average kidney lengths was about 6cm (6.3±0.6cm). The causes of donor death include intracranial tumor (2 cases), severe congenital dysplasia (2 cases), trauma (5 cases), asphyxiation (1 case), and unknown cause (1 case). The average warm ischemia time was 11.5±4.3min. For the 19 adult recipients, the average age was 30.0±9.6 years and the average body weight was 45.8±6.2kg (38-52 kg). The majority of the patients were female (68.4%), and all except one of these patients were transplanted for the first time. The average follow-up time was 12 months. Delayed graft function (DGF) was observed in 3 patients (16%). Most patients (16/19) had a satisfied urine output immediately after the small single kidney transplantation, however, the serum creatinine levels decreased relatively slower in the early period (Fig 1). The average value of eGFR was steadily increased to normal during the 1year follow-up period (Fig 2). Additionally, only one renal graft developed acute rejection (5%), which was successfully reversed by the treatment of high dosed of steroids.

Fig 1 Allograft function of adults receiving small single pediatric kidneys in the early period

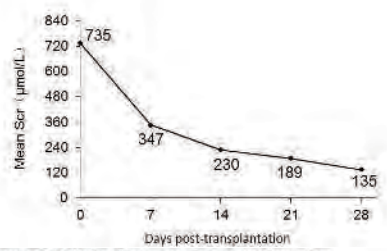

Fig 2 Recipient eGFR during first year after transplantation

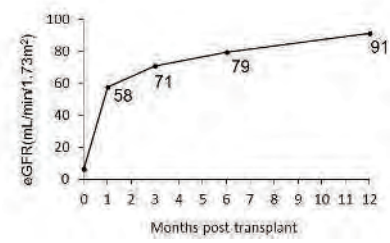

Conclusion: By choosing appropriate adult recipients, excellent short-period transplant outcome can be achieved by using small single kidneys from pediatric donors younger than 3 years, which may represent an important way to expend the donor pool for kidney transplantation.

Overcoming barriers in complex paediatric renal transplantation

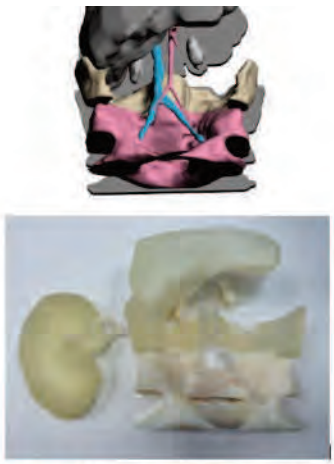
Pankaj Chandak[1], Jelena Stanojovic[2], Nick Byrne[4], Narayan Karunanithy[5], Chris Callaghan[1], Francis Calder[1], Jonathon Olsburgh[1], Martin Drage[1], Geoff Koffman[1], Stephen D.Marks[3], Zubir Ahmed[1], Raphael Uwechue[1], Nizam Mamode[1], Nicos Kessaris[1].
[1]Transplant Surgery, Guy's, Evelina and Great Ormond Street Hospitals, London, United Kingdom; [2]Paediatric Nephrology, Evelina Children's Hospital, London, United Kingdom; [3]Paediatic Transplantation and Nephrology, Great Ormond Street Hospital, London, United Kingdom; [4]Medical Physics and Imaging Sciences, Guy's and St Thomas' and King's College London, London, United Kingdom; [5]Interventional Radiology, Guy's and St Thomas Hospitals, London, United Kingdom.

Introduction: There are increased challenges in transplanting small (<20kg) recipients rendering implantation infeasible or, at best, uncertain. In this context, transplant feasibility is dependent on a multi-disciplinary approach where unconventional interventions may be required. This study evaluates 3 key aspects of transplantation in small children from a large volume combined tertiary UK Paediatric Transplant Centre:
1) A comparative analysis of 350 patients (from 2005-2014) to determine any difference in patient and graft survival in children weighing <20 kg (group1) compared to >20kg (group2) at the time of transplant?
2)Where do we perform graft anastomoses in presence of vascular anomalies?
3)How can we make paediatric transplantation safer? Surgical decisions currently rely on 3D imaging which is limited in evaluating structures by their presentation on 2D screens. As a solution, we assessed the feasibility of using 3D printing technology to fabricate physical models portraying patient-specific anatomy and disease morphology.
Methods: Data was evaluated from a prospectively collected UK Registry (NHSBT) database. We also retrospectively reviewed 5 children with significant vascular anomalies. We prospectivley assessed the value of 3D printing to inform complex transplantation using questionnaires (score 1-5, 1=not useful, 5= very useful).
Results and Discussion: There was no significant difference in graft (p=0.239) or patient (p=1.06) survival between Group1 (<20kg) and 2(>20kg) on Kaplein-Meier analysis. Outcomes for 5 complex vascular cases shown in Fig1. This group had 100% death censored graft survival and median eGFR 46 mls/min/1.73m2 at 10 month median follow up.

Case demographic and vascular issue	Arterial anastomosis site (donor renal artery (RA)→ recipient artery)	Venous anastomosis site(donor renal vein RV→ recipient vein
1. 9yr F, 24 kg : *Mid aortic syndrome- narrowed aorta requiring supra-coeliac to aortic bifucation graft prior to transplant*	Donor RA → Common iliac artery (after inspection of vessels at surgery)	Donor RV→ Common iliac vein
2. 7yr F, 15kg: *Infrarenal IVC occlusion due to recurrent thrombosis*	Donor RA →Aorta	Donor RV→ Suprarenal IVC
3. 6 yr, 18 kg: *IVC occlusion, supra-coeliac- aortic bifurcation PTFE bypass graft for aneurysmal disease aged 2),*	Donor RA→Below aortic PTFE graft just above bifurcation	Donor RV→Left gonadal vein (dilated collateral)
4. 3yr M 14 kg IVC occlusion due to thrombosis	Donor RA→Aorta	Donor RV→Left Ext Iliac vein
5. 17 yr F 34 kg – Mid Aortic Syndrome- narrowed aorta and occluded left iliac artery and common iliac veins	Donor RA→ "bank" deceased donor iliac vessel used as a supra-coeliac aortic conduit to donor artery	Donor RV→IVC

Conclusions: Our large cohort analysis shows transplantation is feasible and safe with comparable outcomes in smaller weight children with respect to graft and patients survival. Furthermore, vascular anomalies do not necessarily preclude transplantation where unconventional anastomotic approaches may be required. Finally, to our knowledge this is the first reported case of using novel 3D printing in paediatric renal transplantation. Our experience proves promising

with clinical translation of these models into the operating theatre, providing the surgical team with full 3D haptic spatial appreciation for making critical decisions – in particular, aiding the accurate placement of adult size donor kidney into the paediatric abdomen.



3D Model Print of the abdomen of a 10.2kg, 2 year old male showing the liver (soft), aorta and IVC and abdominal wall with the bony pelvis (hard) and his father's adult sized kidney. Models used for planning implantation and consenting the family. Prototype design used for segmentation and processing shown above.

Barriers to preemptive renal transplantation in New Zealand children

Madeleine Didsbury[2], Chanel Prestidge[1], Derisha Naicker[1], Tonya Kara[1].
[1]Paediatric Nephrology, Starship Children's Hospital, Auckland, New Zealand; [2]Centre for Kidney Research , Westmead Hospital, Sydney, Australia.

Introduction: All children with end stage kidney disease (ESKD) in New Zealand are managed at Starship Children's Hospital. We have previously shown that our preeemptive transplantation rates are low, particularly in Maori and Pacific children[1]. The National Renal Transplant Service hopes to increase the rates of preemptive transplantation[2].
We aimed to determine if there are modifiable factors for children having dialysis as first treatment, which may allow for an increase in future rates of Paediatric preemptive transplants.
Methods: We conducted a retrospective review off all entries into ANZDATA from Jan 2006 to Dec 2015 for our centre. We collected demographic and ethnicity data, cause of ESKD, and time from first presentation to first treatment with renal replacement therapy (RRT). Late presentation was defined as requiring RRT within 90 days of presentation, excluding neonates. We reviewed whther those who had dialysis first went onto transplantation, and identified all children who had a medical reason for dialysis as a preferential first RRT.
Results: 65 children were identified via ANZDATA. 9 (13.8%) received a preemptive transplant, none of whom were Maori or Pacific children. Demographic data and medical reasons for dialysis are shown in Table One

		Dialysis n=57	Transplant n=9
Median age at first treatment (years)		8 (range 0 - 16)	15 (range 7 - 16)
Ethnicity	NZ European	29 (50.8%)	8 (89%)
	NZ Maori	13 (22.8%)	0 (0%)
	Pacific Island	10 (17.4%)	0 (0%)
	Asian	4 (7%)	1 (11%)
Median time to ESKD from presentation (months)		7 (range 0 - 182)	59 (range 8 - 204)
Medical reasons for dialysis	Active nephrotic syndrome	16 (28%)	
	Weight <10kg	14 (24%)	
	Oncology stand down	2 (3%)	
	Other Immunesuppression	3 (4.5%)	
	High oxalate level	1 (1.5%)	
	No live donor identified prior to ESKD	2 (3%)	
	Lost to follow up	2 (3%)	
	Late presentation	2 (3%)	

Of the 57 children who recieved dialysis initially, 34 had a medical reason that excluded transplant as first treatment in our centre. However 19 children (29%) presented late, with 10 requiring dialysis within 24 hours of presentation. Of these children 13 (68%) had no medical reason that would have excluded transplant with earlier presentation, and 11of the 13 proceeded to a live donor transplant within the following 12 months, suggesting a potential opportunity for a preemptive transplant if CKD had been identified earlier. Within this group of late presentations 12 (63%) had risk factors for CKD (haematuria, proteinuria, short stature, rickets, genetic diagnoses associated with renal disease and past history of AKI) when previously seen in primary/ secondary care.
Conclusion: The rate of late presentation due to delay in diagnosis of CKD is a potentially modifiable factor to increase our rate of preemptive transplants and offer all children with ESKD optimal care. Improved awareness in primary and secondary care may improve this. Additonally we plan to learn more about families' perceptions of their care via future qualitative research to determine if there are other factors which we can address.

Association of C1q fixing donor-specific HLA antibodies with late graft failure in pediatric renal transplant recipients

Alexander Fichtner[1], Caner Süsal[2], Britta Höcker[1], Susi Rieger[1], Rüdiger Waldherr[3], Jens H.Westhoff[1], Anja Sander[4], Gerhard Opelz[2], Burkhard Tönshoff[1].
[1]University Children's Hospital, Heidelberg, Germany; [2]Department of Transplantation Immunology, Institute of Immunology, Heidelberg, Germany; [3]Institute of Clinical Pathology Heidelberg, Heidelberg, Germany; [4]Institute of Medical Biometry and Informatics, University of Heidelberg, Heidelberg, Germany.

Purpose: Because the clinical relevance of donor-specific HLA antibodies (DSA) in non- presensitized patients after renal transplantation (Tx) is currently being debated, we investigated the diagnostic and prognostic value of over-all and complement-binding DSA in pediatric patients undergoing clinically indicated graft biopsies and their association with graft outcome and specific histological lesions.
Methods: Sera of 62 pediatric renal transplant recipients at time of indication biopsy ≥ 1 year post-transplant were assessed for DSA and C1q-fixing DSA by Single Antigen-Bead technology.
Results: Twenty-six patients (42%) were DSA-positive at time of indication biopsy, 9 of the 26 (35%) C1q-positive. At 4 years post-biopsy, patients with C1q-positivity had a strikingly low graft survival (11%) compared to DSA-positive, C1q-negative patients (82%, $p = 0.001$) and to DSA-negative patients (88%, $p < 0.001$). The sensitivity of C1q-DSA positivity for subsequent graft failure was 73%, the specificity 93%. The vast majority (89%) of C1q-positive patients were diagnosed with active chronic antibody-mediated rejection. C1q DSA-positivity (adjusted hazard ratio (HR) 6.35), presence of transplant glomerulopathy (HR 9.54) and estimated glomerular filtration rate at the time of indication biopsy (HR 0.91) were risk factors associated with subsequent graft loss.
Conclusions: The presence of C1q-positive DSA in the context of an indication biopsy identifies a subgroup of pediatric renal transplant recipients with a markedly increased risk of subsequent graft loss. Because a fraction of DSA-positive patients escape rejection or graft dysfunction, the C1q assay markedly increases the specificity of a positive DSA result regarding unfavorable transplant outcome.

Acceptable post-heart transplantation outcomes of children listed in total renal failure

Nassiba Alami Laroussi[1], Manjula Gowrishankar[2], Jennifer A.Conway[1], Paul Kantor[1], Lorie J.West[1], David B.Ross[3], Ivan M.Rebeyka[3], Simon Urschel[1].
[1]Pediatric Cardiology, Stollery Children's Hospital, Edmonton, AB, Canada; [2]Pediatric Nephrology, Stollery Children's Hospital, Edmonton, AB, Canada; [3]Pediatric Cardiovascular surgery, Stollery Children's Hospital, Edmonton, AB, Canada.

Introduction: Renal dysfunction (RD) at heart transplant (HTx) is widely recognized as a poor prognostic factor for survival and post-HTx renal function (RF). There is wide variability of practice in listing patients while depending on renal replacement therapy (RRT). We hypothesized that RD is most frequently pre-renal due to low cardiac output and tends to resolve after HTx. We sought to determine the outcome and long term RF of patients listed for HTx while on RRT.
Methods: This retrospective study included pediatric patients on RRT: (peritoneal dialysis, hemodialysis or hemofiltration) at time of listing for HTx between 2000 and 2014. Data was collected from medical charts and included: RRT pre and post-HTx, mechanical ventricular support pre- and post-HTx and potential risk factors such as ischemic time, donor-recipient size mismatch, HLA-sensitization, ABO-compatibility and concomitant morbidities.
We documented RF by measuring or estimating glomerular filtration rate (GFR) over time until October 2015. GFR was measured by radioisotope, estimated with CKiD formula when cystatin C was available, or Schwartz formula when only creatinine was available.
Results: 12 patients required RRT at time of listing; 11 of which survived to HTx. The median age was 1.1 y ranging [0.01-14.8] at listing, 1.6 y [0.03-15.7] at HTx with a median waiting time of 40 days [1-342]. The primary cardiac diagnosis was congenital cardiopathy in 9/12, myocarditis, dilated cardiomyopathy and ischemic in the 3 others patients. Pre-HTx, they had RRT for a median time of 11 days [3-299]: 7 had continuous hemodialysis/filtration, 3 peritoneal dialysis and 2 both. 9 patients (82%) were on ECMO, 6 (54%) on VAD and 3 patients were highly sensitized prior to HTx (cPRA>50%).
Median post-HTx follow-up of this cohort was 6.4 y [3.3-8.8]. Actuarial post-HTx survival was 90% at 2 weeks, 73% at 1 month, 73% at 6 months, and 55% at 1 and 5 years. One patient was delisted and subsequently died. 4/5 patients died from cardiac failure and one from RD. 2 patients required ECMO for a mean duration of 19 days and one patient required VAD post-HTx. 8/11 patients required RRT for a median time of 17 days [0-240] post-HTx. All survivors were weaned off RRT and most recent mean GFR was 62±9 mL/min/1.73 m2.; which represent mild renal dysfunction (CKD stage II).
Conclusion: RD is associated with a high post-HTx mortality of 45% in our experience, however, death was mainly not due to RF. All survivors recovered RF with only mild impairment in the long-term follow-up.
Dependency on RRT at the time of HTx assessment should not, as a sole factor, preclude patients from being listed.

Contributing factors to transplant medication errors in pediatric patients

Chow Fen Tang[1], Lee Jin Koh[1], U. Mya Than[1], Kar Hui Ng[1,2], Perry Y.W. Lau[1], Min Yie Gong[1], Jolene R.Y.Ong[1], Qiao Zhi Chee[1], Hui Kim Yap[1,2].
[1]Shaw-NKF-NUH Children's Kidney Centre, KTP-National University Children's Medical Institute, National University Hospital , Singapore, Singapore; [2]Paediatrics, Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore.

Introduction: Medication errors which impact on patient safety may result in a significant burden to healthcare systems. Medication discrepancy is the most common type of medication error, and is especially worse with polypharmacy. The aim of this study was to define the factors contributing to medication discrepancies during transition of care between different clinical settings in a Paediatric Renal Transplant Programme.
Materials and Methods: Renal transplant recipients on follow-up at the Shaw-NKF-NUH Children's Kidney Centre, Singapore were recruited. At each patient-provider encounter (in the clinic, on admission to the ward, or on discharge from the hospital), medicine reconciliation was performed to determine the occurrence of medication errors. The medications were reconciled using inpatient and outpatient electronic records, as well as by patient or parental verbal confirmation. A 65-item Medication Regimen Complexity Index (MRCI)[1] was obtained for each patient. The primary outcome was discrepant medicine reconciliation events (DMRE) defined as the presence of any discrepancy in drug name, dose or dosing interval for any drug that the patient was taking in that encounter. Multivariate analysis was performed using binary logistic regression to examine the association between the presence of DMRE and demographic/clinical parameters including age, gender, duration of end-stage renal disease (ESRD), patient educational and socioeconomic status and MRCI. Receiver-operating characteristic (ROC) curve analysis was used to determine the MRCI which could predict the likelihood of occurrence of DMRE.
Results and Discussion: 43 patients (19 males and 24 females), with median age 23.0 years (range 8.3-37.4 years), had medication reconciliation performed at a median of 2 (range 1-6) encounters. The median MRCI score was 41 (range 19-80). In total, medication reconciliations were performed at 95 encounters. 30 (31.6%) of these encounters had DMRE. Of these 30 DMRE, 11 (36.7%) involved immunosuppressive drugs, 10 (33.3%) and 19 (63.3%) were patient- and doctor-related errors respectively. 16 (37.2%) patients had at least one DMRE. In these patients, the median number of DMRE per patient was 1.5 (range 1-4). Binary logistic regression showed that male gender (OR 7.8; 95% CI 1.05-58.14) and higher MRCI (OR 1.08, 95% CI 1.01-1.16) were associated with DMRE. There was no significant association with age of patient, duration of ESRD, and patient educational status. The area under the curve (AUC) for MRCI as a predictive factor for the presence of DMRE was 0.78 (95% CI 0.64-0.92). An MRCI score of 33 predicted the presence of DMRE with a sensitivity of 100%, specificity of 44.4%, positive predictive value of 51.6% and negative predictive value of 100%.
Conclusion: Male patients are at risk of DMRE, especially if the medication regimen is complex with multiple medications and dosing. MRCI was a good screening tool to identify patients at risk of DMRE.

359.9

Cytokine profiles in children after pediatric kidney transplantation with acute cellular compared to chronic humoral rejection and stabile patients

Nadja Borsum, Thurid Ahlenstiel-Grunow, Lars Pape.
Division of Pediatric Nephrology, Center for Child and Adolescent Medicine, Hannover Medical School, Hannover, Germany.

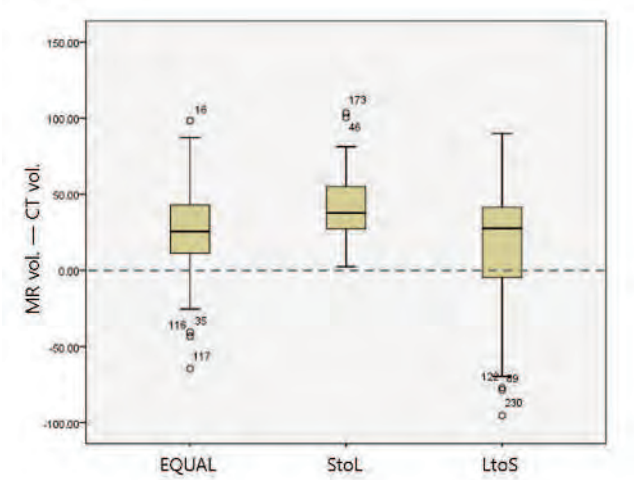
Background: Actually, a diagnosis of acute cellular or chronic humoral rejection after pediatric kidney transplantation (KTX) can only be secured by graft biopsy. Until now, no blood biomarkers have been determined that enable early diagnosis of these two entities. As rejection episodes are associated with an adoption of B- and T-cellular immunity, changes in plasma cytokines can be expected.
Patients and Method: Heparinized blood samples from 24 pediatric kidney transplant patients (11 f, mean age 12.2 ± 4.5 years) were analyzed for interleukin (IL)-2, IL-4, IL-6, IL-10, IL-17A, TNFa und IFNy by flow cytometric analysis (FACS Verse, CBA Human Th1/Th2Th17 Cytokine Kit, BD Biosciences) at time of renal protocol biopsy (6 months after KTX) or indication biopsy. The results of 10 children with acute cellular rejection BANFF ≥ Ia (4 f, mean age 13.8 ± 4.0 years) and 5 children with biopsy proven chronic humoral rejection (3 f; mean age 13.5 ± 3.5 years) have been compared with those of 9 children with baseline creatinine and normal protocol biopsy (4 f, mean age 9.6 ± 4.8 years).
Results: In patients with acute rejection BANFF ≥ 1a, IL-6 concentration was significantly higher (median: 7.85 pg/ml range: 4.87-13.81) than in the control group (median: 3.05 pg/ml range 1.56-5.55, p=0.0007). In contrast, the IL-6 concentration in patients with chronic humoral rejection was significant decreased (median 1.96 pg/ml range 1.03-2.42) compared to the control group (p=0.05) and to the patients with acute rejection (p =0.0007). Measurements of IL-10 concentration showed the same tendency: increased IL-10 concentrations could be detected in patients with acute rejection (median 1.90 pg/ml range: 0.27-20.24 pg/ml, p=0.13) and decreased levels of IL-10 in patients with chronic humoral rejection (median: 0.10 pg/ml, range: 0.00-1.80, p=0.88) compared to the control group (median 0.85 pg/ml, range 0.04-6.86). For IL-2, IL-4, IL-17A, TNFa and IFNy, no differences could be detected between the groups.
Conclusion: The cytokine-analyses in pediatric kidney recipients resulted in elevated levels for IL-6 and IL-10 in children with biopsy proven acute rejection BANFF ≥ Ia compared to controls. In contrast, patients with chronic humoral rejection showed low IL-6 and IL-10 levels. The differences in the IL-6 and IL-10 profile between acute cellular rejection, chronic humoral rejection and controls could be a useful marker to substantiate suspicion of rejection before biopsy.

370.1

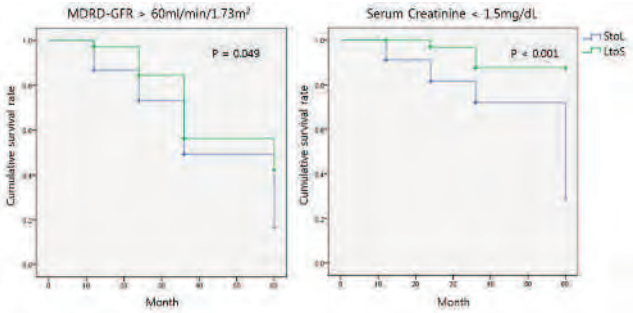
Clinical impact of graft volume change after body weight mismatched kidney transplantation: Based on data of postoperative magnetic resonance volumetry

Mi-Hyeong Kim, Kang-Woong Jun, Hyun-Kyu Kim, Young-Hwa Kim, Kyungjai Ko, Jeong-Kye Hwang, Sang-Dong KIm, Sun-Cheol Park, In-Sung Moon, Ji-Il Kim.
Department of Surgery, College of Medicine, The Catholic University of Korea, Seoul, Korea.

Introduction: Graft volume is an important prognostic factor after kidney transplantation (KT) for representing nephron mass. Optimal graft volume is relative to recipient. Several studies reported preoperative graft volume measurement using CT or MR image, however there is few report about a change of graft volume after KT. We aimed to investigate the change of graft volume after KT between donor and recipient with significant difference in body weight (BW) and to analyze clinical impact of this change.
Methods: We retrospectively analyzed medical records of patients who were undertaken living donor KT, from September 2009 to July 2014. Enrolled patients were divided into three groups according to difference of BW between donor and recipient; EQUAL – BW difference is less than 10kg, StoL (Small-to-Large) – small donor to large recipient with BW difference over 10kg, LtoS (Large-to-Small) - large donor to small recipient with BW difference over 10kg. Donors took CT angiography to evaluate kidney volume preoperatively. We measured real graft weight during the surgery. Postoperative graft volume was assessed using MR angiography at 13th day after KT. To confirm a reliability of MR data, we compared consistency of these three kinds of data and assessed graft volume change after KT among three groups. We evaluated outcome on the basis of MDRD-eGFR > 60ml/min/1.73m2 and serum creatinine < 1.5mg/dl.
Results: Total 236 patients were included this study. CT volume, intraoperative weight and MR volume were well correlated and CT volume was the least and MR volume was the greatest in most cases. The increase of volume between MR and CT, the StoL group was greatest with 41ml, in contrast to EQUAL and LtoS group was 20 and 27ml, and it was statistically significant. (p=0.004 and p<0.001, respectively) The difference of volume between MR and CT had wide variation in EQUAL and LtoS groups with negative and positive values, while every cases of StoL group had positive value (Figure 1).



StoL group, however, had worse graft function than LtoS group in both MDRD-eGFR and serum creatinine (Figure 2).



Discussion: MR angiography can give information about arterial stenosis and perfusion defect which frequently failed to detect by duplex ultrasonography. MR can find complications such as lymphocele and hematoma seated in deep pelvic and retroperitoneal space. This study gives additional information about graft volume, so we planned to investigate usefulness of this data. Gadolinium using MR evaluation is not nephrotoxic but can increase a risk of systemic fibrosis in patient with impaired renal function. We concerned about this, so we checked MR angiography on 13th postoperative day after recipients getting recovered renal function.
Conclusions: Graft volume increment after KT does not mean an increase of renal function, so it is not suitable to estimate graft outcome.

370.2

Long term, single centre experience with simultaneous aortoiliac allogenic reconstruction and kidney transplantation

Tomas Marada[1], Tomas Rohal[2], Libor Janousek[1], Jiri Fronek[1], Ondrej Viklicky[2].
[1]Transplant Surgery, IKEM, Prague, Czech Republic; [2]Department of Nephrology, IKEM, Prague, Czech Republic.

Chronic renal failure is associated with accelerated atherosclerosis. Servere aortoiliac atherosclerosis is often considered to be a relative contraindication for kidney transplantation. In management of those patients should be discussed possibility of simultaneous aortoiliac reconstruction and kidney transplantation. We refer our 18-year experience with aortoiliac reconstruction using fresh arterial allograft and renal transplantation as one-stage procedure.
From 1997 till 2015 we collected data from 15 dialyzed patients treated with aortoiliac arterial reconstruction with simultaneous kidney transplantation. There were 11 men and 4 women with average age 53 +/- 8,6 years. Main reason of renal failure was chronic pyelonephritis (47%). We performed 9 aortofemoral and 6 iliac reconstrunctions with fresh arterial aortoiliac allograft as conduit for consecutive renal transplantation. Mean CIT was 11,8 +/- 4,6 hours. Allograft and kidney graft were obtained from the same brain dead donor. Average age of donors was 33,8 +/- 11 years. Follow up was 2 till 18 years.
Patency of aortoiliac allogenic reconstruction was 100%. 5-year patient survival was 87%. 1 and 5 year graft survival was 87% resp. 73%. Average serum creatinine in 1, 3, 6 months and one year after transplantation was 156, 115, 137 resp. 123 umol/l. DGF was in 2 cases (13%). Lower limb amputation was occured in 2 cases (13%). There was no case of higher limb amputation.
Simultaneous aortoiliac reconstruction and kidney transplantation is safe and useful advance in specific group of dialyzed patients with sever aortoiliac atherosclerosis. Our experiences present succesful surgical treatment of peripheral artery disease and renal failure in one-stage procedure as a chance for patients excluded from an other transplant centres.

Laparoscopic donor nephrectomy: A comparison of retroperitoneoscopic versus transperitoneoscopic approach

Zi Qin Ng[1], Gabrielle Musk[2], Bulang He[1].
[1]WA Liver & Kidney Transplant Service, Sir Charles Gairdner Hospital, Perth, Australia; [2]Animal Care Service, University of Western Australia, Perth, Australia.

Introduction: Laparoscopic donor nephrectomy has become the standard of care for live kidney donors due to multiple benefits. The techniques include Retroperitoneoscopic Approach (RA) and Transperitoneoscopic Approach (TA). The aim of this study is to determine the superiority of RA versus TA.
Materials and Methods: From January 2010 to December 2015, 93 live donor nephrectomies were performed without hand assistance with both techniques. Of 93, 37 were RA (RA group) whereas 56 were TA (TA group). Donor age ranged from 26 to 75 years (mean 51 years). The variables of peri-operative complications, operative time, the kidney warm ischaemic time (WIT) and length of hospital stay (LOS) were analyzed. All patients received patient-control analgesia for the first 24 hours after surgery. Oral analgesia was then administered. All forms of analgesia were converted to a morphine equivalent for comparison. The average recipient age was 40.3 years (2 to 83 years). 49 recipients underwent pre-emptive kidney transplantation. The graft function and urological complications were also analyzed. $P<0.05$ is considered significant.
Results: All donor nephrectomies were completed successfully with no conversions. There was no blood transfusion and no intra-operative complications were observed in either group. There was no significant difference in operating time, graft WIT (5.3±1.5 vs 4±1.3 minutes), LOS (3.5 ±1.4 vs 3.5±1.1) and requirements for analgesia between RA and TA. Three cases developed mild chyle leakage in the RA group and recovered with conservative management. In the recipients, all kidneys were transplanted successfully and followed-up for between 2 and 61 months. There was no delayed graft function or urine leakage in either group. One recipient developed ureteric stenosis in TA group and required surgical urinary tract reconstruction. Both the patient and graft function recovered well. The mean creatinine level of recipients was not different between the two groups at 1, 3 and 12 months post-operatively.
Conclusion: RA delivers the same outcomes for donor and recipient as TA. Most importantly, RA obviates the entrance into the intra-abdominal cavity and disturbance of the bowel. Therefore, it ultimately prevents the potential risk of adjacent organ injury whilst maintaining a virgin abdomen for the donor.

The upper urinary tract urothelial carcinoma behaviors after kidney transplantation in Taiwan

Chia-Shen Chien, Hao Lun Luo, Yen-Ta Chen, Yuan Tso Cheng, Chou Shu Ling, Po-Hui Chiang.
Department of Urology, Kaohsiung Chang Gung Memorial Hospital, Kaohsiung, Taiwan.

Purpose: To determine upper urinary tract urothelial carcinoma (UT-UC) behavior in patients with end-stage renal disease (ESRD) after kidney transplantation (KT).
Methods: From 2005 to 2012, 117 ESRD patients with localized UT-UC underwent nephroureterectomy at our institution. We divide these patients into two groups according to having had kidney transplantation or not. Kaplan Meier survival plot and multivariate analysis were used to evaluate whether kidney transplantation interfered with the UT-UC outcome.
Results: The mean age was younger in ESRD with KT group ($p=0.001$), but there was no difference in gender, smoking, or previous bladder cancer history between these two groups. The pathological features were more aggressive in group 1 compared with group 2 in regard to incidence of carcinoma in situ ($p=0.025$) and multifocality ($p=0.001$). Kidney transplantation did not interfere with the oncological outcome of UT-UC in ESRD patients. There were no differences in oncological outcome. 5-year metastasis free survival rate was comparable.
Conclusions: In our sample, for patients with ESRD after kidney transplantation, the postoperative onset of UT-UC was younger and the pathological features were more aggressive. Standard surgical intervention resulted in satisfactory and similar outcome as did ESRD.

Comparison of baseline co-morbidity and mortality in living donors – 10 year UK cohort study

Nithya Krishnan[1], Lisa Bradbury[2], Neil Raymond[1].
[1]Renal Unit, University Hospitals Coventry & Warwickshire NHS Trust, Coventry, United Kingdom; [2]Statistics, National Health Services Blood & Transplant, Bristol, United Kingdom.

Introduction: Living kidney donation has significantly improved recipient and graft survival world wide. With a move to increase these numbers further, it becomes mandatory to have a better understanding of the long term outcomes and risks of kidney donation.
Aim: To investigate the effect of baseline co-morbidity on all-cause and mortality in kidney transplant living donors – 10 year follow up.
Methods: National Health Service and Blood and Transplant, U.K (NHSBT), obtains informed consent from all patients undergoing a transplant in the UK for continuing data collection and subsequent analyses. The study protocol was reviewed and passed by the Renal Registry (RR) projects advisory group, UK. From January 1, 2001 until December 31, 2013 inclusive, all live kidney donors were included in the study. No formal sample size estimate was produced for the study; all eligible patients records were used. December 31, 2014 was considered the study end, meaning that all patients had at least one year of follow-up. Datasets, based on regular returns from individual transplant centres across the UK, were obtained from NHSBT.
Results: There were 9750 live donor records available. All cause mortality and baseline comorbidity was analysed. 9043 donors had no baseline co morbid condition. The baseline comorbidities analysed were kidney stones (9), microscopic haematuria (9), angina/ischemic heart disease (6), CABG (4), CVA/TIA (5), hypertension (HT) (220), HT on more than 3 medications (1), HT with left ventricular hypertrophy (12). diabetes (2), depression (33), asthma (130), hypercholesterolemia (22) and different BMI bands, BMI <18.5 (82), 18.5 -<25 (3208), 25-<30 (4270), 30-<35 (1449), 35-<40 (158), 40+ (28). There were 48 deaths in total; out of which 2 had baseline HT (2/220), 3 had unspecified comorbidities (3/258) ; and 43 deaths had occurred in the group which had no baseline co-morbidities in the 10 year follow up period. Cox proportional hazards regression modelling, showed no individual baseline comorbidity or "any" combined baseline comorbidity to be a significant predictor of mortality over the follow-up period.
Conclusion: There is no significant association between baseline co-morbidities and mortality in living donors in the 10 year follow up UK cohort study.

370.6

Effectiveness of three-dimensional image analysis for surgical simulation of living donor kidney transplantation with multiple renal artery grafting

Koichi Tomita, Yuki Nakamura, Takayoshi Yokoyama, Naokazu Chiba, Osamu Konno, Yu Kihara, Hitoshi Iwamoto, Shigeyuki Kawachi.
Digestive and Transplantation Surgery, Tokyo Medical University Hachioji Medical Center, Tokyo, Japan.

Background: There are several strategies for the surgical management of kidney transplantation with multiple renal arteries grafting in different institutions. At our center, we have tried to reconstruct as many side arteries as possible, particularly the inferior polar artery that is responsible for ureter perfusion. Small side arteries, which are difficult to reconstruct and perfuse less than 10% of the kidney graft, are sacrificed. However, perfusion areas are based on subjective observations during perfusion in bench surgery. This technique is not very objective and reliable, and there is no available method to evaluate the perfusion area for each renal artery in detail. In the present study, we evaluated the perfusion area of each main and side artery involved in multiple artery kidney grafting using a three-dimensional (3D) image analysis system and determined the validity of the conventional rule regarding the reconstruction of multiple renal arteries at our institution.
Methods: We enrolled 38 consecutive patients who had undergone living kidney transplantation with multiple renal artery grafting. The transplantation procedures were performed at Tokyo Medical University Hachioji Medical Center between 2006 and 2015. All donors underwent dynamic enhanced computed tomography (CT) before transplantation for evaluation of the kidney graft. The CT images were obtained using 64 multidetctor-row CT with a 1.25 mm interval. All CT images were retrospectively analyzed using a 3D image analysis system called Synapse Vincent® (Fuji Medical Systems, Inc., Tokyo, Japan). The volume of the kidney, number of renal arteries, diameter of each artery, and perfusion area for each artery [both volume (mL) and proportion (%)] were assessed in detail. We used the following reconstruction methods: conjoined, side-to-end, individual, simple ligation, or a combination of them.
Results: All grafting procedures were performed using the left kidney of donors. The number of renal arteries was two in 33 patients, three in four, and four in one. The side arteries were classified according to the individual anastomosis method used. There was no significant difference in diameter among the side arteries ($p = 0.062$). The perfusion area for side arteries was statistically equal among the conjoined (42.5 mL, 24.2%), side-to-end (30.8 mL, 18.5%), and individual methods (37.0 mL, 20.5%). On the other hand, the perfusion area for the simply ligated side arteries was 10.3 mL, 6.1%; this was significantly different from the areas obtained with other methods ($p < 0.001$). Considering it was less than 10%, it was concordant with our arterial reconstruction rule. No artery-related complications were observed in our study.
Conclusions: In living donor kidney transplantation, the advantage of using a 3D image analysis system is an accurate visual display of the construction of the renal artery, vein, and ureter and their relationships before surgery. Furthermore, the perfusion area for each artery can be calculated, and the necessity of arterial reconstruction can be predicted preoperatively. These features will promote safe kidney transplantation surgery without complications.

Which is the predictable values of post-transplant HCC recurrence in patients received down staging therapy or bridging therapy?

Seung Hwan Song, Jee Youn Lee, Su-Kyung Kwon, Jae Geun Lee , Juhan Lee, Dai Hoon Han, Gi Hong Choi, Soon Il Kim, Myoung Soo Kim, Myoung Soo Kim, Dong Jin Joo.
Department of Surgery and The Research Institute for Transplantation, Yonsei University College of Medicine, Seoul, Korea.

Introduction: Liver transplantation (LT) is one of the best treatment for small hepatocellular carcinoma (HCC) in patients with liver cirrhosis. However, many patients do not have available donor. For that reason, many patients received the bridging therapy such as TACE, RFA, and surgical resection during the waiting LT. Furthermore, some patients need the down staging therapy for LT. The aim of this study is to evaluate the predictable values of recurrent HCC in patients received other treatment modality before LT.
Methods: The 261 recipients with HCC who underwent liver transplantation between January 2007 and December 2014 in Severance hospital were retrospectively reviewed. Among 261 patients, 189 patients received the other treatment such as TACE, RFA, chemotherapy, and surgical resection before LT.

Study Characteristics	Univariate OR(95% CI)	p-value	Multivariate OR(95% CI)	p-value

PIVKA ≥ 100 at transplantation			
AFP ≥ 200 → AFP ≥ 200			
AFP ≥ 200 → AFP < 200			
PIVKA ≥ 100 → PIVKA ≥ 100			
PIVKA ≥ 100 → PIVKA < 100			

The Results: The mean age of the HCC recurrence group was younger than non-recurrence group (51.2 ± 6.1 vs 54.6 ± 6.9, $p<0.006$). There was no significant difference of the etiology of HCC between the groups. The patients above Milan criteria showed a higher tumor recurrence rate than those within Milan criteria in both diagnosis and transplantation. In univariate analysis, Milan criteria at first diagnosis,

Milan criteria at liver transplantation, AFP≥200 ng/mL at first diagnosis, AFP≥200 ng/mL at liver transplantation, PIVKA≥100 mAU/mL at liver transplantation affected HCC recurrence. In multivariate analysis, Milan criteria at liver transplantation and PIVKA≥100 ng/mL at liver transplantation affected HCC recurrence. (Odds ratio 3.632 and 5.245, respectively)
Conclusion: PIVKA ≥100 ng/mL and Milan criteria at transplantation are predictable value of post-transplant HCC recurrence in patients received down staging therapy or bridging therapy.

371.2

Ischemic cholangiopathy is the only biliary complication that impacts outcome following donation after cardiac death liver transplantation

Shiva Kumar.
Center for Liver Disease & Transplantation, Aurora St. Luke's Medical Center, Milwaukee, WI, USA &, Digestive Disease Institute, Cleveland Clinic Abu Dhabi, Abu Dhabi, United Arab Emirates.

Donation after cardiac death (DCD) allografts offer the potential of increasing the donor pool for liver transplantation (LT). However, their utilization has been limited by concerns regarding increased morbidity and mortality, primarily due to a higher incidence of biliary complications (BC). A wide spectrum of BC has been reported to occur following DCD LT. However, the relative impact of the various types of BC on graft survival is unclear. Our aim was to determine the frequency and relative impact of the various types of BC following DCD LT on graft survival.
Consecutive patients undergoing LT at a single center over a 7 year period from July 2007- Feb 2014 were included in the analysis. All DCD procurements were done by the same team using standard protocol. Patients undergoing DCD LT were compared to those undergoing donation after brain death (DBD) LT during the same period. The following variables were analyzed: donor age, warm and cold ischemic time, recipient age, MELD score, HCV status, presence of hepatocellular carcinoma (HCC). Ischemic cholangiopathy (IC) was defined as diffuse strictures affecting the allograft biliary system in the absence of hepatic artery thrombosis or stenosis. Modeling for the impact of the various types of BC on graft loss was done to evaluate for an interaction between DCD status and BC to see how they influence graft loss. Categorical variables were analyzed using Chi-square test and continuous variables using Student t-test. Time to event comparison was performed using Kaplan-Meier method.
A total of 196 patients underwent LT during the study period. Among these, 61 (33%) underwent DCD LT. The DCD and DBD groups were comparable with respect to all baseline variables, except median MELD at LT, which was higher in the DBD group (22.4 vs. 28; $p<0.01$). Overall 56 (28.5%) patients developed BC. Among DCD recipients, anastomotic stricture (AS; 42.9%) and bile leak (32.1%) were the commonest type of BC. Others included IC (17.9%), biliary cast disease (3.6%) and isolated intrahepatic small duct disease (3.5%).
Using competing risk analysis to determine incidence, there was trend towards higher risk of BC at 1 year among DCD recipients (21.5% vs. 35.3%; $p = 0.10$). Phreg Models looking at impact of BC on predicting graft survival showed that BC was associated with an increased risk of graft loss at 1 year in DCD compared to DBD recipients (DBD 0.9% vs. DCD 7.8%; $p = 0.02$). Overall, patients undergoing DCD LT that developed BC had a nearly 3-fold increased risk of graft loss compared to DBD recipients. (HR (95% CI): 2.97 (1.42-6.23); $p <0.01$). Modeling, using AS as a reference, to examine which types of BC may increase risk for graft loss compared to others, showed that IC was the only type BC associated with risk of graft loss following DCD LT. IC had an almost 4-fold greater risk of graft loss than AS following DCD LT (HR (95% CI): 3.92; 1.19-12.98, $p=0.02$).
Even though there is an increased frequency of BC after DCD LT, only IC appears to adversely affect graft survival. The pathogenesis of IC in DCD LT is unclear and is presumably due to the effects of warm ischemia on the peribiliary vascular plexus. Strategies to lower the likelihood of development of IC could significantly improve outcomes following DCD LT.

371.3

Impact of donation after cardiac death allografts on outcome following simultaneous liver kidney transplantation

Shiva Kumar.
Center for Liver Disease & Transplantation, Aurora St. Luke's Medical Center, Milwaukee, WI, USA &, Digestive Disease Institute, Cleveland Clinic Abu Dhabi, Abu Dhabi, United Arab Emirates.

Extended criteria donors, including donation after cardiac death (DCD) organs, offer the potential of increasing the available donor pool in liver transplantation (LT). Kidney dysfunction is common in patients with liver failure awaiting transplantation. The number of simultaneous liver kidney transplants (SLK) has increased substantially in the MELD era, mandating the consideration of extended donor grafts for SLK, including DCD. Although the use of DCD donor organs has been shown to be a viable option for kidney transplantation, limited data is available regarding outcomes of SLK using DCD donors. Our aim was to compare outcomes following DCD and donation after brain death (DBD) transplantation in patients undergoing SLK and to determine predictors of outcome.

We performed a retrospective analysis of all liver transplants performed over a 7 year period at a single center (July 2007 - Feb 2014), to compare the outcomes of DCD SLK to DBD and determine the impact of donor and recipient factors on allograft and patient survival. The following donor and recipient variables were analyzed: donor age, warm and cold ischemic time, recipient age, MELD score at LT, hepatitis C (HCV) status, and presence of hepatocellular carcinoma (HCC). Categorical variables were analyzed using Chi-square test and continuous variables using Student's t-test. Survival comparison was performed using Kaplan-Meier method and multivariate analysis of predictors of outcome using Cox regression method.

A total of 196 patients underwent liver transplantation over the study period, of which 33 (20.2%) underwent SLK. All DCD procurements were done by the same team of surgeons using standard protocol. Among the SLK recipients, 23 (Group 1) and 10 patients (Group 2) respectively received DBD and DCD allografts. The outcomes of these two groups were retrospectively compared. The DCD and DBD recipients were comparable with respect to age, gender, HCV status, and presence of HCC. The median MELD score was significantly higher in the DBD group (28 vs. 22.4; p less than 0.01). Liver allograft survival was comparable between DBD and DCD LT recipients of SLK (p= 0.82). Estimates for graft survival among the 2 groups were as follows: 1 year (64% vs. 55.6%), 3 years (64% vs. 55.6%) and 5 years (57.6% vs. 55.6%). Although there was a trend toward decreased graft survival among DCD SLK recipients, this did not reach statistical significance. Multivariable and univariate analysis identified DCD recipients > 50 years old of HCV donors as the only predictor of outcome among SLK recipients following DCD LT (Hazard Ratio (95% CI): 5.08 (1.5-17.19); p = 0.0089).

DCD grafts offer the potential to safely expand the donor pool for recipients of SLK without compromising liver allograft and patient survival. Limiting DCD SLK transplants to non-HCV recipients from younger donors may enable further expansion of the donor pool without compromising graft and patient survival. Although long-term outcomes remain unclear, the utilization of DCD organs should be considered a valid approach to safely expand the donor organ pool in the subset of patients undergoing SLK.

Ex vivo subnormothermic oxygenated liver perfusion just before liver transplantation from non-heart-beating donors might improve graft viability, in pig model

Yuta Kakizaki, Shigehito Miyagi, Kenji Shimizu, Hiroyuki Kumata, Muneyuki Matsumura, Yuki Miyazaki, Kengo Fukuoka, Satomi Suzuki Uematsu, Yasuyuki Hara, Chikashi Nakanishi, Naoki Kawagishi, Noriaki Ohuchi.
Division of Advanced Surgical Science and Technology, Graduate School of Medicine, Tohoku University, Sendai, Japan.

Introduction: The shortage of donors has become a big problem. Liver transplantation (LTx) from non-heart-beating donor (NHBD) is an effective way to enlarge donor source. However, primary graft non-function and some complications are often caused. We previously reported that short oxygenated warm perfusion (SOWP) before cold storage improved graft function and survival in rat model of marginal donors. In this study, we investigated the effectiveness of short-term subnormothermic oxygenated perfusion just before LTx from NHBD in pigs.

Objectives: The aim of this study is to investigate the effect of subnormothermic oxygenated liver perfusion just before LTx from NHBDs.

Materials and Methods: White landrace pigs, weighing 25-30kg, underwent LTx. Pigs were divided into three groups: (1) the heart-beating (HB) group (n = 5), whose livers were retrieved from HB donors and after 4 hours cold storage in UW solution, grafts were transplanted; (2) the NHB group (n = 5), whose livers were retrieved 20 minutes after cardiac arrest and after 4 hours cold storage, grafts were transplanted; and (3) the ex vivo liver perfusion (EVLP) group (n = 3), whose livers were retrieved the same manner as the NHB group and after 4 hours cold storage, those grafts were perfused by subnormothermic oxygenated Krebs-Henseleit buffer (room temperature about 25℃, 10-15cmH2O for 30 minutes in dripping manner, not machine perfusion. The grafts were transplanted orthotopically.

Results and Discussion: In the HB group, all five recipients survived for more than seven days but in the NHB group, all five cases died within 24 hours. In the EVLP group, two recipients survived for more than seven days and one recipient survived five days. The survival rate was significantly better in the EVLP group than that in the NHB group (p =0.0082, Kaplan-Meier log-rank test). On the other hand, aspartate aminotransferase (AST) in the EVLP group was significantly higher than that in the HB group until 3 postoperative day (POD), but there were no significant differences between those two groups in 7 POD. On the historical examination, the EVLP group in 7 POD showed well-preserved sinusoidal endothelial cells.

Ischemia-reperfusion injury causes AST elevation in the EVLP group until 3 POD. However, Subnormothermic oxygenated perfusion does not cause graft failure and might be considered to reduce oxygen consumption and allow a minimum level of cellular metabolic activity, which leads to protect sinusoidal endothelial cells and support the recovery of microcirculation.

Conclusion: Ex vivo subnormothermic oxygenated perfusion just before liver transplantation might improve graft function and the survival rate.

ABO incompatible dual graft living donor liver transplantation

Jae Hyun Kwon, Sung-Gyu Lee, Shin Hwang, Ki-Hun Kim, Chul-Soo Ahn, Deok-Bog Moon, Tae-Yong Ha, Gi-Won Song, Dong-Hwan Jung, Gil-Chun Park, Jee Yeon Kim, Min Kyu Sung.
Division of Hepatobiliary Surgery and Liver Transplantation, Department of Surgery, Asan Medical Center , Seoul, Korea.

Introduction: ABO blood group compatibility has been regarded as an essential prerequisite for successful adult LDLT. However, the result of ABO-incompatible (ABOi) LDLT has been remarkably improved owing to novel strategies for overcoming ABO blood group barrier. In this report, we adopted the strategies for overcoming ABO-blood group barrier in dual graft LDLT to cope with ABO-incompatibility and small-for-size graft syndrome.
Method: From January 1, 2008, to July 31, 2014, 17 patients underwent dual graft LDLT by using ABOi and ABO-compatible (ABOc) graft combination and 10 patients received both of dual graft from ABOi donors. Clinical data were collected prospectively and analyzed retrospectively. Regeneration rate of each graft was evaluated and calculated by computed tomography (CT) volumetry.
Results: Mean graft-to-recipient weight ratio (GRWR) was 1.0%. All 17 patients who received combination of ABOc and ABOi grafts were survived and mean follow-up period was 50.3 months. One mortality occured in ABOi dual graft LDLT group during mean follow-up period of 30.6 months. Biliary complications showed no significant difference (p=0.365) between ABOc and ABOi grafts. Regeneration rate of each graft for 1 month, 6 months, and 1 year after transplantation were similar between ABOc and ABOi grafts (p=0.215, 0.158, and 0.340, respectively).
Conclusions: There was no episode of antibody-mediated rejection and biliary complication associated with ABO incompatibility. Dual graft LDLT with ABOi and ABOc graft combination can be the feasible solution for overcoming both ABO-blood group barrier and small-for-size graft syndrome simultaneously.

Inflammation-based prognostic score in living donor liver transplantation for hepatocellular carcinoma

Norifumi Harimoto, Tomoharu Yoshizumi, Shinji Itoh, Toru Ikegami, Hideaki Uchiyama, Tetsuo Ikeda, Yuji Soejima, Yoshihiko Maehara.
Department of Surgery and Science, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan.

Background: Some inflammation-based prognostic score has been attracting attention as a prognostic factor of malignant tumor, such as neutrophils / lymphocyte ratio (NLR), platelet / lymphocyte ratio (PLR), modified Glasgow Prognostic Score (mGPS), Prognostic Nutritional Index (PNI). We previously reported that the NLR is useful to properly assess the patient without decreasing the long-term survival after Living donor liver transplantation (LDLT). We investigated the significance of inflammation-based prognostic score in (LDLT for Hepatocellular carcinoma (HCC).
Methods: Among 213 cases who underwent LDLT for HCC from 1997 until May 2015, 11 cases who died within three months were excluded. Outcomes in 190 patients who has an observation period for more than 6 months were analyzed retrospectively. DFS (disease-free survival) rates after LDLT were calculated, and we divided into the recurrence group and the non-recurrence group and compares NLR, PLR, PNI and mGPS. The risk factors for tumor recurrence were identified in univariate and multivariate analysis.
Results and Discussion: Recurrence we have observed in 28 cases (14.7%). The 1-, 3-, and 5-year DFS rates after LDLT were 92.7%, 85.9%, and 85.1%, respectively. NLR, PLR was significantly higher in the recurrence group. NLR is AUC 0.647, sensitivity 64.29%, and specificity 66.07% of the cut-off 2.66. PLR is AUC 0.704, sensitivity 85.71%, specificity 53.85% of the cut-off 70.44. Univariate analysis showed that DFS was poor significantly prognosis in alpha-fetoprotein concentration ≥300 ng/ml, DCP concentration ≥300 mAU/ml, NLR≥2.66, PLR≥70.44, Platelet count≥4x104/μl, CRP>0.27mg/dl, tumor number ≥5, tumor size ≥5 cm, duration of last treatment of HCC to LDLT <3 months, biolobar distribution and exceeding Milan criteria. Multivariate analysis showed that DCP concentration ≥300 mAU/ml, NLR≥2.66, duration from last treatment to LDLT <3 months were the independent predictor of DFS. Among preoperative factor of inflammation-based prognostic score, NLR was the independent predictor of DFS.
Conclusion: Preoperative NLR in LDLT for HCC is useful as a recurrence predictor.

Significant changes in the organ donor pool over the last 10 years: Donors from anoxic cause of death (COD) more than double which includes a 300% increase in donors with a drug overdose

Richard Hasz, Howard Nathan, Sharon West.
Gift of Life Donor Program, Philadelphia, PA, United States.

Purpose: This study characterizes one OPO's expanding anoxic donor pool and donation outcomes over a 10 year period.
Methods: Characteristics examined: cause (COD) and mechanism of death (MOD), age, sex, race, and driver's license designation status. We also examined the outcomes: potential donors, actual donors, and donation rates (actual donors as a percentage of potential donors identified).
Results:

Potential Donors, Actual Donors & Donation Rates by Cause of Death
2006 vs. 2015

	2006	2015	% Change
Potential Donors*	813	857	+5.4%
Anoxia	264	460	+74.2%
Cardiovascular MOD	***192***	***308***	***+60.4%***
Drug Overdose MOD	***32***	***102***	***+218.8%***
Cerebrovascular/Stroke	348	224	-35.6%
Head Trauma	189	163	-13.8%
Actual Donors*	401	483	+20.4%
Anoxia	104	244	+134.6%
Cardiovascular MOD	***69***	***136***	***+97.1%***
Drug Overdose MOD	***19***	***81***	***+326.3%***
Cerebrovascular/Stroke	175	131	-25.1%
Head Trauma	117	102	-12.8%
Donation Rates	49%	56%	+14.3%
Anoxia	39%	53%	+35.9%
Cardiovascular MOD	***36%***	***44%***	***+22.2%***
Drug Overdose MOD	***59%***	***79%***	***+33.9%***
Cerebrovascular/Stroke	50%	58%	+16.3%
Head Trauma	62%	63%	+1.1%

**Total Potential and Actual Donors Exceeds Sum of Anoxic, Cerebrovascular/Stroke, and Head Trauma. Other Causes of Death, Like CNS Tumors are Excluded*

Potential Organ Donor Demographics (Cardiovascular and Drug Overdose Deaths)
2006 vs. 2015

	Cardiovascular Deaths		Drug Overdose Deaths	
Demographic	2006 n=192	2015 n=308	2006 n=32	2015 n=102
Mean Age	46 Y	50 Y	29 Y	32 Y
Age Range	r=1.5 Y - 75 Y	r=2 Days - 79 Y	r=15 Y - 50 Y	r=18 Y - 68 Y
Standard Deviation	sd=18.8 Y	sd=18.1 Y	sd=9.5 Y	sd=9.8 Y
Sex	Male (54%)	Male (52%)	Male (56%)	Male (61%)
Race	White (69%)	White (64%)	White (81%)	White (85%)
Designation Rate*	20%	27%	24%	46%

**Based on Refererred Potential Only*

Discussion: There has been a significant increase in both the proportion (32% vs 53%) and number (264 vs 460, 74% increase) of potential donors with anoxic COD. Actual donors also increased in similar proportion (26% vs 51%) and volume (104 vs 244, 134% increase). These increases were driven primarily by an increase in cardiovascular (+60%) and drug overdose (+219%) MOD in anoxic potential donors. Conversion rates in anoxic deaths increased from 39% to 53 % over the 10 year period. Additionally a higher conversion rate was seen in drug overdose MOD vs cardiovascular MOD in both time periods. Potential donors with MOD of drug overdose were more likely to be donor designated, Caucasian and younger.
Conclusion: Organ donors from anoxic COD more than doubled in a ten year period and make up the majority of the organ donor pool. OPOs

need to continually evaluate changes in the donor pool to optimize donation outcomes and to effectively manage donors with anoxic COD. Many of the potential donors with anoxic COD are cared for in medical/cardiac ICUs and require intense evaluation due to comorbities such as HTN, diabetes, and PHS high risk behavior. OPO should make continued efforts to increase conversion rates in the expanding pool of anoxic COD potential donors.

372.2

Can knowledge and attitudes of critical care professionals influence organ donation? - A Malaysian perspective

James William Foong Zhi Wei[1], Wei Loon Oo[1], Jea Sheng Ong[1], Mohammad Moshaddeque Hossain[2], Nirmala Devi Baskaran[3], Hasdy Haron[4], Yuzana Yusop[4], Lela Mansor[4], Raghu Varadarajan[1].
[1]Department of Surgery, Perdana University - Royal College of Surgeons in Ireland, Serdang Selangor, Malaysia; [2]Department of Epidemiology and Public Health, Perdana University - Royal College of Surgeons in Ireland, Serdang Selangor, Malaysia; [3]Department of Nephrology, Hospital Kuala Lumpur, Kuala Lumpur, Malaysia; [4]National Transplant Resource Centre, Kuala Lumpur, Malaysia.

Background: Malaysian organ donation (OD) rates are amongst world's lowest. Whether critical care professionals' (CCPs) knowledge and attitudes relate to brain death (BD), OD and organ transplantation (OT) underlie these low rates remain unstudied.
Objective: Whether tertiary hospital CCPs' knowledge and attitudes related to BD, OD and OT influence decision to offer OD to families of BD patients and CCPs willingness to donate organs.
Methods: Doctors and nurses in the emergency & neurology departments and general & neurosurgical ICUs were surveyed using a validated questionnaire containing 25 knowledge and 16 attitude questions. Sociodemographic data were collected. Data analysed using Stata 14.1 to assess whether sociodemographic, knowledge and attitude variables were associated with respondents' inclination to offer OD and their willingness to donate.
Results: 413 (73%) of 565 participants responded; 163 (39%) doctors & 250 (61%) nurses. Inclination to offer OD associated with BD knowledge tertiles, p<0.001. BD knowledge scores in 3rd and 2nd tertiles (higher scores) had higher inclination to offer OD than 1st tertile (95% vs 76% vs 65%, p<0.001). Inclination to offer OD associated with OD knowledge scores, p<0.001. Of 359 CCPs convinced of BD, 79% inclined to offer OD compared with 43% of 7 unconvinced counterparts, p=0.001. Of 324 CCPs who believed OT is a good form of treatment, 82% inclined to offer OD compared to 55% of 31 who did not believe in OT, p<0.001. Of 290 CCPs who would accept an organ themselves, 82% inclined to offer OD compared with 54% of 43 who would not accept an organ, p<0.001. CCPs unsure of whether their religion objected to deceased OD were less inclined to offer OD (OR=0.46, 95% CI, 0.24-0.91, p<0.026). Chinese (96%) had highest inclination to offer OD followed by Indians (90%), Malays (70%), p<0.001.
Willingness to donate was associated with BD knowledge scores (OR 1.21, 95% CI, 1.11-1.31, p<0.001) and OD knowledge score (OR 1.13, 95% CI, 0.99-1.27, p=0.05). Of 358 CCPs convinced of BD, 72.4% were willing to donate compared with 28.6% of 7 unconvinced counterparts, p<0.001. Of 324 (79.2%) respondents who believed OT is a good form of treatment, 236 (72.8%) were willing to donate compared with 15 (48.4%) who did not believe in OT, p<0.001. 289 (70.5%) of all HCWs would accept an organ themselves of which 225 (77.9%) were willing to donate compared with 48.8% of 43 counterparts who would not accept an organ (p <0.001). CCPs unsure of whether their religion objected to deceased OD were less willing to donate (OR=0.23, 95% CI, 0.12-0.46, p<0.001). Indians (89.8%) had the highest willingness to donate followed by Chinese (86.0%), Malays (60.8%, p<0.001).
Conclusion: Among tertiary hospital CCPs, both knowledge and attitude were associated with inclination to offer OD and willingness to donate organs. Efforts to increase knowledge with changes in attitude may improve organ donation rates.

372.3

Eye donation in Hong Kong: attitudes of family members of deceased patients

Allie Lee[2], Amanda Luk[1], Jessie Lau[1], Karen Lam[1], Catherine Wong[1], Victoria Wong[2].
[1]Eye Bank, Hospital Authority, Hong Kong, Hong Kong; [2]Hong Kong Eye Hospital, Hospital Authority, Hong Kong, Hong Kong.

Introduction: Cornea transplantation is important in restoring vision among patients with corneal diseases. In Hong Kong, there has been a long-standing shortage of cornea. Under the Hospital Authority (HA), 465 patients are waiting for cornea transplants as of 2014. However, the annual average of donated corneas were approximately 240 over the last 10 years.
Informed consent from family members of a potential deceased donor is mandatory for eye donation in Hong Kong. To enhance eye donation in Hong Kong, we need to understand patient and family factors contributing to organ donation.
Objectives:
• To describe the trends in familial consent for eye donation from 2008 to 2014
• To understand attitudes of the families: reasons for consent and refusal
• To identify factors affecting familial consent in eye donation
Methodology: This is a collaboration between the HA Eye Bank and the Hong Kong Eye Hospital. Family members of potential donors approached by Eye Donation Coordinators from 2008 to 2014 were included. Reasons for consent and refusal, sociodemographics of the deceased and the family member approached were reviewed. The data acquired was summarized using descriptive statistics. Multiple logistic regression was employed to examine determinants for donation among individuals approached from 2013 to 2014.
Results and Outcomes: From 2008 to 2014, a total of 1740 cases were identified. The overall consent rate was 36.8% and the consent rate did not significantly change throughout the years (p=0.237).
Among families who consented to donation, the most common reason was "the wish to help others" (86.0%), followed by "respect deceased's choice" (12.6%). Regarding reasons for refusal, the most common was "traditional Chinese culture to keep the body intact" (42.7%), and other reasons included communication problems (e.g. lack of expressed wish of the deceased or consensus in the family) and beliefs of the family (e.g. fear of donation bringing more sufferings or disfigurement to the deceased, mistrust of hospital).
Among 628 patients from 2013 to 2014, 22 patients (3.5%) were registered donors and all family members of registered donors consented to organ donation. Moreover, family members of the decreased were more likely to consent to eye donation when the deceased was female (OR 1.47, p=0.03), with a do-not-resuscitate (DNR) order (OR 2.20, p<0.001) and was admitted to oncology or palliative wards (OR 2.12, p=0.05).

Knowledge and attitudes regarding brain death and organ donation among young males in the northeastern Thailand

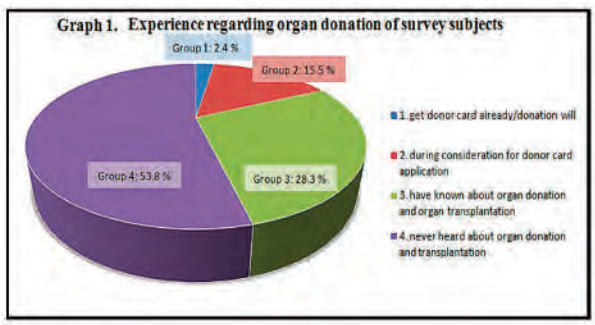
Cholatip Pongskul[1], Jongruk Pongskul[2], Chitranon Chan-on[1].
[1]The Nephrology Division, Faculty of Medicine, Khon Kaen University, Khon Kaen, Thailand; [2]The Organ transplantation unit, Faculty of Medicine, Khon Kaen University, Khon Kaen , Thailand.

Introduction: The organ donation rate in Thailand was remarkably low with only 3.2 deceased donors per 1,000,000 populations in 2015. Public understanding regarding brain death, organ donation and transplantation affects organ donor rates and the peoples' willingness to donate. The northeastern part of Thailand has the highest deceased organ donation rate in the country. However, there has been little research done to determine public perception of brain death and organ donation in this region. So, the answered questionnaires were reviewed to identify any misunderstanding or negative attitudes in local people.
Materials and Methods: The organ donation campaign exhibition was shown in 15 locations throughout 3 provinces in the northeastern Thailand from July 1st to December 31st 2012. This exhibition was arranged by the Organ Transplantation Unit, Faculty of Medicine, Khon Kaen University. The participants were mostly young male government officers were asked to fill out a self-response questionnaire before receiving correct information about organ donation and brain death policy from well-trained officers.

Figure 1. Demographic data and experience regarding organ donation of survey subjects

Table 1. Demographic data

	Number	%
Total subjects	775	100%
Gender		
Male	770	99.4%
Age range		
19-30 years old	769	99.2%
31-45 years old	4	0.5%
46-59 years old	2	0.3%
Education		
1.Lower than master degree	733	94.6%
2 Master degree	41	5.3%
3.Higher than master degree	1	0.1%
Occupation		
1. student	7	0.9%
2. business owner/private	27	3.5%
3. private business employees	47	6.1%
4. bureaucrats/government employee	615	79.3%
5. others	79	10.2%
Marital status		
1. single	690	89.0%
2. married	75	9.7%
3. divorced/seperated	3	0.4%
4. others	7	0.9%



Results and Discussion: There were total 775 subjects who took the survey. 99.4 % were male and 99.2% were between 19-30 years old. Importantly, 54.3% did not feel that brain death truly defined death and 36.3% thought that brain dead patients could recover. 14.8% believed that organ donation could cause disability in the next life and 29.2 % expressed fears that the donated organs may be sold. 26.5 % felt organ

donation is not justified in their religious principles. Critically, our results showed that a high percentage of subject did not trust the donation process, believing it to be a waste of time as well as it might lessen therapeutic willing from physician when the patients turn to the potential donors. Unfortunately, the percentage of subjects in our survey who believed that organ donation could result in organ trafficking (52.7%) was even larger than that shown in the previous survey published in 2002 (34.3%).

Conclusion: While many Thais patients have benefitted from organ transplantation, there is a substantial number of people who has a chance to be organ donors still lack of knowledge about the process, which forms a significant barrier to organ donation.

The development and management of China Organ Procurement Organization Alliance

Qifa Ye[1], Xiaoli Fan[1], Yanfeng Wang[1], Francis Delmonico[2], Marti Manyalich[3], Shusen Zheng[4], Jiefu Huang[5].

[1]Zhongnan Hospital of Wuhan University, Wuhan, People's Republic of China; [2]New England Organ Bank, Waltham, United States; [3]Barcelona University, Barcelona , Spain; [4]Zhejiang University, Hangzhou, People's Republic of China; [5]Peking Union Medical College Hospital, Beijing, People's Republic of China.

For the purpose of implementing the Regulations on Human Organ Transplantation and the Regulations on Procurement and Distribution of Organ Donation promulgated by National Health and Family Planning Commission of China (NHFPCC) in August 2013, promoting China Donation after Citizen's Death (CDCD) and realizing healthy, ethical and scientific development of organ transplantation, the National Organ Donation and Transplantation Committee (NODTC) establishes China Organ Procurement Organization Alliance (COPO). COPO strictly abide by the Regulations on Human Organ Transplantation and regulations on organ donation and transplantation; devote itself to industrial management of Organ Procurement Organization (OPO) and scientific norms of CDCD and transplantation, and guarantee that citizen's organ donation is the only source of organ transplantation. COPO is divided into seven regions based on the current situation and geographical factors of organ donation and transplantation in China. COPO responsibilities including: work out the trial measures for industrial norms and scientific management of organ procurement and living related organ procurement; work out a scientific rescue procedure of CDCD donor, a scientific quality assessment system of donated organs and formulate scientific norms of organ procurement; organize industrial experts to work out admittance criteria of OPO staff, OPO responsibilities, application qualifications of OPO medical institute, necessary facility standards of OPO operation and formulate OPO development and quality control standard; organize experts to account necessary costs of organ donation and procurement, and work out charging standard of principle and guidance fee; work out scientific norms and management measures of coordination and operation between OPO and transplant hospital, as well as service scope of OPO and operation code and norms of transplant hospital. A scientific OPO function and management mechanism has been found in China. Medical institute with organ transplantation qualification shall sign a contract with an OPO-qualified medical institute. OPO shall be responsible for organ procurement and ensure that the transplant hospital has priority in using the organ donated, and the transplant hospital shall pay related costs on organ donation and procurement to OPO. Besides, OPO shall sign an agreement with potential organ donation medical institutes and pay for the costs on donor's rescue and maintenance to medical institutes of successful organ donation. Until 2016.01.29 in China, 65837 citizens have registered to be donation volunteers; 16707 organ failure patients have been cured by the organ retrieved from the 6171 successful donation cases. COPO is playing an important role in management of organ procurement in China and prompt the work of China organ donation after citizens' death.

Outcomes of kidney transplantation using kidneys from expanded criteria donors and donors with acute kidney injury in Thailand

North Techawathanawanna.
Kidney Transplant Institute, Praram 9 Hospital, Bangkok, Thailand.

Background: Deceased-donor kidney transplantation using kidneys from expanded criteria donors and donors with acute kidney injury are increasingly utilized in many countries, including Thailand, due to organ shortage. The short-term and long-term outcomes in our country are still not well described.
Methods: We reviewed our database of cadaveric kidney transplants from January 1997 through December 2015, comparing the outcomes of transplantation of kidneys from expanded criteria donors (ECD group, 41 cases), donors with acute kidney injury (AKI group, 63 cases) and standard criteria donors (SCD group, 42 cases). Baseline characteristics of donors and recipients were correlated with short-term and long-term graft function.
Results: One-year graft survivals were 92.68%, 100%, and 100% in ECD, AKI, and SCD group, respectively. Mean five-year estimated glomerular filtration rates were 40.83, 55.29, and 58.99 ml/minute in ECD, AKI, and SCD group, respectively. Risk factors for decreased graft survival included the ECD group and the number of hemodialysis sessions required within the first few weeks after transplantation. Risk factors for decreased glomerular filtration rate included the ECD group, and age of the donor.
Conclusions: Kidneys from donors with acute kidney injury can potentially be used for transplantation with equivalent outcomes to standard criteria donors. ECD kidneys had satisfactory but inferior short-term and long-term graft outcomes.

373.1

Expression of three allogeneic MHC Class I in recipient liver significantly prolongs survival of fully-allogeneic vascularised cardiac allografts

Mamdoh Moawadh[1], Moumita Paul[1], Eithne Cunningham[1], Chuanmin Wang[1], Szun Tay[3], Sharon Cunningham[3], Grant Logan[3], Ian Alexander[3], Patrick Bertolino[2], David Bowen[2,3], Alex Bishop[1], Alexandra Sharland[1].
[1]Transplatation Immunobiology, The University of Sydney, Sydney, Australia; [2]Liver Immunology Group, Centenary Institute, Sydney, Australia; [3]Gene Therapy Research Unit, The Children's Hospital Westmead, Sydney, Australia.

Background and Aim: In previous studies, AAV-mediated gene transfer of a single mismatched donor MHC class I molecule (K^d or K^b) to C57BL/6 or B10.BR recipient liver respectively induced tolerance to skin grafts expressing the same mismatched MHCI molecule. However, such survival is not extended to fully mismatched skin or heart grafts. Tolerance induction may require expression of all mismatched MHC molecules (3 class I and 2 class II). To facilitate expression of multiple MHCI in recipient liver, we created a construct in which the three d-haplotype heavy chains D^d, L^d and K^d were separated by an F2A linker (DaLeK), and then determined the effect of administration of this vector upon heart graft survival.
Methods: DaLeK was packaged into a liver-specific rAAV2/8 vector. Fully-allogeneic hearts from DBA/2 (H-2d) were transplanted into C57BL/6 (H-2b) at either d7 or d14 post-inoculation.
Results: Administration of $5x10^{11}$ vector genome copies AAV-DaLeK to C57BL/6 mice yielded strong expression of Dd, Ld and Kd on hepatocytes. Expression was enhanced by co-transduction with a vector encoding β2 microglobulin, ALT levels remained normal and no inflammatory infiltrates were detected. Survival of DBA/2 hearts transplanted into AAV-DaLeK treated mice was prolonged from a MST of 7 days to 23 days. Administration of a control vector did not alter survival (figure). Rejected grafts showed a mixed inflammatory infiltrate with damage to blood vessels but without cardiac myocyte necrosis. Cardiac myocytes of DBA/2 hearts express only class I whereas vascular endothelium expresses MHC class I and II.
Conclusion: AAV-DaLeK permits expression of multiple MHCI from a single vector, and its administration significantly prolongs survival of fully-allogeneic heart transplants. A combination of AAV-DaLek with vectors expressing CIITA and/or allogeneic MHC class II may produce tolerance to fully-allogeneic grafts.

373.2

Heightened expression of HLA-DQB2 and HLA-DPB1 genes in pre-implantation kidney biopsies is associated with poor graft function

Karina L.Mine[1], Tuíla B.Mourão[1,3], Larissa A.Salzedas[1], Érika F.Campos[1], José O.Medina-Pestana[2,3], Hélio Tedesco-Silva[2], Maria Gerbase-DeLima[1,3].
[1]Immunogenetics Institute, AFIP - Associação Fundo de Incentivo à Pesquisa, São Paulo, Brazil; [2]Hospital de Rim e Hipertensão, Fundação Oswaldo Ramos, São Paulo, Brazil; [3]Universidade Federal de São Paulo, São Paulo, Brazil.

Introduction: In a previous gene expression microarray investigation in pre-implantation biopsies (PIB) from kidneys of deceased donors (DD) we showed, for the first time, association between increased expression of HLA class II genes in PIB and poor graft function at 1 year post-transplant (1y post-Tx). This study was conducted in 51 PIB, with the GeneChip® Human Gene 1.0 ST Array, Affymetrix, and the expression of all HLA class II genes, but particularly of HLA-DQB1 (p=0.0001), DQB2 (p=0.0003) and DPB1 (p=0.0007) was higher in PIB of grafts that presented eGFR (estimated glomerular filtration rate, calculated with the abbreviated MDRD formula) < 58.9 L/min (median value for the group) at 1y post-Tx. In the present study, we sought to validate, in a different cohort and by quantitative PCR (qPCR), the relationship between expression of HLA-DQB1, DQB2 and DPB1 and poor graft function.
Materials and Methods: This prospective single-center study included 38 PIB from transplants with DD, performed in 2014 and 2015, in low immunological risk adult recipients who received triple immunosuppressive therapy (a calcineurin inhibitor combined with prednisone and either azathioprine or mycophenolic acid) plus induction with thymoglobulin. The 19 transplants with eGFR < 51.0 mL/min (median of the group) at 6 months post-Tx comprised the poor graft function group. The expression of HLA-DQB2 and HLA-DPB1 was determined by qPCR (TaqMan® assays, Applied Biosystems). HLA-DQB1 expression could not be tested due to the lack of TaqMan® assays able to detect transcripts of most of the HLA-DQB1 alleles. The TATA-binding protein (TBP) gene was used as internal control. Relative expression units (RU) were determined with the 2-Δ ΔCt method and were compared by the Mann-Whitney test.
Results: Both genes presented higher expression in cases with 6-month eGFR < 51.0 mL/min: 2.82 vs 1.01RU, for HLA-DQB2, p=0.04; 1.57 vs 1.00 RU, for HLA-DPB1, p=0.008.
Conclusions: Since there was a highly significant correlation (Spearman correlation test, p=1.55e-007) between the eGFR at 6 months and at 1 y post-Tx in the patients that were included in the previous microarray study, we considered that we have validated the results even if we had to use, in the present cohort, the graft function at 6 months as the end-point, since not all the patients had reached the 1-y post-Tx follow-up at the time of this analysis. A particularly interesting finding of our work was the confirmation of the differential expression of HLA-DQB2, a poorly polymorphic gene, with unknown function, and whose expression has only been so far described in epidermal Langerhans cells (Lenormand et al, 2012). The increased expression of HLA-DPB1 in PIB as an early marker of poor later graft function is consistent with the assumption that heightened expression of HLA genes contributes to increase allograft immunogenicity and consequently affects the long-term graft function and survival.

373.3

Improving perfusion fluid for the next generation of transplants: Identifying agents that lower cellular oxygen consumption and reduce tissue hypoxia

Abul Siddiky, Pavitra Kannan, David Grimes, Thomas Ashton, Ruth Muschel.
CRUK/MRC Centre for Radiation Oncology & Biology, University of Oxford, Oxford, United Kingdom.

Introduction: As the need for transplantation increases, the boundaries of what is a marginal organ is being pushed further back. The development of appropriate perfusion fluid has greatly helped in maximising available organs through reducing the effects of unavoidable tissue hypoxia. We believe we can improve this further.
Materials and Methods: Four colorectal cancer cell lines (COLO320DM, DLD1, HCT116 and HT29) and a non-transformed cell line (MRC5) were investigated. Clonogenic and cytotoxicity assays of a range of agents were used to determine sub-lethal concentrations. The oxygen consumption, mitochondrial and glycolytic function of treated cells were assessed with the XF96 Analyser. Flow cytometry, gene array, western blot and high-performance liquid chromatography (HPLC) were performed to delineate mechanisms of action. The most responsive cell lines and promising agents were progressed to spheroids for 3D hypoxia modelling and then advanced to in vivo and radiosensitivity testing. In vivo tissue hypoxia analysis was achieved with the in vivo imaging system (IVIS).
Results: The oxygen consumption of all cell lines were markedly reduced with a number of the agents. DLD1 and MRC5 cell lines showed the greatest balance of toxicity resistance and reduction in oxygen consumption. Hypoxia imaging of the subsequent spheroids further demonstrated a reduction in hypoxia consistent with drug induced decrease in oxygen consumption. This was further replicated in the xenografts resulting in improved radiosensitivity (see Figure 1).

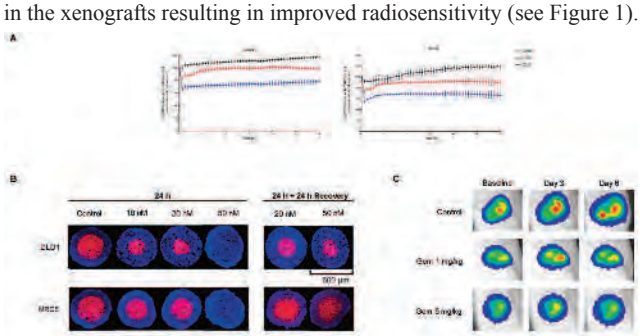

Figure 1. Sub-therapeutic doses of gemcitabine can lower OCR and improve tissue hypoxia in spheroids and in vivo as seen on IVIS. A. Oxygen consumption rate for gemcitabine in DLD1 and MRC5 human cell lines. B. Hypoxia staining of normal spheroid sections for HP5 (red) with Hoechst as a counterstain (blue). C. Representative IVIS images of subcutaneous DLD1 human tumour bearing luminescence (red) in nu/nu mice (mice). Treatments were administered by i.v. via I.P. injection. Each group had at least 6 mice and entered into study once tumour volume reached 80 mm³. Error bars represent standard error.

Discussion: A variety of agents originally identified through our studies on improving tumour hypoxia have shown a reduction in oxygen consumption in malignant and non-malignant cells alike, which has been demonstrated to lead to an increase in oxygen availability and hypoxia improvement. This has been shown in monolayer and 3D in vitro models. We hypothesise that by reducing cellular oxygen consumption, cells will be able to withstand hypoxia for a greater period of time and thus lengthen the preservation period. If the data shown in our work in cancer can be replicated in the transplant setting, we can potentially increase the donor pool by enhancing the preservation period of an organ. Ultimately, this will help reduce the waiting time for patients and improve morbidity.
Conclusion: The preservation period of an organ can potentially be increased through using agents that reduce oxygen consumption. This will improve graft function and increase the donor pool.

Long-term survival of human stem cell-derived insulin producing cells (SCIPCs) transplanted to the subcutaneous space in a diabetic murine model

Steven Wisel[1], Gaetano Faleo[1], Holger Russ[2], Ryan Chang[3], Tejal Desai[3], Matthias Hebrok[2], Qizhi Tang[1].
[1]Division of Transplantation, Department of Surgery, University of California, San Francisco, San Francisco, United States; [2]Diabetes Center, Department of Medicine, University of California, San Francisco, San Francisco, United States; [3]Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, United States.

Introduction: Recent improvements in stem cell differentiation protocols now allow for reliable production of human Stem-Cell-derived Insulin-Producing Cells (SCIPCs), which mimic the functional properties of human beta cells and represent an unlimited supply of cells for the treatment of Type 1 diabetes. Selection of an appropriate transplant site will be important for human translation, favoring a site which allows for graft monitoring and retrievability in the case of cell de-differentiation and tumor formation. The subcutaneous space provides ease of graft monitoring and an abundance of space, but prior pre-clinical efforts have demonstrated poor graft survival attributable to the relative hypoxia of the subcutaneous tissue. Our group has demonstrated long-term survival of subcutaneous SCIPC transplants. We have also attempted to induce prevascularization of the islet bed prior to SCIPC transplantation by pre-implantation of a thin-film polymer disc, to further optimize graft survival.

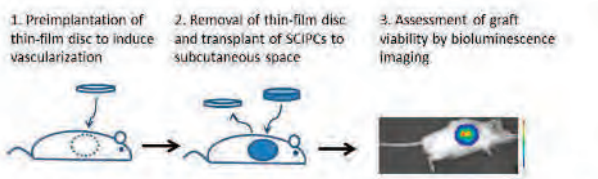

Figure 1. Schematic of transplant site prevascularization (1), SCIPC transplantation (2), and evaluation of SCIPC viability (3).
SCIPC: Stem Cell-derived Insulin Producing Cells

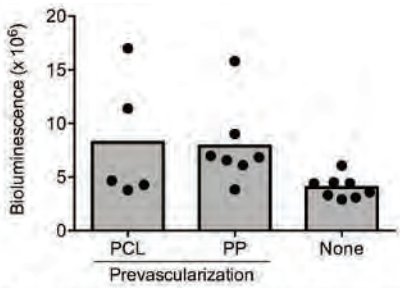

Figure 2. Graft viability at 28 days post-transplant to pre-vascularized sites, as measured by SCIPC luciferase bioluminescence.
SCIPC: Stem Cell-derived Insulin Producing Cells

Materials and Methods: Prevascularization of a subcutaneous transplant site was achieved by implantation of a 1.5cm-diameter polycaprolactone (PCL) or polypropylene (PP) thin-film disc to the dorsum of NSG mice for a duration of 10-21 days. At time of transplant, thin-film discs were explanted and 2-3 million SCIPCs were delivered to prevascularized sites (PCL = 6, PP = 6) or to naïve NSG mice as controls (n=3; Figure 1). SCIPCs were differentiated as described previously[1], with constitutive expression of firefly luciferase by this reporter line allowing for in vivo real-time bioluminescence imaging of viability. SCIPC grafts were serially imaged for viability up to 6 weeks post-transplant for evidence of graft viability.
Results: SCIPCs transplanted to the subcutaneous space showed long-term viability, as assessed by luciferase bioluminescence imaging. Prevascularization of the subcutaneous space with PCL or PP showed a trend toward improved graft survival (p=0.058 and 0.087, respectively), while no significant difference was seen between use of PCL versus PP thin-film discs for prevascularization (p= 0.690).
Conclusion: Prevascularization of the subcutaneous space by pre-implantation of a thin-film polymer disc may improve SCIPC viability as one mechanism to overcome the hypoxic milieu of the subcutaneous space. Studies are ongoing to further optimize graft survival and to assess impact of prevascularization on graft function.

Secretory leukocyte proteinase inhibitor: A biomarker for acute kidney injury has a protective role in kidney transplantation

Nella Ambrosi[1], Julia R.Rocamora[1], Ana Dotta[3], Diego Guerrieri[1], Fiorella Caro[1], Francisco Osella[3], Juan Salaberry[1], Francisco Sánchez[1], María del Carmen Rial[3], Claudio Incardona[2], Domingo Casadei[3], Eduardo Chuluyan[1].
[1]CEFYBO, Facultad de Medicina, Universidad de Buenos Aires, CABA, Argentina; [2]Fundación Gador, CABA, Argentina; [3]Fundación Argentina de Trasplante de Organos y Tejidos 3er Milenio, Instituto de Nefrología de Buenos Aires, CABA, Argentina.

Secretory leukocyte protease inhibitor (SLPI) is a serine protease inhibitor produced mainly by epithelial cells. It has anti-inflammatory and antimicrobial activity, and enhances wound healing. Recently, it has been proposed that SLPI could be a novel biomarker for acute kidney injury[1]. In fact, we have found that kidney transplanted patients had higher serum values compare with healthy donor ($p < 0.0001$).
The aim of the present study was to assess a putative activity of SLPI on human kidney epithelial cells and lymphocyte proliferation. First, the activity of SLPI on kidney epithelial cell apoptosis was determined by *in vitro* culture human proximal tubular epithelial cell line (HK-2) under serum starving conditions or by treating the cells with FK506, in the presence of SLPI (40 ng/ml). Apoptosis was examined by flow cytometry with annexin V/propidium iodide and MTT assays. Either FK506 or serum starving conditions induced a high degree of apoptosis. However, when cells were incubated with SLPI, the apoptosis induced by both treatments were statistically reduced in both apoptosis assays. Next, lymphocyte proliferation were assessed by culture human peripheral blood mononuclear cells (PBMCs) derived from healthy dnors or kidney transplant patients. Cell proliferation was induced with phytohemagglutinin (PHA), in the presence or absence of SLPI for 5 days. Then cells were labeled with 3H-thymidine, harvested and counted in a beta-counter. Cells derived from either healthy donors or transplanted patients, treated with PHA + SLPI showed lower proliferation index compared with those treated with PHA alone.
These results prove that SLPI has a protective role on epithelial kidney cells and favors the immunossupresive activity by decreasing lymphocyte cell proliferation. Furthermore, we can speculate that the objective of high level of SLPI observed in transplant patients tend to both protect the kidney cells from the noxa and control the immune response in order to reduce the kidney injury by the allogeneic immune response.

Expression of CXCR3 by islet-infiltrating memory T cells in the pancreas transplant with recurrent type 1

Francesco Vendrame[2], Ivan Gerling[3], Alberto Pugliese[1,3,5], Linda Chen[4], George Burke[4].
[1]Diabetes Research Institute, University of Miami, Miami, United States; [2]La Jolla Institute of Allergy and Immunology, La Jolla Institute of Allergy and Immunology, La Jolla, United States; [3]Medicine, Division of Diabetes, Endocrinology and Metabolisim, University of Tennessee Health Science Center, Memphis, United States; [4]Surgery/Miami Transplant Institute, University of Miami Miller School of Medicine, Miami, United States; [5]Medicine, Division of Endocrinology and Metabolism, University of Miami Miller School of Medicine, Miami, United States.

Clinical studies link memory T cells with type 1 diabetes (T1D). A recent trial in new onset patients has shown preserved insulin secretion in those treated with a drug that targets memory T cells. In initial studies we have shown a considerable frequency of memory T cells in the insulitis lesions of pancreata from SPK (simultaneous-pancreas-kidney) transplant recipients (79-83%), nPOD organ donors with T1D (23-54%) and autoantibody-positive, non-diabetic donors (10-60%). Gene expression studies of laser-captured islets showed increased expression of the chemokines CXCL9 and CXCL10. Therefore, we have begun to investigate whether islet infiltrating memory T cells expressed CXCR3 receptors, which bind these chemokines. For this proof of concept study we examined pancreas sections from nPOD donors 3678 (SPK, recurrent T1D) and 6070 (T1D, 7 years duration). We stained sections by multiple immunofluorescence for insulin, CD3, CD45RO and CXCR3. Insulitis lesions (CD3+ cells >15/islet) were identified in both the SPK and nPOD cases, which contained CD3+CD45RO+ memory T cells; a significant proportion of the memory T cells stained for CXCR3. Fig. 1 shows an example of an infiltrated pancreatic islet from T1D donor 6070 (panel A, 52.5% of the CD45RO+ CD3 T cells stained for CXCR3) and T1DR SPK recipient 3678 (panel B, 88% of the CD45RO+ CD3 T cells stained for CXCR3). In this preliminary study we show memory T cells infiltrating the islets expressed CXCR3. This finding supports the concept that the expression of CXCL9 and CXCL10 ligands by the islets, as shown previously, leads to the recruitment of CXCR3 positive memory T cells. We are currently completing studies on additional 3 SPK and 6 nPOD (T1D or autoantibody-positive donors) for an initial quantifying of CXCR3 expression. Of note, in related studies of SPK recipient with T1D recurrence, we find increased peripheral blood frequency of autoreactive memory CD4 T cell expressing CXCR3. Thus, if confirmed in additional studies, CXCR3 may become a target for immune intervention to antagonize islet autoimmunity.

Fig. 1: INSULIN-CD3-CD45RO-CXCR3 staining in a pancreas section from A: nPOD donor 6070 (20x); B: SPK recipient 3678 (40x)

Knowledge and attitude of people towards end-stage kidney disease, kidney transplantation and kidney donation: Opinion from a developing country

Palash Mitra[1,2], Muhammad A.Rahim[1], Mohammad A.Mansur[1,2].
[1]Nephrology and Dialysis, BIRDEM General Hospital, Dhaka, Bangladesh; [2]Transplant Unit, BADAS, Dhaka, Bangladesh.

Introduction: Organ transplantation is the most preferred treatment modality for end-stage kidney diseases (ESKD). The success of transplantation program depends on knowledge, awareness and positive attitudes. Our aims of this study were to assess the knowledge and attitudes of the people including physicians and other health care related professionals (HCPs) about ESKD, it's treatment options and their views towards kidney transplantation.
Methodology: This cross-sectional survey was conducted from July to December 2015, among trainee physicians and other HCPs of four tertiary care hospitals and adult people seeking general health care service as outpatients in two rural areas of Bangladesh. Data were recorded in preformed semi-structured forms. Data was analyzed using SPSS version 20.
Results: Among the 1312 participants, physicians were 17.7%, other HCPs 22% and general people 60.3%. Male: female was 1.1:1. Participants were from urban (74.4%) and rural (25.6%) areas with an educational background of higher secondary (HSC) or less in 36% and above HSC in 64%. Overall 65.8% had knowledge about ESKD and its' treatment options. About 90% thought that kidney transplantation is the best treatment option and live related donor renal transplant (LRDT) is better (58%). Chance of better function and survival of donated kidney (48.8%) and easy to convince both the recipient and donor (50%) was the benefit of LRDT. Unavailability of suitable donor was marked (42.7%) by the participants as the main disadvantage of LRDT. Only 43.3% participants were agreed to donate kidney and the rest had fear of developing renal failure (40.2%) after donation as well as non-cooperation of the other family members (33.7%). They were positive (53%) for cadaveric or deceased donor kidney transplant, as a brain dead person can donate two kidneys (72%). But 50% thought that the concept of cadaveric kidney donation is still not well accepted and 45% believe that there is religious barrier. There is no significant difference of opinions between the physicians or other HPCs or general people except there is significant difference regarding motivation of kidney donation (p=0.001 and p=0.000). The rural people's knowledge regarding ESKD and treatment options are significantly (p=0.000) less than the urban people and also significantly (p=0.000) less motivated for kidney donation and deceased donor kidney transplantation. Though the awareness about ESKD, its treatment and motivation for kidney donation is significantly less (p=0.000) among the respondents with educational background of HSC or less but there is no significant difference (p=0.126) of opinion regarding deceased donor kidney transplantation among the persons with higher educational background.
Conclusion: In spite of high level of awareness about ESKD, kidney transplantation and donation, a high proportion of the participants did not have positive attitudes towards kidney donation. We will have to address their misconceptions and fear about kidney transplantation and donation to continue a successful kidney transplant program in a developing country like ours.

Development of a deceased donor program in New Caledonia through an international hybrid model

Nicolas Quirin[1], Fadi Haidar[1], Caroline Mesguen[1], Jean-Michel Tivollier[1], Jean-François Cantin[1], Cedric Formet[1], Yves Doussy[1], Frederic Touzain[2], Veronique Biche[5], Hervé Lecoq[4], Charbel Sandroussi[3], Richard Allen [3], Josette Eris[3].
[1]Nephrology, CHT de Noumea, Noumea, New Caledonia; [2]HLA laboratory , CT de Noumea, Noumea, New Caledonia;
[3]Transplantation, Royal Prince Albert Hospital, Sydney, Australia;
[4]Intensive Care, CHT de Noumea, Noumea, New Caledonia;
[5]Transplant coordination, CHT de Noumea, Noumea, New Caledonia.

Introduction: New Caledonia (NC) is a French Territory located 2000 Km from Sydney and 17000 km from France and has 266767 inhabitants. It has the fifth highest worldwide prevalence of ESRD at 2407 pmp. There are 514 patients on dialysis. Living donor transplantation is available both in France and Sydney for NC patients. In the absence of a living donor, transplantation access had until 2013 been dependent on relocation of the individual to France to be waitlisted. This was not a feasible option for many. Thus to enable transplantation access for all suitable recipients the implementation of a deceased donation program in New-Caledonia was required.
Aims and Methods: The aim was to establish a deceased donation and retrieval program in NC with subsequent transplantation of NC kidneys to NC recipients being undertaken in Sydney.
Firstly, brain death legislation was enacted in NC in accordance with French and New Caledonian laws. The French "Agence de la Biomedecine" standards of organ retrieval and organ allocation were implemented in NC. A tissue typing laboratory was established in NC in 2010. Transplant clinicians from Royal Prince Alfred Hospital (RPAH) in Sydney assisted in recipient assessments in NC and with initial retrieval surgery. Collaboration at all levels (clinical, administrative, government) addressed issues of customs, logistics of air transportation and surgery in order to deliver an acceptable cold ischemic time. Two matched recipients were transported with each set of donor kidneys to Sydney for transplantation. The results of this international collaborative model (2013-2015) are reported.
Results: 40 patients were initially waitlisted in November 2012 and assessment clinics are undertaken twice a year. The first retrieval occurred in April 2013. 39 brain dead patients have been evaluated to date leading to 9 procedures and 8 retrievals (1 in 2013, 5 in 2014 and 2 in 2015). Donation rates were 3,72 pmp, 18,6 pmp and 7,4 pmp in 2013, 2014, 2015 , respectively. Consent refusal rate was 50%, medical and administrative reasons accounted for 29 % not proceeding; resulting in a mean retrieval rate of 21%.
16 recipients received kidney transplants in Sydney with a mean cold ischemic time of 15 hours [11h – 22h]. Time for return trip for the RPAH retrieval team was a mean of 10 hours. Immediate graft function was observed in 78 % of cohort. Recipients returned to NC after 8 weeks. Patient and graft survival to date is 94 % (one death with a functioning graft from infection at 12 months).
Conclusion: This novel international medical collaboration model of transplantation has delivered access to deceased donor transplantation for New Caledonians unable to relocate to France. Similar collaborations should be explored to enable access to high standard ethical transplantation programs for isolated communities.

Success transformation of organ donation system brings positive feedback to donation manner of medical frontiers in China

Nga-Lei Tam[1,2], Wen-Feng Xie[2], Xiao-Sun He[2].
[1]Department of surgery, The Hong Kong University- Shenzhen Hosptial, Shenzhen, People's Republic of China; [2]Organ Transplantation Center, The First Affiliated Hospital of Sun Yat-Sen University, Guangzhou,, People's Republic of China.

Introduction: China has initiated the donation after cardiac death (DCD) pioneer programme since 2010 and nationally enforced on 1st January 2015. Organs from DCD donors has thus officially become the only deceased organ for transplantation. The donation manner of ICU staff, the frontier to approach the potential DCD donors, reflects the success transformation of organ donation.
Method: A questionnaire survey was designed for the attendees in both ICU and OPO (Organ procurement organization) conferences in July to December, 2014 and 2015. A 12 multiple self choice questionnaires were facilitated and immediately collected. Demographic data and the participants' recognition, participation, as well as their acquaintance of organ donation procedures were recruited.
Results: In 2014 and 2015, a total of 1099 and 734 questionnaires were collected and 1079 and 675 were available, respectively. The awareness of DCD was 88.5% in 2014 and 96.0% in 2015. There were 13.5% attendees have been participated in DCD activity in 2014 whereas 61.3% in 2015. Among these 2 years, 8.8% and 48.0% of them owned correct DCD criteria, policies and procedures, while 76.6% and 86.1% expressed willingness of future DCD activities participation. In 2014, unfamiliar to the donation policies and procedures obstructed most of the donations. In 2015, the main barrier of DCD work was selected to the fierce conflict between medical workers and patients. The enforcement of DCD population and organ donation law were most recommended to improve donation success in whole survey.
Conclusion: It has been a half decade since the launch of DCD programme and full enforcement last year. The ratio of DCD awareness and participation, as well as the correct DCD concept has obviously improved by the organ donation system enforcement. The establishment of organ donation law is still to ensure the transformation of organ donation system.

Organ donation and transplantation in Montenegrin population

Marina Ratkovic, Branka Gledovic , Danilo Radunovic , Vladimir Prelevic , Batric Babovic , Elvir Mucic .
Nephrology and Hemodialysis Department , Clinical Center of Montenegro , Podgorica, Montenegro.

Introduction: In Montenegro there was no transplantation program until 2012. The transplantations were performed abroad; 15% in areas of black organ markets. The first kidney transplantations from living donors were performed in September 2012. Until now 25 kidney transplantations from living related donor were performed. Legislation was finalized in 2012. Montenegro is young country with many traditional attitudes. Death in is followed by numerous customs and represents one of the greatest sociological phenomenon in our society. Until now only one deceased donor has been realized. The attempt to legally provide presumed consent was not adopted by the Parliament in 2014. Less than 300 citizens took donor card.
Materials and Methods: We organized a public survey, about the attitudes of population on organ donation. It was conducted by team of physicians, renal nurses and medical students. It was anonymous and conducted in public places and in different institutions like University, medical institutions and other organizations. This was the biggest survey in this topic ever done in Montenegro.
Results and Discussion: The survey covered 6000 respondents, 48% male, 52% female, with the highest number in the age group between 30 – 50 years. The largest number of respondents was with higher education (58%), 36 % with secondary and 6% with elementary education. The highest proportion of respondents belongs to the Orthodox religion, 63%, 20% belong to the Islamic, 10 % to Catholic, and 2% were atheists and others. 45% of respondents said they would like to be deceased donors, but 52% had negative attitude. Among respondents with positive attitude, 80% would donate any organ, and 20 % answered that they would donate only few organs. 70% of respondents were only partially informed about the legal regulations. Only 20% of respondents had some experience in this area. 96% of respondents said that there are no enough information about organ donation in public media. In the last question respondents wrote the main problems they recognized: lack of information, lack of interest, religious dogma, fear and distrust. We made a stratification of respondents by age, gender, religious affiliation and level of education, but we found no statistically significant differences in answers in any group.
Conclusion: Despite great effort of activities, discrepancies still exist counted prejudices and open issues that need to be systematically considered in order to raise the number of deceased donors and deceased transplantation rate.

374.5

Comparison of cost and quality of life outcomes (qol) in hemodialysis patients and renal transplant recipients

M. M. Iqbal[1], S. Iqbal[2], R. M. Hossain[3], S. K. Saha[2], S. F. Islam[3], A. A. Chowdhury[4], M. A.W. Khan[5].
[1]Nephrology, SSMC&MH, Dhaka, Bangladesh; [2]Nephrology, BIRDEM, Dhaka, Bangladesh; [3]Nephrology, BSMMU, Dhaka, Bangladesh; [4]Nephrology, NIKDU, Dhaka, Bangladesh; [5]Nephrology, Square Hospital, Dhaka, Bangladesh.

Introduction: Outcome and patient benefits in different types of renal replacement therapies (RRT) are often debated and compared on the basis of cost involvement and finally improvement in quality of life (QoL) parameters. In this work cost and QoL of maintenance hemodialysis (MHD) and the renal transplant recipient (RTx) is compared.
Materials and Methods: The MHD and RTx subjects were selected from a number of tertiary renal care facilities where patients were initially on hemodialysis and later some opted for transplantation. The quality of life was assessed by KDQOL-SF 36 v1.3. The MHD patients were on bicarbonate dialysis and majority getting 3 sessions/week. Renal function was stable at the time of evaluation in RTx subjects and they were taking prednisolone, cyclosporine/tacrolimus and mycophenolate mofetil/azathioprine.
Results and Discussion: The RTx recipients (n=40) and MHD subjects (n=80) were matched for age as 36±8 vs.39±8, years, (p=NS).The score of major items in general health related scale evaluated by short form (SF36) among these 2 groups respectively showed that general health score 62±20 vs. 39±16; physical functioning 90±17 vs. 57±25; role physical 62±54 vs. 24±43; emotional well being 73±35 vs. 46±12; social function 91±16 vs. 42±29 and energy/fatigue 55±15 vs. 42±12; ($p<0.001$).The physical component aggregate was 75±22 vs. 48±21 and for mental component 68±20 vs. 51±16, ($P<0.001$). These results showing a persistently higher score in RTx subjects than those on MHD. On the other hand the estimated annual maintenance cost of 3 drug regimen in RTx was approximately US$ 2000 where as for MHD the standard cost for only dialysis service was around US$5000.
Conclusion: It is concluded that renal transplantation is by far the best option of renal replacement therapies. It is cost effective and undoubtedly provides superior quality of life over hemodialysis which as is evident from higher score in all items of QoL parameters in this study. Therefore transplantation should be emphasized in the economically disadvantaged less developed nations having the advantage of larger family structure.

401.1

Are women in transplant leadership roles judged more harshly than their male colleagues?

Nithya Krishnan[1], Deborah Biggerstaff[2], Neil Raymond[1], Monica Dolton[3], Hillary Braun[4], Sondra Livingston[5], John Hattersley[1], Josette Eris[6], Nancy Ascher[4], Robert Higgins[1], Kathryn Wood[3], Ala Szczepura[7]. [1]Renal Unit, University Hospitals Coventry & Warwickshire NHS Trust, Coventry, United Kingdom; [2]Psychology, University of Warwick, Coventry, United Kingdom; [3]Transplantation Research Immunology Group, University of Oxford, Oxford, United Kingdom; [4]Transplantation , University College San Francisco, San Francisco, CA, United States; [5]The Transplantation Society, Montreal, QC, Canada; [6]Transplantation , University of Sydney, Sydney, Australia; [7]Health Technology Assessment, University of Coventry, Coventry, United Kingdom.

Introduction: Despite the introduction of many positive changes aimed at helping women who work in medicine to flourish, the number of women holding senior leadership roles are a minority across many specialities. Research from other professions has found that when women do reach senior positions they appear to be judged more harshly and are more likely to fall from their position of seniority, the 'glass cliff effect'.
Aim: To explore any engendered differences in participants' perceptions and their views on potential wrong decisions by senior medical transplant staff, using hypothetical clinical scenarios in an online survey.
Methodology: The study was a prospective web-based survey involving five clinical scenarios, with either a male or female protagonist (Set1 and Set2). Each scenario was followed by two questions regarding the clinical performance. Respondents were invited to comment on their reasoning. Data were analysed using thematic analysis. To ensure elimination of any inherent biases in responses the survey was advertised as a study exploring whether adequate actions are taken following adverse clinical incidents in transplantation. Participants were recruited by advertising through the websites of various professional bodies. Individuals were randomly assigned to either Set1 or Set2 questionnaires, with each Set receiving the same scenarios in the same order, differing only in whether a male or female protagonist was mentioned.
Results: 102 participants provided further explanation and comments on the clinical performance. Themes identified included: issues of informed consent and acceptable risk; clinical judgement; systems errors; consensus among clinical teams; training issues; mentoring; and judgements as to whether appropriate actions had been taken at the time. Participants' described male protagonists as "forceful individual"; "maverick who ignores his colleagues" or, "one who has "cautious colleagues". Meanwhile, female protagonists were described using slightly different, more nuanced characteristics like competency; mentoring; training needs; need for supportive senior colleagues; or as having 'saved the day'. However, when things went wrong, participants were more likely to opine that female protagonists should not have gone ahead. Risk was perceived by respondents to be a more male leadership trait.
Conclusions: The quantitative survey showed no significant differences between the sets but the thematic analysis of participants' comments provided evidence of a subtle and nuanced use of language; where those traits identified in male leadership being viewed and described differently to those applied to women leaders. While gender may no longer be such an issue as in the past, respondents' use of language and their choice of words display elements of an engendered description. These findings suggest that the 'glass cliff" effect may still be a problem in transplantation but has become subtle and therefore, may not be so easily identified in the workplace.

The impact of ritonavir-boosted protease inhibitors and non-depleting antibody induction on outcomes in HIV-infected kidney transplant recipients

Brett Rollins, Susan Lerner, Meenakshi Rana, Shirish Huprikar, Leandra Miko, Vinay Nair, Sander Florman, Ron Shapiro.
Mount Sinai Hospital, New York, United States.

Introduction: One-year rejection rates in HIV-infected kidney transplant recipients range from 15-40%, compared to overall rejection rates of 10% in HIV-negative patients. Protocols for immunosuppression and highly active antiretroviral therapy (HAART) regimens in this population vary substantially among transplant programs. The potential for significant drug-drug interactions, specifically between ritonavir-boosted protease inhibitors (rtv+ PI) and calcineurin inhibitors, and the choice of induction therapy may influence outcomes.
Materials and Methods: This is an IRB-approved, single center, retrospective study of adult HIV-infected patients with a kidney transplant performed between 5/2009 to 8/2014 with one-year follow up for each patient.
Results and Discussion: 36 patients were identified with a median age of 52 (interquartile range [IQR] 46, 57) years. 78% were male, 53% were African American, 19% were Caucasian, and 17% were Hispanic. The most common cause of renal failure was hypertensive nephrosclerosis (51%) followed by HIV-associated nephropathy (17%), and the median duration of pre-transplant dialysis was 6.2 (3.2, 8.9) years.
All patients received IL-2 receptor antagonist (IL-2 RA): 81% with basiliximab and 19% with daclizumab induction. One patient also received thymoglobulin. Calcineurin inhibitor therapy included tacrolimus (75%), cyclosporine (19%), or transitions between these two (6%). 44% of patients received a rtv+ PI-based HAART regimen.
Overall one-year patient and graft survival was 94% and 92%, respectively, and the mean serum creatinine was 1.35 (1.21, 1.80). Treated biopsy-proven rejection within one year was 33% for the overall cohort; 44% for patients on rtv+ PI and 25% for patients on other HAART regimens (p=0.29).
Conclusion: Despite high rates of acute rejection, HIV+ kidney transplant recipients have excellent outcomes. Though not statistically significant (likely related to the small number of patients), higher rejection rates were observed in the rtv+ PI group. Future studies should evaluate whether thymoglobulin induction is associated with lower rejection rates compared to IL-2 RA induction.

420.2

Trends in immunosuppressive medication use among hemodialysis patients with failed kidney transplants in Europe, Australia, New Zealand and North America: results from the dialysis outcomes and practice patterns study

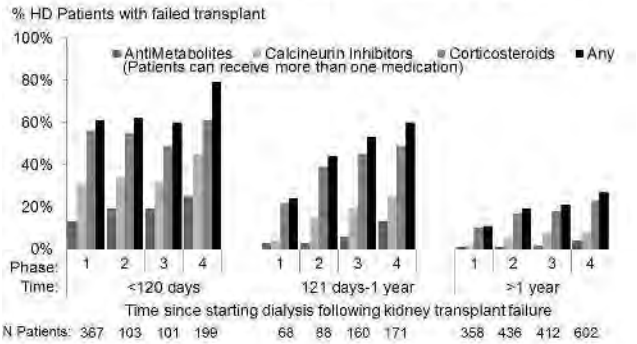
Jarcy Zee[1], Maria Larkina[1], Bruce M. Robinson[1], Francesca Tentori[1], Joan Fort[2], Richard J. Fluck[3], Hal Morgenstern[4], Alan B. Leichtman[1]. [1]Arbor Research, Ann Arbor, MI, United States; [2]Hospital Vall d'Hebron, Barcelona, Spain; [3]Royal Derby Hospital, Derby, United Kingdom; [4]University of Michigan, Ann Arbor, MI, United States.

Kidney transplant recipients who experience transplant failure and transition to dialysis typically are discontinued from their immunosuppressive medications (IM). However, the optimal timing of discontinuation is unknown and practices vary. Early IM discontinuation is undertaken with the intention of avoiding infections and other adverse effects from IM use; whereas, later IM discontinuation may prevent human leukocyte antigen antibody sensitization and need for graft nephrectomy. We used data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) to investigate trends in the timing of IM withdrawal among hemodialysis (HD) patients following kidney transplant failure.

DOPPS is a multinational prospective cohort study of HD patients ≥18 years of age. For the current study, we assessed DOPPS enrollees in Australia, Belgium, Canada, France, Germany, Italy, New Zealand, Spain, Sweden, United Kingdom, and United States in four study phases: Phase 1 (1996-2001), Phase 2 (2002-04), Phase 3 (2005-08) and Phase 4 (2009-2012). A total of 3065 patients with a history of a failed kidney transplant and information about medication prescriptions were included. The percent of patients at time of enrollment receiving antimetabolites (azathioprine, mycophenolate mofetil, or mycophenolate sodium), calcineurin inhibitors (cyclosporin or tacrolimus), and oral corticosteroids (prednisone, prednisolone or methylprednisolone) were calculated by study phase and the time since initiation of dialysis after transplant failure.

From DOPPS Phase 1 to Phase 4, the percent receiving any IM increased from 61% to 79% for those patients within 120 days after transplant failure, from 24% to 60% for patients 121 days to 1 year after transplant failure, and from 11% to 27% for patients >1 year after transplant failure. The percentage of patients maintained on each class of IM also increased from DOPPS Phase 1 to Phase 4 (Fig). Corticosteroids were the most commonly used IM across phases and at any time after transplant failure, followed by calcineurin inhibitors and antimetabolites. IM prescription also varied across countries, 2 fold among patients <1 year since transplant failure, and 5 fold among patients >1 year since transplant failure.

Increasing use over time of immunosuppressive medications in dialysis patients with failed kidney transplants



In Europe, Australia, New Zealand and North America, there has been a temporal trend towards longer use of IM in patients with failed kidney transplants who have transitioned to dialysis. Corticosteroids remain the most commonly used IM, but prolonged calcineurin inhibitor and antimetabolite use are also more common. Studies are needed to determine whether longer periods of immunosuppression following kidney transplant failure result in lesser degrees of sensitization and fewer graft nephrectomies, or alternatively in higher rates of infections or other complications, and whether outcomes are dependent on the choice of maintained IM.

420.3

Long term outcomes of highly sensitized kidney transplant recipients

Jude Yagan[1], Anil Chandraker[2], Colm Magee[2].
[1]Nephrology, Organ Transplant Centre, Kuwait, Kuwait;
[2]Nephrology, Brigham and Women's hospital, Boston, MA, United States.

Aim: To follow the clinical outcomes of 45 highly sensitized patients who had undergone a desensitization protocol prior to kidney transplantation, and report the incidence of complications, allograft survival, and patient survival.
Methods: We conducted a retrospective review of 45 kidney transplant recipients transplanted between 9/2002 and10/2011, who had a positive T or B cell complement dependent cytotoxic (CDC) crossmatch assay. B cell CDC crossmatches were confirmed with a solid-phase assay to determine presence of class II anti-HLA antibodies.
Results: All subjects completed a desensitization protocol of plasmapheresis, intravenous immunoglobulin, +/- rituximab to render a negative T cell crossmatch or a negative or weak titer B cell crossmatch 24 hours prior to transplantation. Post-transplant all recipients received antibacterial and antiviral prophylaxis; allograft biopsies were performed when clinically indicated. The mean and median follow-up was 5 years. Thirty-three subjects (73%) suffered acute rejection of the allograft, 30 (67%) occurred in the first year post-transplant, and 27 (60%) occurred in the first month post-transplant. There was 1 case of hyperacute rejection necessitating transplant nephrectomy. Twenty-nine of the 33 (88%) were cases of acute antibody mediated rejection. BK viremia occurred in 7 patients (15.5%), leading to graft loss in 3. There were 5 patients that suffered multiple pneumonias, 5 cases (11%) of bacteremia, 1 case of fungemia, and 4 patients (8.8%) with cytomegalovirus infection. There were no cases of lymphoproliferative disease, although 1 patient developed an aggressive cutaneous angiosarcoma and died. There was also one case of renal cell carcinoma, and 4 cases (9%) of skin malignancies. The 1, 3, and 5 year allograft survival was 87%, 76%, and 68% respectively. The 1, 3, and 5 year patient survival was 93%, 91%, and 84% respectively.
Conclusion: Patients with a positive CDC crossmatch that are transplanted after a plasmapheresis-based desensitization protocol have high rates of acute rejection and infectious complications. Despite increased rate of rejection and over-immunosuppression, patient and graft survival in the desensitized group is comparable to the 1, 3, 5 year survival (graft: 89%, 78%, 67% respectively; patient: 95%, 90%, 85% respectively) of recipients of repeat transplants from living donors.

420.4

Use of mobile internet application to improve adherence to immunosuppressive medication adherence in kidney transplant recipients: preliminary results of the PRIMA (ImPRoving Adherence to Immunosuppressive Therapy by Mobile Internet Application) study

Ahram Han, Min-Ji Cho, Sungshin Cho, Chang Hwan Lee, Chanjoong Choi, Song-Yi Kim, Hyejin Hong, Sanghyun Ahn, Seung-Kee Min, Sang-Il Min, Jongwon Ha, Sang Joon Kim.
Department of Surgery, Seoul National University College of Medicine, Seoul, Korea.

Background: Nonadherence to immunosuppressive medication after renal transplantation is critical in terms of graft and patient outcome. The goal of this study was to determine whether usage of mobile application can improve adherence to calcineurin inhibitors.
Methods: Renal allograft recipients aged 15-70 years old, who were at least 12 month post-transplant, and on tacrolimus or cyclosporine based immunosuppressant regimen were enrolled. The internet based mobile phone application for androids providing alarm reminders at the time of dosing, data logs, and medication information (e.g., dosages, adverse effects, toxicities) was developed for this study. Patients were randomly assigned either to the mobile application (MA) group or the control group. The MA group were educated to use mobile phone application. Adherence were assessed with medication event monitoring system (MEMS), and self-reported surveys [Basel assessment of adherence to immunosuppressive medications scale (BASIS), visual analog scale (VAS)] in both group. The primary outcome was proportion of participants with adequate adherence (≥ 80% of prescribed doses taken by MEMS) during the 6 month trial. The study is ongoing and we hereby report the preliminary results of 124 participants; the complete data of 138 patients will be available at the meeting.
Results: Among 124 participants, 45 (36.2%) were male, 70 (56.4%) received a kidney from a living donor, and 103 (83%) had high education (more than high school education). The proportion of patients with adequate adherence did not differ between the MA group and the control group (74.1% vs. 66.1%, P=0.360). Similarly, there was no between-group difference in the adherence by MEMS as continuous variable (median 96.2%, IQR 20.8 vs. median 92.5% IQR 29.0, P=0.243) or adherence measured using the BASIS (at 6 month, 56.8% vs. 43.8%, P=0.192) or VAS scale (at 6 month, 41.2% vs. 50.0%, P=0.378). Proportion of adherent patient by self-reported surveys tend to increase at 1 month after study participation, but the improvement was not sustained at 3 or 6 months.
Conclusion: Six month intervention with mobile phone application was not associated with significant difference in adherence to immunosuppressant in patients with renal transplantation.

420.5

Characterization of genetic variation influencing pharmacokinetics of once-daily tacrolimus formulation by next generation sequencing technologies in Korean

Song-Yi Kim[1], Min-Ji Cho[1], Sungsin Cho[1], Chang Hwan Lee[1], Seonghae Yoon[2], Ahram Han[1], Chanjoong Choi[1], Sanghyun Ahn[1], Sang-il Min[1], Seung-Kee Min[1], Injin Jang[2], Sang Joon Kim[1], Jongwon Ha[1].
[1]Surgery, Seoul National University College of Medicine, Seoul, Korea; [2]Clinical Pharmacology and Therapeutics, Seoul National University College of Medicine, Seoul, Korea.

Therapeutic drug monitoring (TDM) is highly recommended for Tacrolimus (Tac) formulation and is currently baased on the measurement of blood trough concentrations after dosing. Pharmacogenomics has rapidly emerged as an additional tool to refine dose selection and to select the first dose to administer. CYP3A5*3 (rs776746) has been clearly demonstrated as a main genetic factor influencing Tac dose-adjusted trough blood concentrations. CYP3A4*22 (rs35599367), although to a lesser extent, has been also shown to influence Tac dose-adjusted trough blood concentration. However, a significant amount of variation still exists. In an effort to identify genetic variants associated with pharmacokinetic variation in once-daily tacrolimus (Advagraf®), we evaluated genotypic effect using DMETTM Plus Array.
The genotypic effect of the drug metabolism/transporter on the pharmacokinetic characteristics of Advagraf® was explored in 25 Korean de novo kidney transplant patients. The target genes for analysis was the drug absorption, distribution, metabolism and elimination related enzymes (ADME) and transporters. The 1,836 single nucleotide polymorphism (SNP) and 5 copy number variations (CNV) were evaluable after removing the variants, which were homozygous in (nearly) all samples. The Full AUC data were obtained around 10 days after transplantation. We tested for possible associations between ADME and transporter variants and tacrolimus trough level, concentration/dose (C/D) ratio, dose/weight-normalized AUClast and AUCinf.
Three novel genetic variants (CYP3A4 (rs3735451), CYP3A4 (rs4646440), and CYP3A4 (rs2242480) as well as CYP3A5*3 (rs776746) were identified. rs3735451 (CYP3A4) T-carriers, rs4646440 (CYP3A) G carriers and rs22422480 (CYP3A4) C-carriers were associated with higher C/D ratio and dose/weight-normalized AUCinf, with similar trough concentrations.
This research suggests that next generation sequencing allow us to detect new population-based pharmacogenetic biomarkers. Further larger investigation is needed to determine whether these associations have clinical utility beyond TDM.

420.6

Adverse events of maintenance immunosuppression following kidney transplantation reported in randomized controlled trials: A systematic review.

Martin Howell[1,2], Reichelle Yeo[1,2], Allison Tong[1,2], Jonathan C.Craig[1,2], Kirsten Howard[2], Germaine Wong[1,2,3].
[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [2]School of Public Health, University of Sydney, Sydney, Australia; [3]Centre for Transplant and Renal Research, Westmead Hospital, Sydney, Australia.

Background: Side effects of maintenance immunosuppression have a major effect on quality of life and non-adherence of kidney transplant recipients. It is known that patients are willing to accept side effects as a necessary part of treatment after kidney transplantation, however it is unclear whether clinical trials inform patients of what side effects to expect in terms of both frequency and severity. The aim of this review was to evaluate the completeness of reporting of adverse events in randomized controlled trials (RCTs) of maintenance immunosuppression in kidney transplantation.
Methods: The Cochrane Kidney and Transplant Group Register was searched (January 2003 to December 2015) to identify RCTs reporting adverse events specific to drug related side effects. Reporting was appraised using the harms-extension of the CONSORT checklist. Data extracted included the characteristics of trials reporting and not reporting adverse events, and the adverse events reported.
Results: Of the 233 trials, 151 (68%) reported adverse events, and 99 (65%) of these trials complied with fewer than 11 of the 23 items in the harms-extension CONSORT checklist. Identification and justification of adverse events were reported in only 28 (19%) and 19 (13%) trials respectively, and assessment of severity in 34 (23%) trials. In 98 (67%) trials, adverse events were used to support either positively or negatively the conclusions. Compliance with the CONSORT checklist was positively associated with the year of publication (P=0.01), industry funding (P=0.02), and the number of adverse events reported (P<0.001) and negatively associated with trial duration (P=0.003). In total, 40 types of adverse events were reported in the 151 trials. The three most commonly reported adverse events were gastrointestinal (70%), peripheral oedema (31%), and undefined "adverse events" (22%). In 107 reports involving calcineurin inhibitors, 22% and 3% reported the common side effects of tremors and paraesthesia respectively and none reported anxiety, aggression or mood swings. For mTOR inhibitors (n=27 trials), 41% and 19% reported the common side effects of skin complaints and headaches respectively. All of the 27 mycophenolic acid trials reported gastrointestinal events, with only three other adverse events reported in more than 10% of the trials namely, abdominal pain (15%), headache (11%), and undefined "adverse event" (11%).
Conclusions: Reporting of adverse events in RCTs of maintenance immunosuppression in kidney transplantation is inadequate and poorly defined. Common side effects are rarely reported. Despite this, adverse events influenced conclusions in over half of the trials. Reporting of adverse events in RCTs should adhere to CONSORT and reflect adverse events that are commonly experienced or important to patients. This can inform patient-centred clinical decision-making.

420.7

A high intra-patient variability in tacrolimus exposure is associated with poor long-term outcome of kidney transplantation

Nauras Shuker[1,2], Lamis Shuker[1], Joost van Rosmalen [3], Joke I. Roodnat[1], Lennaert C.P. Borra[2], Willem Weimar [1], Dennis A. Hesselink [1], Teun van Gelder [1,2].
[1]Internal Medicine , Erasmus MC , Rotterdam , Netherlands; [2]Hospital Pharmacy , Erasmus MC, Rotterdam , Netherlands; [3]Biostatistics, Erasmus MC, Rotterdam , Netherlands.

Background: Tacrolimus (Tac) is a critical dose drug with a considerable intra-patient variability (IPV) in its pharmacokinetics[1]. We investigated whether a high IPV in Tac exposure is associated with adverse long-term renal transplantation outcomes.
Methods: Tac IPV was calculated from pre-dose concentrations measured between 6 and 12 months post-transplantation of 808 renal transplant recipients (RTRs) transplanted between 2000 and 2010. As a primary outcome, a composite end-point consisting of graft loss, biopsy-proven rejection, transplant glomerulopathy, or 'doubling of serum creatinine concentration between month 12 and last follow-up' was used.
Results: One hundred eighty-eight (23.3%) patients reached the composite end-point. The cumulative incidence of the composite endpoint was significantly higher in patients with high Tac IPV than in patients with low IPV (hazard ratio 1.41, 95%-CI: 1.06 – 1.89; p = 0.019). After adjustment for several recipient and transplantation factors the higher incidence of the composite endpoint for RTRs with a high IPV remained statistically significant, with a hazard ratio of 1.37 (95%-CI: 1.02 – 1.84; p = 0.035). Younger recipient age at transplantation, worse graft function (eGFR) and low mean Tac concentration at 1-year post-transplantation were additional predictors for worse long-term transplant outcome.
Conclusion: A high Tac IPV is an independent risk factor for adverse kidney transplant outcomes which has potential as an easy monitoring tool to help identify high-risk RTRs.

Does post-transplant adherence come at a cost?

Kunal Yadav[1], Thomas Nevins[2], William Thomas[2], William N.Robiner[2], Arthur J.Matas[1].
[1]Transplant Surgery, University of Minnesota, Minneapolis, MN, United States; [2]Pediatric Nephrology, University of Minnesota, Minneapolis, MN, United States.

Background: It is well documented that organ transplant (tx)recipients have an increased incidence of cancer including virus associated cancers like lymphoma. Our objective was to assess the correlation between immunosuppression adherence, patient's cumulative immunosuppression exposure, and incidence of cancer.
Methods: Between 1998 and 2006, 195 kidney tx recipients agreed to prospective electronic medication monitoring. Quantitative adherence to a single immunosuppressant drug (azathioprine, n=17; sirolimus, n=28; mycophenolate, n=150), averaged over 6 months was used to divide the patients into 3 equal groups (Best adherence ≥ 97.8%; Middle 91-97.7%; Worst adherence ≤ 90%). We retrospectively examined the incidence of cancer in these patients.
Results: The mean duration of follow-up (7.6 yrs) was similar in all groups. The cumulative cancer incidence was highest in the best adherent group, and lowest in the worst adherent group, p=0.029 (figure1, table1).

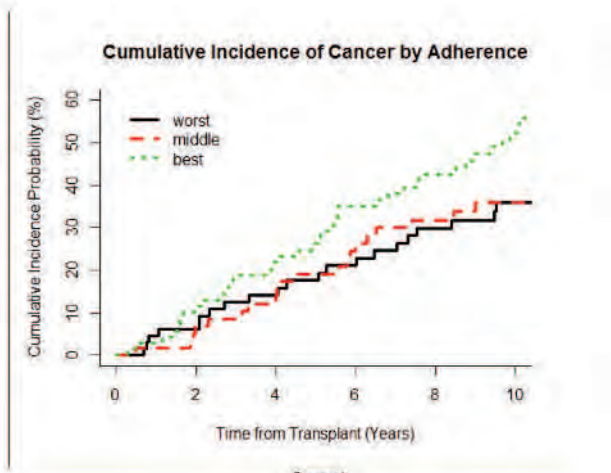

figure1

Table -1, Distribution of cancer by adherence, p=.019 (*Chi* square test)

Cancer	Best	Middle	Worst
Carcinoma	13	8	3
Hematologic (non-PTLD)	1	1	0
PTLD	3	1	1
Skin cancer	33	17	22
No Cancer	29	40	43
Total patients	**69**	**61**	**65**

Those with the best adherence had an absolute cancer rate of 6.2cases (per 100 pt-yrs at risk) during the first 5 yrs; , and 9.9 cases/100 pt-yrs) in yrs 5-10. For the group with least adherence, cancer rate was 4.1/100 pt yrs for the first 5 yrs; 6.0 cases/100 pt-yrs in yrs 5-10. If non-melanocytic skin cancers are excluded, the cancer incidence was significantly higher in the best adherent group (p=0.011). After adjusting for age and treating death as a competing risk, adherence grouping remained a significant factor in the incidence of cancer [p = 0.035], with the cancer hazard (vs best adherence group) 35% lower in the worst adherence group, and 49% lower in the midrange adherence group.

Conclusion: Medication adherence, although lowering AR rates and increasing long-term graft survival, is associated with increased cancer risk. Individualizing treatment to decrease the risk of either graft loss or other adverse outcomes, including malignancy, is necessary. Trials are needed to determine how to achieve this balance.

420.9

Low prevalence of post post-transplant anti-HLA Class 2 antibodies in living donor renal transplant recipients treated with ATG induction therapy – a single centre experience

Galina Severova[1], Aleksandar Sikole[1], Trajceska Lada[1], Ilina Danilovska[1], Zivko Popov[2], Ninoslav Ivanovski[1].
[1]University Clinic of Nephrology, Medical Faculty, Skopje, Macedonia, The Former Republic of Yugoslav; [2]Macedonian Academy of Sciences and Arts, Department od Medical Sciences, Skopje, Macedonia, The Former Republic of Yugoslav.

Background: The mono or polyclonal antibodies induction therapy became a standard treatment after solid organ transplantation. However, the long term effect of induction regarding anti –HLA antibodies is not yet very well known. The aim of our cross-sectional study is to investigate the prevalence of anti- HLA Class 1 and 2 antibodies in living donor kidney recipients treated with different induction therapy (ATG or Simulect) approximately 60 months after the surgery.
Methods: The serum samples from 46 stable living donor transplant recipients 61 months after the surgery (range 12 to 150) were investigated using a single antigen Luminex assay. Mean fluorescence intensity (MFI) more then 800 has taken as a relevant amount of antibodies. All patients were under standard immunosuppression including induction therapy (ATG or Basiliximab) and triple drug maintenance therapy (Tacrolimus or Cyclosporine, MMF and steroids).The pretransplant screening for DSA by CDC cross match was negative in all patients. Living donor renal transplantation was performed using predominantly HLA haploidenthical parents (n=38 or 84.4%) and non-related (spousal) donors (n=7 or 15.6%) with a minimum 1 HLA compatibility. According to the induction therapy, the patients were divided in ATG treated group (Group 1) and Basiliximab group (Group 2).There were no statistical difference in both Groups regarding recipient's age (41 vs. 42.8) gender (male 76% vs. 72%), primary renal diseases and the average time of follow up (61.16 vs. 61.22 months). The renal function (GFR-MDRD), Serum Creatinine, proteinuria and rejection episodes were analyzed
Results: A relevant amount of anti-HLA Class 2 were detected in 13 recipients, 3 in ATG group (15%) and 10 in SIM group (38%) with an average MFI of 980 compared vs. 4630, respectively ($p<0.01$). Regarding anti-HLA class 1 antibodies the differences are not significant (20% vs. 26.6%). The most frequent anti-HLA antibodies identified were against A1, A2, A3, A68, B44, B45, DR18, DR7, DR17, DQ 7, DQ8 and DQ9. The actual serum creatinine was 120 vs. 132 μmol/L, while GFR was 55.5 vs.56.6 ml/min in Group 1 and 2, respectively. Both differences are not statistically significant. In the same time pts in Group I showed significantly less proteinuria than pts in Group 2 (0.44 vs. 0.75 gr/24h, respectively). There was no statistical difference between the rejection episodes (17.6 % vs. 14.2 %) and DSA (one patient in Group 1 and two pts in group 2).
Conclusion: The authors emphasize the positive role of ATG induction therapy on incidence and prevalence of anti HLA-Class 2 antibodies which could be of importance for long term graft and patients survival. More careful investigation including protocol biopsies are needed for more relevant data regarding the long term clinical impact of anti-HLA Class 2 antibodies over the graft and patient survival rate and possible therapeutic approach.

420.10

Simultaneous limited blood sampling models for tacrolimus and mycophenolic acid provide an accurate area under the curve prediction for kidney transplant recipients

Kouhei Nishikawa[1], Manabu Kato[1], Yuko Yoshio[1], Yoshihiro Hasegawa[1], Hideki Kanda[1], Masahiro Kanai[1], Kiminobu Arima[1], Tomoyuki Enokiya[2], Yuichi Muraki[2], Takuya Iwamoto[2], Masahiro Okuda[2], Yoshiki Sugimura[1].
[1]Department of Nephro-Urologic Surgery and Andrology, Mie University School of Medicine, Tsu, Mie, Japan; [2]Department of Pharmacy, Mie University Hospital, Tsu, Mie, Japan.

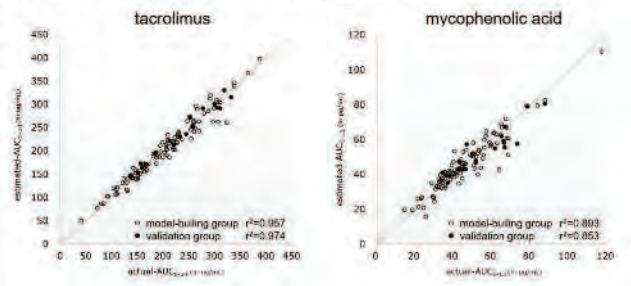
Introduction: Immunosuppressive therapy consisting of extended-release tacrolimus (TAC-ER) and mycophenolate mofetil (MMF) has been widely used for kidney transplant recipients in Japan. Although the area under the curve (AUC) is considered to be the best marker of overall exposure to tacrolimus (TAC) and mycophenolic acid (MPA), multiple blood concentration measurements obtained during the full dosing duration can be invasive for patients and increase the cost. Therefore, limited sampling strategies, where the AUC is estimated from less measurements using multiple linear regression analysis, could be very useful in clinical practice. To date, there have been no reports describing limited sampling models for TAC-ER and MPA to predict the corresponding AUCs using samples from the same time points.
Objectives: The purpose of this study was to build and validate limited sampling models for TAC-ER and MPA to predict the corresponding AUCs using samples from the same time points among kidney transplant patients.
Methods: We retrospectively analyzed 120 full sets of TAC and MPA blood concentration measurements from 46 kidney transplant recipients at our institution from August 2010 to April 2015. The immunosuppressive regimen used for participants was the combination of TAC-ER, MMF and methylprednisolone. Blood samples were taken to determine the blood concentrations of TAC at 0, 1, 2, 3, 4, 6, 8, 12, 16, and 24 hours and MPA at 0, 0.5, 1, 2, 3, 4, 6, 8, and 12 hours after oral administration of TAC-ER or MMF, respectively. The blood concentrations of TAC and MPA were measured using an affinity column mediated immunoassay and enzyme multiplied immunoassay technique, respectively. The actual-$AUC_{0\text{-}24}$ of TAC and actual-$AUC_{0\text{-}12}$ of MPA were calculated by the trapezoidal method. Patients were randomly divided into 2 groups; one group was for model-building (n=100) and the other group was for validation (n=20). In the model-building group, stepwise multiple linear regression models for estimating the AUCs of TAC and MPA were applied based on 4 sampling time points after drug administration in order to make this approach acceptable in clinical practice. In both groups, a correlation coefficientswas calculated between the actual- and estimated-AUCs.
Results: The best sampling points to estimate the actual-AUCs of both TAC and MPA were 1, 3, 8 and 12 hours after oral administration (Table 1).

Table1. Estimating equation for AUC of tacrolimus and mycophenolic acid

Immunosuppressive agents	Regression formula	r^2
tacrolimus ($AUC_{0\text{-}24}$)	14.92+1.88×C1+2.48×C3+5.29×C8+11.58×C12	0.957
mycophenolic acid ($AUC_{0\text{-}12}$)	6.72+1.06×C1+2.81×C3+4.49×C8+2.53×C12	0.893

The correlation coefficients (r^2) between the actual- and estimated-AUCs of TAC in the model-building and validation groups were 0.957 and 0.974, respectively. The correlation coefficients between the actual- and estimated-AUCs of MPA in the model-building and validation groups were 0.893 and 0.853, respectively (Figure 1).

Figure1. Correlation between actual-AUC and estimated-AUC



Conclusion: We demonstrated that it was possible to precisely estimate the AUCs for both TAC and MPA by taking blood samples at only 4 time points, which could be more clinically beneficial for kidney transplant patients.

420.11

A comparative study between low dose anti-thymocyte globulin versus basiliximab as induction therapy for standard immunologic risk kidney transplant patients

Paolo Miguel David[1], Glenda Eleanor P.Pamugas[1].
[1]Adult Nephrology, National Kidney and Transplant Institute, Quezon, Philippines.

Introduction: Induction therapy with immunosuppressive medications has changed the world of solid transplants today. rATG, a lymphocyte depleting polyclonal antibody, is typically used in either medium-risk or high-risk kidney transplants. Basiliximab, a monoclonal antibody, is often used in patients who are at low or standard immunologic risk. Based on results of previous studies done using low dose rATG , our center has been using either basiliximab or rATG at 1.0-1.5 mg/kg/day for 3 days for standard immunologic risk patients, but no comparison of clinical outcomes has ever been done.
Methods: A retrospective cohort study with 165 patients who underwent kidney transplant at NKTI from June 2012 until December 2014 and given either Basiliximab or rabbit ATG until 1 year post transplant. The following were collected: age, gender, native kidney disease, induction therapy used, maintenance immunosuppression used, number of HLA mismatches, episodes of acute rejection, delayed graft function, infections and incidence of malignancies. Statistical treatment of data was done using SPSS version 22. Log rank test and Cox-regression were used to analyze graft and patient survival. Mann Whitney and Fischer's Exact test were used to compare differences of outcomes between the groups.
Results: Among the 165 patients, there were no graft failures nor deaths within 1 year post transplant. There was no significant difference in terms of renal function and incidence of acute rejection but severity of acute rejection was lower in the ATG group. 7 patients had episodes of acute rejection with 6 of them belonging to the Basiliximab group. 1 patient had an acute antibody mediated rejection and treated with methylprednisolone pulsing combined with plasmapharesis and CYA was shifted to Tacrolimus. The others were acute cellular rejection and steroid responsive. There was no significant difference in terms of delayed graft function. 1 patient under the Basiliximab group had delayed graft function due to surgical complications and CNI toxicity. There was no significant difference in terms of infections within 1 year post transplant. 7 patients in the rATG group and 32 in the Basiliximab group had infections. Among the Basiliximab group, 1 presented with CMV infection while another presented with sepsis secondary to Bartholin cyst abscess. The most common type of infection was urinary tract infection. No patients developed malignancy within 1 year after transplant.
Conclusion: Based on this study, low dose rATG is effective and safe for induction therapy in standard risk patients. It also showed that low dose rATG when compared to basiliximab was as effective in preventing acute rejection and incidence of infection was not greater. Having the option of using low dose rATG has a huge impact on clinical management since this will be less costly. Further studies are needed to see the long term outcomes of low dose rATG in comparison to Basiliximab.

Introduction: It is commonly known that complements play important roles in antibody-mediated rejection in renal transplantation and drugs that control complements are sometimes used for treating affected patients. However, the association of complements with progression of acute T cell mediated rejection (ATCMR) has not been fully elucidated. We investigated the production of complement components and complement regulatory proteins (Cregs) in ATCMR using rat and human renal allografts.
Methods and Methods: We prepared rat allograft (n=6) and syngeneic graft (n=3) models of renal transplantation. The expressions of C1q, C3, C3aR, C4, Factor B, C5, C5aR, C9, CD59, and the rodent-specific complement regulator complement receptor 1-related gene/protein-y (Crry) over time were assessed in the rat grafts using quantitative real-time PCR (qRT-PCR) and immunofluorescent staining. We also administered anti-Crry and anti-CD59 antibodies to the rat allograft model, and assessed overall survival. Further, we obtained data from 67 human renal transplant recipients diagnosed with ATCMR, and divided them into high and low membrane cofactor protein (MCP) expression groups by immunohistochemical staining, and assessed the relationship between the expression of MCP and their clinical course.
Results and Discussion: qRT-PCR results showed that the expression of Cregs, CD59 and Crry, was diminished in the rat allograft model especially on day 5 after transplantation in comparison with the syngeneic model ($p < 0.01$). In contrast, the expression of complement components and receptors: C1q, C3, C3a receptor, Factor B, C5a receptor, C9 was increased, but not the expression of C4 and C5, indicating a possible activation of the alternative pathway. Compared to the IgG control group, the group that was administered the anti-Crry mAb had a significantly shortened median survival period from 8.60 (1.03) days to 4.80 (0.49) days ($p<0.01$). Delivering anti-CD59 mAb also reduced the survival duration to 5.86 (0.70) days, but this value did not reach the level of significance ($p=0.08$). In the human ATCMR cases, the group with higher MCP expression in the grafts showed improved serum creatinine levels after the ATCMR treatment as well as a better 5-year graft survival rate ($p<0.05$ for each).
Conclusion: We conclude that the expression of Cregs in allografts is connected with ATCMR. Our results suggest that controlling complement activation in renal grafts can be a new strategy for the treatment of ATCMR.

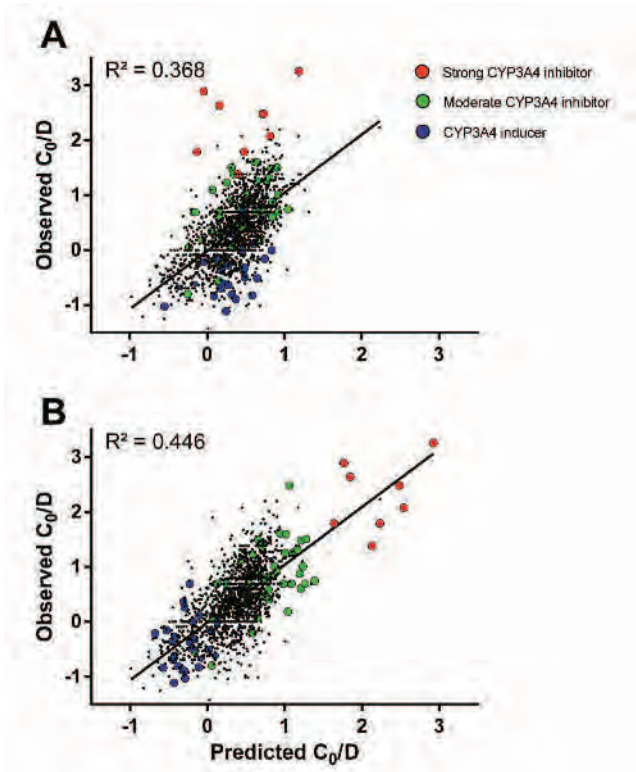
Effect of MDR1 diplotype on tacrolimus disposition in renal recipients depends on CYP3A5 and CYP3A4 genotype

Thomas Vanhove[1], Pieter Annaert[2], Dirk R.J.Kuypers[1].
[1]Nephrology and Renal Transplantation, University Hospitals Leuven, Leuven, Belgium; [2]Pharmaceutical and Pharmacological Sciences, KU Leuven – University of Leuven, Leuven, Belgium.

Introduction: Several clinical and genetic determinants of tacrolimus disposition have been identified. Tacrolimus exposure is decreased in patients possessing the CYP3A5*1 allele (CYP3A5 expressers) and increased in patients possessing the CYP3A4*22 polymorphism. The effect of polymorphisms in other genes such as MDR1 (coding for P-glycoprotein, P-gp), PPARA and NR1I2 has varied between studies.
Methods: We constructed a predictive linear mixed model for tacrolimus dose-corrected trough level (C/D ratio) at months 3, 12 and 24 after transplantation in a retrospective cohort of 766 predominantly Causasian adult renal recipients (n=2042 trough levels). All patients were genotyped for 32 single nucleotide polymorphisms with a proven or possible relevance to tacrolimus disposition. ABCB1, MRP2, OATP1B1, COMT, FMO, PPARA and APOA5 were analyzed as (functional) diplotype groups.



Results: Predictors of C/D ratio were presence of the CYP3A5*1 allele (n=118), hematocrit, age, presence of CYP3A4*22 (n=83), use of a CYP3A4 inhibitor or inducer, serum ALT and albumin, eGFR, tacrolimus formulation (once vs. twice daily), ABCB1 haplotype and time after transplantation. The final model explained 42.9% of interindividual variability in C/D. MDR1 diplotype had no effect in CYP3A5 expressers. In CYP3A4 wild type patients, model predicted C/D ratio was 1.46 (1.14-1.87), 1.47 (1.15-1.87) and 1.62 (1.28-2.07) ng/ml/mg for MDR1 CGC-CGC, CGC-TTT and TTT-TTT diplotypes, respectively, compared with 1.57 (1.13-2.17), 1.83 (1.35-2.49) and 2.55 (1.85-3.52) ng/ml/mg in CYP3A4*22 carriers (p=0.017). Overall model fit was significantly improved by correcting for whether or not patients

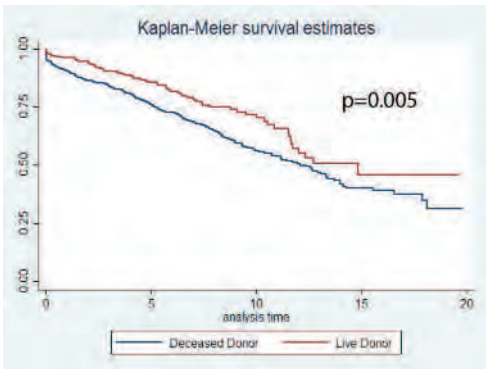
used concomitant CYP3A4 inhibitors or inducers, see Figure (A depicts model fit without correction for concomitant medication, R^2=0.368; B depicts model fit with correction, R^2=0.446).
Conclusion: Most genetic polymorphisms beyond CYP3A5*1 and CYP3A4*22 seem of limited use for tacrolimus modeling on a population level in Caucasians, after correction for clinical confounders. However, the effect of loss-of-function diplotypes in P-gp on tacrolimus disposition was strongly accentuated in CYP3A4*22 carriers but non-existent in CYP3A5 expressers, likely because high CYP3A activity reduces the importance of the P-gp transporter. The combination of loss-of-function in CYP3A5, CYP3A4 and P-gp might have a multiplicative effect leading to strongly increased tacrolimus exposure in specific patients.

421.1

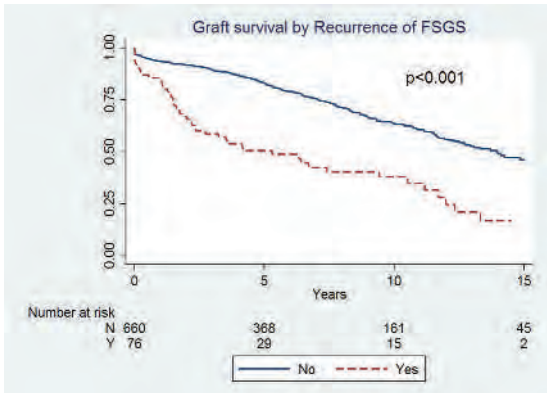
Outcomes of recurrent focal segmental glomerulosclerosis post kidney transplantation

Anna Francis, Peter Trnka, Steven McTaggart.
Paediatric Nephrology, Lady Cilento Children's Hospital, Brisbane, Australia.

Introduction: Recurrent focal segmental glomerulosclerosis (FSGS) after kidney transplantation contributes to poor graft outcomes[1]. There is uncertainty around using living donors for patients with FSGS because of concerns of an increased risk of disease recurrence in the transplanted kidney resulting in poorer transplant outcomes[2]. We aimed to determine the effect of donor source on recurrence and graft survival in patients with FSGS.
Materials and Methods: Using the Australian and New Zealand Dialysis and Transplant registry, we compared the risk of FSGS recurrence and graft loss between living donor (LD) and deceased donor (DD) kidney transplants in children and adults with biopsy proven FSGS over a twenty-year period. Statistical analysis included paired t test, chi squared and logistic regression analysis.
Results: Between 1992 and 2011, 736 first kidney transplants were performed in 666 adults and 70 children with primary FSGS. FSGS recurred in 76 (10.3%) patients and was more common in recipients of a LD transplant compared with DD (14% vs 8%, respectively, p=0.03). However, graft failure due to recurrent disease in the first 5 years after transplant (30 patients, 39%) was more common in DD recipients compared with LD recipients (20 vs 10, p=0.011) and median graft survival was significantly better for LD compared to DD grafts (14.8 years vs. 12.1 years; P=0.005).



On logistic regression, younger age and non-caucasian ethnicity were the only independent factors associated with increased risk of recurrence. Disease recurrence predicted poor graft outcomes with 51% (95% CI 38-62%) 5 year graft survival in the recurrence group compared to 83% (95% CI 79-86%) 5 year graft survival in the group without recurrent disease (p= <0.0001).



In those with disease recurrence, the majority of graft loss occurred in the first two years.

Discussion: Our study confirms that recurrent FSGS after kidney transplant predicts poor graft outcomes. Whilst FSGS more commonly recurred in LD grafts, graft survival in LD recipients was significantly better for both children and adults with FSGS. We postulate that the well described graft survival advantage of LD grafts may overcome the negative effect of increased risk of recurrence, with its attendant poor prognosis. Short term studies of outcomes of kidney transplantation for FSGS would only capture the adverse effects of early recurrence and graft loss, but long term follow up reveals the improved outcomes for LD grafts.

Conclusion: We propose live donor transplantation should not be avoided in patients with FSGS.

Age-independent influence of pre-transplant coronary artery disease and diabetes mellitus on patient survival after kidney transplantation

Fabian Halleck, Anna Kleinsteuber, Dmytro Khadzhynov, Lukas Lehner, Klemens Budde, Oliver Staeck.
Nephrology, Charite Universitaetsmedizin Berlin, Berlin, Germany.

Background: Pre-existing coronary artery disease (CAD) and diabetes mellitus (DM) are frequent comorbidities in kidney transplant candidates. Only limited data exists examining the influence of pre-existing CAD and DM on the long-term outcomes of kidney transplant recipients (KTR) in different age categories.

Methods: This long-term retrospective single center analysis included 839 deceased donor KTR transplanted 1999-2014. Prevalence and history of CAD and DM at time of transplantation were determined. Follow-up analysis over a maximal period of 15 years included patient and graft survival.

Results: 212 KTR (24.8%) with CAD and 138 KTR (16%) with DM were identified among all included patients. Mean follow-up in the cohort was 5.9±3.7 years. KTR with CAD or KTR with DM had a significantly worse 7-year survival compared to recipients without CAD or DM (after 7 years 58.7% vs. 84.0 %, p<0.0001; and 58.6% vs. 81.6%, p<0.0001, respectively).

KTR were further categorized according to age at transplantation. Due to the nature of the Eurotransplant senior program KTR ≥65 years of age were significantly more likely to have older donors, shorter median waiting time on dialysis, shorter cold ischemia time, more HLA-mismatches and a higher proportion of delayed graft function. In addition, these patients were less likely to have prior kidney transplantations and had higher creatinine levels after transplantation. CAD and DM were more frequently observed in the group of elderly KTR compared with the group of young KTR: 47% vs. 16% (p<0.001) for CAD, and 32% vs. 10% (p<0.001) for DM. Comparing elderly (≥65 years) and younger (<65 years) KTR with and without CAD, we found survival rates of 44.8% vs. 69.5% in elderly KTR, and 74.2% vs. 87.9% in younger KTR at 7-years post-transplant (Fig. 1a). Similar survival was observed for DM (Fig. 1b) in old (45.9% vs. 64.2%) and young recipients (74.6% vs. 87.1%). Graft survival rates, however, were not significantly influenced by these pre-existing conditions.

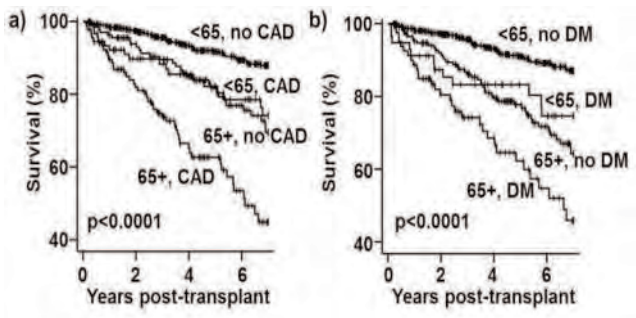

FIGURE 1. Patient survival depending on preexisting CAD (a) and DM (b) categorized by age at transplantation

Conclusion: Both, pre-existing CAD and DM significantly worsen patient survival in younger and elderly KTR. Our findings emphasize the importance of careful pretransplant evaluation as well as thorough monitoring and consequent treatment of these crucial comorbidities.

421.3

Frailty in kidney transplant recipients

Mara McAdams-DeMarco, Hao Ying, Israel Olorundare, Elizabeth King, Dorry Segev.
Surgery, Johns Hopkins, Baltimore, United States.

Background: Among kidney transplant (KT) recipients, frailty increases the risk of DGF, early hospital readmission, MMF intolerance and mortality. While it is clear that frail KT recipients represent a high risk group, the frailty correlates and high-risk patterns of the frailty components are unclear. Furthermore, it is unclear the best way to measure frailty in KT recipients of all ages.
Materials and Methods: 663 KT recipients were enrolled in a prospective cohort study (12/2008-8/2015) at Johns Hopkins Hospital. The Fried frailty phenotype (5 components: weight loss, poor grip strength, low activity, exhaustion and slowed walk speed), activities of daily living (ADL)/ instrumental activities of daily living (IADL) disability, Centers for Epidemiologic Studied-Depression Scale (CESD), education and health related quality of life (HRQOL) were measured at evaluation and KT admission. Additionally, age, sex, race, obesity status, smoking status, time on dialysis, cause of ESRD and donor type were also ascertained from the medical record. We used adjusted multinomial regression to identify frailty correlates. We identified which pattern of the 5 components was associated with mortality using adjusted Cox proportional hazards models.

Table: Correlates of Frailty Status Among Kidney Transplant (KT) Recipients (n=663).

Correlate	Intermediately frail		Frail	
	PR (95% CI)	P value	PR (95% CI)	P value
Age ≥ 65 years	1.83 (1.14, 2.98)	0.01	2.11 (1.16, 3.85)	0.015

Donor type				
Live	Ref		Ref	
Deceased	1.50 (0.98, 2.29)	0.06	1.13 (0.65, 1.97)	0.68

Results: Among KT recipients 19.1% were frail. The only factors associated with frailty status were older age (≥65) (2.11, 95%CI:1.16-3.85), IADL disability (3.21, 95%CI:1.66-6.22), CESD depressive symptoms (11.87, 95%CI:4.33-32.58), less than a high school education (3.66, 95% CI:1.54-8.73) and HRQOL (Good: 2.95, 95%CI:1.36-6.43 and Fair/Poor: 3.62, 95%CI:1.66-7.88). The most common pattern of the 5 components was poor grip strength, low physical activity and slowed walk speed (19.4%) among KT recipients. KT recipients with exhaustion and slowed walking speed (HR=2.41, 95%CI:1.17-5.01, P=0.02) and poor grip strength, exhaustion and slowed walking speed (HR=2.48, 95%CI:1.09-5.64, P=0.02) were at increased mortality risk.
Discussion: Frailty is common among KT recipients of all ages. Age was the only conventional factor associated with frailty; however, factors rarely measured as part of clinical practice, namely HRQOL, IADL disability and depressive symptoms, were significant correlates of frailty among KT recipients. Only 2 patterns of the 5 components emerged as having the strongest association with post-KT mortality.
Conclusion: Frailty is a novel risk factor among KT recipients and not all of the 5 components may be relevant for risk prediction in the population.

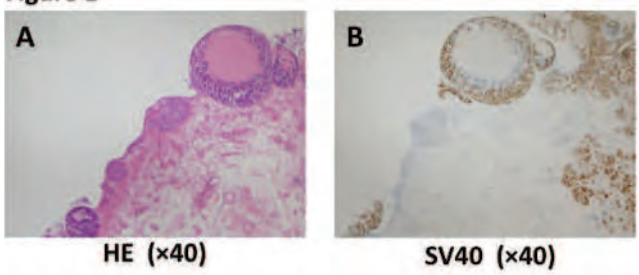
421.4

BK virus infection is a high risk factor for urothelial carcinoma in renal transplant recipients

Masashi Takenaka[1], Mamoru Kusaka[1], Naohiko Fukami[1], Taihei Ito[2], Hitomi Sasaki[1], Takashi Kenmochi[2], Ryoichi Shiroki[1], Kiyotaka Hoshinaga[1].
[1]Urology, Fujita Health University School of Medicine, Toyoake, Japan; [2]Transplantation and Regenerative Medicine, Fujita Health University School of Medicine, Toyoake, Japan.

Introduction: BK virus (BKV) latently infects 70-100% of the human population during childhood and subsequently remains lifelong latent in the epithelium of the urinary tract. Urinary reactivation of the BKV occurs in approximately one-third of renal transplant (RTx) recipients under the current immunosuppression protocols. BKV infection in immunodeficient patients may have a pathogenic role in the development of urothelial carcinoma (UC), but the role of BKV in UC is a controversial topic and is difficult to determine. Several reports have demonstrated BKV associated UC diagnosed in the native urinary bladder.
In this study, we report the cases of high-grade UC in RTx recipients, and investigate the potential role of BKV in post-transplant UC by immunostaining tumor tissue with simian vacuolating virus-40 (SV-40) and p53.
Case 1: A 36-year-old woman underwent RTx from donation after cardiac death (DCD) donor after developing end-stage renal disease (ESRD). The immunosuppressive regimen included ciclosporin, mycophenolate mofetil (MMF), and prednisolone. The patient developed BKV reactivation 1 month post-transplantation, diagnosed on urine cytology and polymerase chain reaction (PCR). Seven years later, the patient presented with intermittent asymptomatic gross hematuria with preserved renal function. The urine cytology was negative, but Computerized tomography showed a cT3a transplant renal pelvis carcinoma. The patient subsequently underwent a transplant nephroureterectomy. Histopathologic findings revealed a high-grade UC, pT3, in the renal pelvis carcinoma with SV40-positive staining.
Case 2: A 63-year-old man underwent RTx from DCD donor after developing ESRD. The immunosuppressive regimen included tacrolimus, MMF, and prednisolone. The patient developed BKV reactivation 4 months post-transplantation, diagnosed on urine cytology and PCR. The patient developed BKV-associated nephropathy 2 years post-transplantation. Five years later, cytologic diagnosis of the urine revealed a high-grade UC, and cystoscopy revealed papillary lesions. A transurethral resection of the bladder tumor was performed, and the pathology result confirmed existence of high-grade UC, pT1 with SV-40 and p53-positive staining.
Result: We experienced two cases of high-grade UC in RTx recipients with BKV reactivation. In both cases, polyomavirus immunohistochemistry performed on the tumor specimens were strongly positive, whereas the surrounding normal tissue was negative (Figure 1). And positive staining for p53 is consistent with an abnormal state of the UC.

Figure 1



Conclusion: An association between BKV and UC has been reported in a small number of case reports involving RTx recipients. These cases are an addition to accumulating body of evidence implicating BKV in the development of UC.
There is evidence suggesting that BKV infection may be a high risk factor for UC in RTx recipients.

Intravoxel incoherent motion imaging is an effective way to monitor chronic allograft dysfunction in rat models

Qiang Zhang[1], Lu Liang[2], Song Zeng[1], Yue Xu[1], Wenrui Xue[3], Zijian Zhang[1], Wei Wang[1], Xiaodong Zhang[1], Xiaopeng Hu[1].
[1]Department of Urology, Beijing Chao-Yang Hospital, Beijing, People's Republic of China; [2]Department of Radiology, Beijing Chao-Yang Hospital, Beijing, People's Republic of China; [3]Department of Urology, Beijing YouAn Hospital, Beijing, People's Republic of China.

Objectives: To evaluate effect of intravoxel incoherent motion (IVIM) imaging MRI on monitoring chronic allograft Dysfunction (CAD) in rat models.
Materials and Methods: For experimental group, twenty Fisher donor kidneys were transplanted into Lewis recipients. For control group, twenty Lewis kidneys were transplanted into Lewis recipients. Serum creatinine (sCr) was monitored every two weeks. All the rats underwent IVIM examination at 4, 12, 20 weeks after modeling. IVIM parameters were obtained using region of interests (ROI) drawn over the renal parenchyma. Five rats from both groups were chosen randomly for histological analysis at different time points. Histological changes in the kidney were evaluated by chronic allograft damage index (CADI) scores. Differences between groups were analyzed by Mann-Whitney U test, and the correlation of IVIM parameters with CADI was determined by Spearman correlation analysis.
Results: All the rats in the experimental group developed into CAD which was confirmed by histological analysis at 4 weeks after transplantation. However, sCr showed no significant difference between two groups until 10 weeks after modeling. IVIM revealed impairment of renal perfusion and diffusion in experimental group at 4 weeks after transplantation compared with the control group. And these changes became severe over time. IVIM parameters were significantly correlated with CADI ($P<0.05$)
Conclusions: Intravoxel incoherent motion imaging MRI is an effective technique for detecting early signs of CAD and monitoring progress of CAD in rat model.

The efficacy of sonoelastography method for the diagnosis of fibrosis in renal transplant patients

Arash Soudmand[1], Nihal Uslu[1], Nihan Haberal[2], Funda Ulu Ozturk[1], Fatih Boyvat[1], Gokhan Moray[3], Mehmet Haberal[3].
[1]Radiology, Baskent University, Ankara, Turkey; [2]Pathology, Baskent University, Ankara, Turkey; [3]Transplantation Center, Baskent University, Ankara, Turkey.

Introduction: Allograft biopsy is the most important method in the diagnoses of ethological factors of dysfunction of renal allografts. Sonoelastography is a new ultrasound method which is used to distinguish the soft or hard nature of the lesions and this can be determined numerically by this method. The aim of this study is to investigate the efficacy of sonoelastography method for the diagnosis of fibrosis in renal transplant patients.
Material and Methods: This study was performed prospectively in the Department of Radiology of Baskent University. Patients over the age of 18, to whom clinical biopsies were recommended were included in this study. Sonoelastography measurements for the renal transplant patients, who were admitted to the clinic for biopsy, were performed just before the biopsy procedure. Sonoelastography measurements were not used for final decision of biopsy. In all cases Siemens S 3000 Ultrasound was used for examination. Measurements were made by two experienced radiologists. Comparison of sonoelastographic values with biopsy results was made by SPSS 20 Statistics program.
Results and Discussion: Total of 65 transplant patients, 15 (23, 1 %) were female and 50 (76.9 %) were male. The average age of the patients was 38.84 ± 14. Of all patient, 51 (78.5 %) had live donors and 14 (21.5 %) had cadaveric donors. Pathology has approved chronic active humoral rejection in 11 patients (18.3%), acute T-cell mediated rejection in 37 patients (61.7 %), acute humoral rejection in 2 patients (3.3 %) , acute tubulointerstitial nephritis in 1 patient (1.7 %), inhibitor toxicity of Chronic calcineurin in 8 patients (11.7%) and thrombotic microangiopathy in 1 patient (1.7 %)
Renal parenchymal echogenicity of patients differed by gender which was an average grade 1 renal echogenicity in women and grade 0 in men, T-test results showed that this difference was statistically significant (P=,009<0,05). Also, statistically significant difference was found between the age and the kidney volume of the patients as well as the age and resistive index (RI) values. Both the kidney volume and the resistive index (RI) values elevated as the age increased. T test results showed that there was a statistically significant directional correlation between the serum creatinine values and Banfii degrees of the patients (r = 362; P=003<0, 05). Besides, there was a strong (r=, 382) correlation (r=, 382) between the degree of Banfi and ARFI values (P=002<0, 05). It was seen that as the means values of the degree of Banfi increased the means values of the ARFI increased. Finally, this showed that ARFI values increased in kidney transplants as the rate of interstitial fibrosis increased.
Conclusions: Our study reveals that there is a statistically significant correlation between the Banfi degrees and ARFI values of renal transplant patients. It is shown that sonoelastography is a method which can be beneficial for the diagnosis of fibrosis in renal transplant patients besides biopsy.

Prevalence and characteristics of duodenal villous atrophy in renal transplant patients presenting with persistent diarrhea

Farina Hanif[1], Nasir Hassan Luck[1], Tahir Aziz[2], S. Mujahid Hassan[1], Zaigham Abbas[1], Muhammad Mubarak[3], Anwar Naqvi[4].
[1]Hepatogastroenterology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [2]Nephrology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [3]Pathology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [4]Urology and Transplantation, Sindh Institute of Urology and Transplantation, Karachi, Pakistan.

Introduction: Persistent diarrhea (PD) is a common complication after solid organ transplantation (SOT), including kidney transplantation. Duodenal villous atrophy (DVA) as a cause of PD has not been investigated exclusively in renal transplant recipients (RTRs).
Methods: Data of 207 RTRs with PD who underwent upper gastrointestinal (GI) endoscopy and duodenal biopsies was collected from 2009 to 2012. The duodenal biopsies were examined for DVA. Age, gender, time taken for onset of symptoms after transplant and drugs used were compared between patients with and without DVA. After exclusion of known causes of DVA, a three-month course of antibiotics was given and the outcome analyzed.
Results: Out of 207 patients, 104 (49.8 %) were diagnosed as DVA. Of these, 92 (88.5%) were males. The mean age of patients with DVA was 34.9 ± 10.3 years. The mean post-transplant duration of DVA positive patients was 2.16 ± 0.8 years. Celiac disease (CD) serology was positive in 18 (%) patients. Giardiasis was demonstrated in 11 (10.7 %) patients, while immunoproliferative small intestinal disease (IPSID) in 7 (6.8 %) biopsies. Remaining 68 patients received antibiotics. Of the latter, 50 (74.6%) recipients showed complete response while 13 patients relapsed after initial response. Among the remaining 18 patients, other causes were found in nine cases and in nine no cause could be found. Isoniazid (INH) prophylaxis showed statistically significant negative association with DVA.
Conclusion: Duodenaol villous atrophy is common in RTRs irrespective of age, gender and duration of transplant. Tropical sprue, giardiasis, immunoploferative small intestinal disease and celiac disease are important causes of DVA in our set-up. Therefore, duodenal biopsy is recommended in all renal transplant recipients with persistent diarrhoea.

421.8

Different patterns of risk factors for late graft loss according recipient age after renal transplantation in the real medicine. An observational, multicenter and prospective study at ten years

Jose Morales, Roberto Marcen.
Research Institute, Hospital 12 de Octubre, Madrid, Spain.

The purpose of the present work was to define the most important risk factors (RF) for late graft loss(GL) after renal transplantation (RT) in three different subgroups of patients: young (under forty), midle aged (40-60 yr) and old (more than 60 yr) in the real medicine in our country with universal national health.
We study 2592 patients who received a cadaveric renal transplant between 2000-2002 prospectively followed for ten years, representing the clinical practice. According recipient age, 672 were under forty, 1320 among 40-60 yr and 600 were older than 60 yr. They received steroids, tacrolimus preferently than Cyclosporine and MMF with or without induction.
Censored death graft survival (CDGS) (K-M) was 71%, 76% and 65% while non-censoring death GS (NCGS) was 68%, 65% and 38% respectively at ten years., Recurrent/de novo glomerulonephritis and Chronic allograft nephropaty in young patients were the most frequent causes of GLwhile death with function was the the main one the other groups. In the multivariate analysis including 2259 patients with more than 12 monts of functioning graft, especially serum creatinine (SCr) at 6 mo. (HR 4.1, 5.7 and 5.3 p <0.001 respectively) and then proteinuria > 1gm at the same time .were the most important significant RF for late GL in all groups, in CDGS and in NCGS.
In addition, pretransplant diabetes (HR 3.2 p <0.001) and smoking (HR 3.4 p <0.001) in youngs, previous transplant (HR 3,3 p <0.001) in middle age and hepatitis C virus infection (HR 3,3 p<0.001) in older patients were also clearly significant RF for GL especially in CDGS.
Patient survival at 10 yr was 94%, 84% and 65 % respectively. As expected cardiovascular diseases and infections were the most frequent causes of death in all groups. In the multivariate analysis we identify recipient age in all groups, pre-transplant diabetes in patients under forty and among 40-60 yr while SCr at 6mo and pretransplant cardiovascular disease in older patients as the most significant RF for mortality.
Conclusions: Our results strongly suggest that although renal function and proteinuria at 6 mo are the most universal RF for late GL other ones in relation with recipient age such as pretransplant diabetes and smoking in youngs, previous transplants in midle age and HCV infection in old people can be also considered as significant RF for late GL after renal transplantation.

Age adapted immunosuppression for elderly kidney allograft recipients: balancing risks for cancer versus rejection

Francesca Jackson-Spence[1], Holly Gillott[1], Sanna Tahir[1], Jay Nath[3], Felicity Evison[2], Adnan Sharif[3].
[1]Medical School, University of Birmingham, Birmingham, United Kingdom; [2]Department of Medical Informatics, Queen Elizabeth Hospital, Birmingham, United Kingdom; [3]Department of Nephrology and Transplantation, Queen Elizabeth Hospital, Birmingham, United Kingdom.

Introduction: Cancer is a significant cause of morbidity and mortality after kidney transplantation, driven by the mileau of immunosuppression. Age is one of the strongest risk factors for developing cancer after transplantation and, with immunosenescence in the elderly well documented, age-adapted immunosuppression may be warranted for older adults to reduce overall immunosuppression burden but this requires further investigation.
Methods: Data was extracted by the University Hospitals Birmingham informatics team for all kidney allograft recipients transplanted at the Queen Elizabeth Hospital between 2007 and 2015. Electronic patient records were then manually searched to facilitate data linkage between various sources to create a comprehensive database of baseline demographics, donor details, clinical/biochemical parameters, histology and clinical events. SPSS version 22 was utilised for all statistical analysis.
Results: Data was extracted for 1,140 patients who received a kidney allograft, with median follow up 4.4 years post-transplantation. Median age for the study cohort was 47 and we classified older at this dichotomised age of 47 and over compared to younger recipients aged under 47. Older versus younger recipients had increased risk for death post-transplantation (10.6% versus 3.3% respectively, p<0.001) but not death-censored graft losses (9.1% versus 11.3% respectively, p=0.130). Cancer-related mortality for older versus younger recipients was 12.9% versus 5.9% respectively. Cancer was more common in older versus younger recipients (9.0% versus 3.1% respectively, p<0.001), with increased risk among older versus younger adults for both skin cancer (3.0% versus 0.9%) and non-skin cancers (6.1% versus 2.2%). Cancer-related mortality occurred in 12.9% of patients who developed cancer post-transplant (all non-skin cancer related). As a further sign of increased immunosuppression-related complications, older versus younger recipients were more likely to have cardiac events (9.6% versus 2.2% respectively, p<0.001) and cerebrovascular events (3.2% versus 1.5% respectively, p=0.039) post-transplant. However, older versus younger recipients had the same risk for cellular rejection (13.7% versus 12.6% respectively, p=0.324) but reduced risk for either antibody-mediated rejection (2.7% versus 4.7% respectively, p=0.047) or mixed rejection (1.4% versus 3.5% respectively, p=0.015). Of note, older recipients were more likely to be receiving their first kidney allograft versus younger recipients (94.6%versus 85.6% respectively, P<0.001), which confounds the risk for rejection among this cohort.
Conclusion: Older kidney allograft recipients have increased risk for death and immunosuppression-related complications including cancer, cardiac and cerebrovascular events but reduced risk for rejection. Our data supports the rationale that older recipients may benefit from tailored immunosuppression to reduce risk from immunosuppression-related complications but this will require targeted clinical trials to investigate further.

Cancer-related outcomes in kidney allograft recipients in England versus New York State: a comparative population-cohort analysis between 2003 and 2013

Francesca Jackson-Spence[1], Holly Gillott[1], Sanna Tahir[1], Jay Nath[3], Felicity Evison[2], Jemma Mytton[2], Adnan Sharif[3].
[1]Medical School, University of Birmingham, Birmingham, United Kingdom; [2]Department of Medical Informatics, Queen Elizabeth Hospital, Birmingham, United Kingdom; [3]Department of Nephrology and Transplantation, Queen Elizabeth Hospital, Birmingham, United Kingdom.

Background: Global studies have confirmed higher cancer-related incidence and mortality for kidney allograft recipients versus the general population. However, no study has compared cancer-related epidemiology between different population cohorts and it is unclear whether country-specific data is translatable across countries. In this population-cohort study, we compared cancer-related incidence and mortality in kidney allograft recipients in England versus New York State.
Methods: We obtained data from every kidney-alone transplant procedure performed in England and New York State between 2003 and 2013, collecting patient demographics that included age, gender, donor type (living or deceased), transplant year, medical co-morbidities and ethnicity. Cancer data was derived from ICD-10 and ICD-9 codes from English and New York State cohorts respectively. English data was extracted from Hospital Episode Statistics, with linkage to the Office for National Statistics for mortality data. New York State data was extracted from Statewide Planning and Research Cooperative System (SPARCS).
Results: Data was analysed for 18,493 and 11,602 patients from England and New York State respectively, with median follow up in England and New York State 6.3 years and 5.5 years respectively. Baseline demographics revealed English patients were younger and more likely to be of White ethnicity compared to New York State patients, but no difference was observed in gender between the cohorts. English patients were significantly less likely to have a history of pre-transplant cancer compared to New York State patients (0.8% versus 3.1%, p<0.001). Admissions to hospital post kidney transplantation with a cancer diagnosis was more common in England versus New York State (12.3% versus 5.9%, p<0.001). Cancer-incidence was disparate between the two different cohorts; English compared to New York State patients were more likely to develop cancers of the skin (5.3% versus 0.3%, p<0.001), breast (0.5% versus 0.2%, p=0.001), bladder (0.3% versus 0.2%, p=0.01) and post-transplant lymphoproliferative disease (1.6% versus 1.1%, p=0.001), but less likely to get cancer of the lung (0.4% versus 0.7%, p<0.001). Kidney allograft recipients in England had lower mortality compared to their New York State counterparts during the immediate post-operative stay (0.7% versus 1.0%, p=0.011), after 30-days (0.9% versus 1.8%, p<0.001) and after 1-year post-transplantation (3.0% versus 5.1%, p<0.001). Logistic regression analysis demonstrated patients admitted with cancer within the first year post-transplant were more likely to die within the first 12 months in England (Odds Ratio 4.28 [95% CI 3.09 - 5.93], p-value <0.001) and New York State (Odds Ration 2.88 [95% CI 1.70 – 4.89], p<0.001).
Conclusion: Kidney allograft recipients in England compared to New York State have different cancer-related epidemiology and outcomes. Our analysis demonstrates significant differences between kidney allograft recipients in England versus New York States and suggests caution in translating post-transplant cancer-related epidemiology between different countries. However, in both countries we observed admission with cancer within the first year post kidney transplantation is associated with increased risk for mortality.

Effect of ureteral stents on BK virus activation in kidney transplant recipients

Rachid Akiki[1,2], Ronald Akiki[1], Linda Pelletier[2], Jean Francis[1,2], Amitabh Gautam[1,2].
[1]Transplant Surgery, Boston University School of Medicine, Boston, United States; [2]Medicine, Boston Medical Center, Boston, United States.

Introduction: Ureteral stents have been used, in kidney transplantation surgery, to minimize the risk of urinary leakage in the early post-operative period. Whether these stents predispose to, and are a risk factor favoring, BK virus replication has been controversial[1],[2]. We have two kidney transplant surgeons in our program, with one routinely using ureteric stents and the other not, and we analyzed our patients to see if there is a difference in the incidence of BK Virus activation in these two cohorts of patients.
Methods: Retrospective chart review of all kidney transplants done in our center, over a 8 years period from January 1, 2007 to December 31, 2014 was done and all patients had at least one year of follow up.. Whole blood and urine BK virus PCR, were done, as part of routine transplant follow up starting at 4 weeks post-transplant and repeated at least monthly for the first three months and then with all subsequent clinic visits. This study was approved by the IRB of Boston Univeristy.
Results: A total of 261 kidney transplant were done in 257 patients. Four patients had an early graft loss and were re-transplanted successfully during the study period. Nine kidney recipients died, within the first year, after transplantation and 9 other patients had an early graft loss and were all excluded from the study analysis and thus a total of 239 kidney transplants were included in our study and their data was analyzed. Of these, 119 had a ureteric stent placement and 120 did not. A total of 90 (37.6%) cases of BK viruria were detected, 41 (34.4%) in those with ureteric stent, and 49 (40.8%) in those without ureteric stent. Fifty patients (20.9% of total) with viruria went on to develop viremia, 25 (20.8%) in those with ureteric stent and 25(20.8%) in those without ureteric stents. The differences are not statistically significant. Although a majority of cases with BK virus activation (69-77%) occurred within 12 months of transplantation, a significant number (21-23%) occurred after the first year after transplantation.
Conclusion: There is no difference in the incidence of BK Virus activation in kidney transplant recipients, whether or not they had ureteric stent placement at the time of surgery. Other risk factors such as immunosuppression intensity, and rejection should be explored to reduce the incidence of BK Viremia.

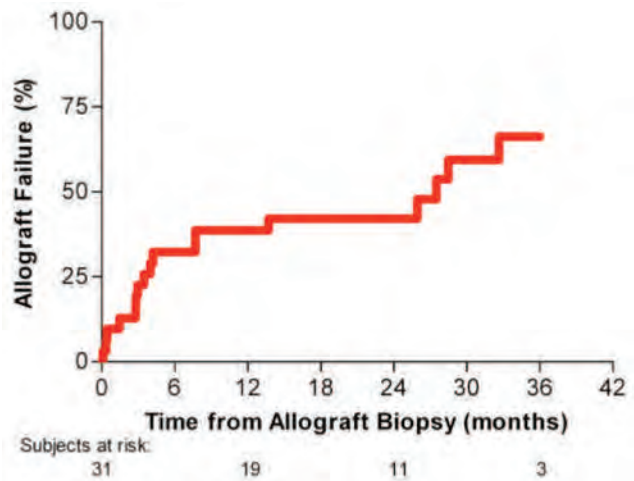
Clinical profile and messenger RNA transcriptome sequencing of kidney allograft recipients with plasma cell rich acute rejection (PCAR)

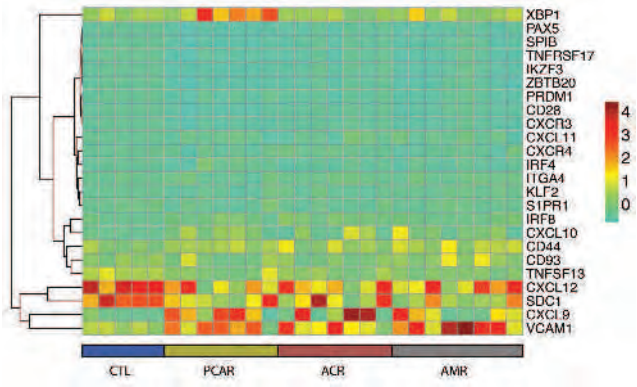
Laurent Mesnard[1], Fabien Campagne[1], Hua Yang[2], Carol Li[2], Catherine Snopkowski[2], Liana Perry[2], Elly Varma[2], John Lee[2], Darshana Dadhania[2], Ruchuang Ding[2], Manikkam Suthanthiran[2], Thangamani Muthukumar[2].
[1]Department of Physiology and Biophysics, Weill Cornell Medicine, New York, United States; [2]Department of Medicine and Transplantation Medicine, Weill Cornell Medicine, New York, United States.

Introduction: PCAR portends a poor prognosis. Better understanding of its mechanistic basis may pave way for development of biomarkers and targeted therapies.
Methods: We studied 31 consecutive kidney allograft recipients with PCAR (plasma cells constituting >20% of the interstitial infiltrating cells) at our center from 7/2007 to 6/2013. We obtained demographic and follow up information on these patients. We did 100bp single-end messenger RNA sequencing of kidney allograft biopsies with PCAR (n=7), acute cellular rejection (ACR, n=7), acute antibody mediated rejection (AMR, n=8) and normal (Normal, n=5) on a HiSeq 2000 sequencer. Reads were aligned against the reference genome (Ensembl 75 Genome, hg19). Differential expression analysis was done on R language (3.1) and Bioconductor. Low count tags were filtered out (threshold: 0.5 cpm/sample for a given gene) and significantly regulated genes were identified (FDR<0.05 and log fold change >1.5). For each subset build by the Venn analysis, genes list were sorted and was used as input for pathway analysis using DAVID.
Results: Mean (SD) age: 43 (16) years. Women: 14 (45%). Time from transplant to biopsy: 41 months. Documented non-adherence of immunosuppressive medicines: 9 (29%). Serum creatinine at biopsy (median): 3.9 mg/dl. Tacrolimus trough level (median): 3.5 ng/ml. Seventeen (55%) patients developed graft failure within 4 months (median) from the diagnosis (Figure-1). Time from transplantation to biopsy (HR: 1.21, 95%CI: 1.03-1.41, P<0.02) and creatinine at biopsy (HR: 1.11, 95%CI: 1.05-1.17, P<0.01) were independently associated with allograft failure.



Total RNA yield (mean[SD]): 1927ng[784ng]; RNA integrity number: 7.4[0.6]. There were 1190 gene transcripts significantly regulated between PCAR and Normal, 969 between AMR and Normal and 751 between ACR and Normal.
Next we did pathway profiling limited to renal expressed transcripts that appeared specific for each condition after Venn diagram analysis. We identified pathways specific for the rejection type that included

tryptophan metabolism and PPAR signaling pathways (PCAR), pyruvate metabolism (AMR) and ECM interaction (ACR). We also analyzed 24 genes that have been documented as associated with plasma cells biology (Nutt SL et al, Nature Review Immunology 2015) to seek for a specific signature associated with renal plasma cell infiltration.



Among the 24 genes that have been documented as associated with plasma cells biology, except XBP1, the rest were minimally expressed in the renal tissue during PCAR (Figure 2). Thus, XBP1 could represent a potential factor in the crosstalk between plasma cells and renal cells. Moreover, XBP1 interacts with PPAR pathway as well.

Conclusion: In this first characterization of intragraft mRNA transcriptome by sequencing of human allograft biopsies, we have discovered mRNA expression pattern unique to PCAR. Modulating XBP1 associated response or PPAR/tryptophan pathways may improve allograft survival in patients with PCAR.

Treatments against renin-angiotensin-aldosterone system could influence FGF23 and Klotho levels in renal transplant recipients

Siren Sezer[1], Emre Tutal[1], Zeynep Bal[1], Mehtap Erkmen[1], Gokhan Moray[2], Turan Colak[1], Mehmet Haberal[2].
[1]Department of Nephrology, Baskent University Faculty of Medicine, Ankara, Turkey; [2]Department of General Surgery, Baskent University Faculty of Medicine, Ankara, Turkey.

Introduction: Angiotensin-converting enzyme inhibitor (ACEI) and angiotensin II receptor blocker (ARB) are frequently used in post transplant hypertension[1]. Recent trials reported that renin-angiotensin-aldosterone system (RAAS) activation could trigger FGF23 and download Klotho synthesis , a mechanism that plays a role in their adverse influence on cardiovascular system[2]. We cross-sectionally analysed the FGF23 and Klotho levels in a group of stable renal transplant patients and searched for the influence of antihypertensive drug use on FGF23 and Klotho levels.

Materials and Methods: A group of 160 RT recipients were included (median age 52 years old, 67 female, post transplantation duration median 58 months). Patients with stable creatinine levels and no history of acute rejection episodes in last 12 months were included. Serum samples for FGF 23 and Klotho were obtained during routine follow-up controls. Subjects were grouped according to their antihypertensive use: ACEI /ARB administered (n:78) and not using patients(none or any antihypertensive apart from ACEI/ARB (n: 82).

Results and Discussion: Two groups were similar in means of demographic characteristics, medications and creatinine and creatinine clearance levels. Calcium, phosphorus, CaxP and PTH levels were similar. Patients using ACEI/ARB had significantly lower FGF-23 levels (49.5 vs 91.9 pg/mL, p: 0.049) and Klotho levels were significantly higher in this group (14.2 vs 9.2 ng/mL, p: 0.04). FGF-23 levels were also positively correlated with PTH (r:0.221, p:0.049), creatinine (r:0.522, p:0.0001) and negatively correlated with calcium (r:-0.238, p:0.034) levels. Patients under ACEI/ARB treatment had significantly lower proteinuria (p: 0.03). Posttransplant ACEI and ARB use is significantly associated with lower FGF23 and higher Klotho levels.

Conclusion: We suggest that the beneficial influence of ACEI and ARB on long term graft function could take place through lowering these adverse prognostic markers.

Defining the tipping point in surgical performance in laparoscopic donor nephrectomy during abdominal transplant surgery fellowship: a learning curve analysis.

Oscar Serrano[1], Ananta Bangdiwala[2], David Vock[3], Varvara Kirchner[1], Danielle Berglund[1], Ty B.Dunn[1], Erik B.Finger[1], Timothy L.Pruett[1], Arthur J.Matas[1], Raja Kandaswamy[1].
[1]Surgery, University of Minnesota, Minneapolis, MN, United States; [2]Biostatistics and Bioinformatics Core, University of Minnesota, Minneapolis, MN, United States; [3]Biostatistics, University of Minnesota, Minneapolis, MN, United States.

Purpose: Laparoscopic donor nephrectomy (LDN) requires a high degree of surgical competence and skill. UNOS recommends that fellowship-trained surgeons participate in 15 LDN to be considered proficient. However, evaluating proficiency among transplant surgery fellows (TSF) in the modern training paradigm has yet to be defined.
Methodology: A retrospective, single center case analysis was performed of all LDN procedures between January 2000 and December 2014 to construct a learning curve model. Measures of surgical performance included 3 dichotomized outcomes: high operating time (ORT) defined as >4.6 hours, high estimated blood loss (EBL) defined as >50 cc, and the presence of a complication graded on an ordinal scale. Case complexity was defined by clinical metrics obtained from donors with BMI>30, prior abdominal surgeries, renal vasculature multiplicity, and those in whom a right nephrectomy was performed. Outcomes and case complexity were compared between junior transplant surgery fellows (jrTSF) and senior transplant surgery fellows (srTSF) using chi-square tests of association. Plots of cumulative risk-adjusted residual error were used to analyze the learning curve in non-parametric fashion. Logistic regression was used to model outcomes, adjusting for fellow experience, case complexity, and institutional experience.

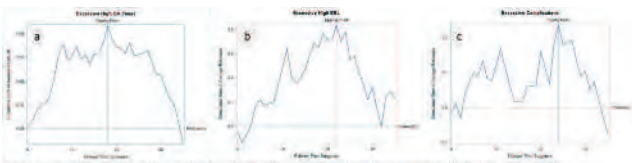

Figure 1. Risk-adjusted cumulative sum plots for ORT (a), EBL (b), and intraoperative complications (c) for jrTSF learning LDN.

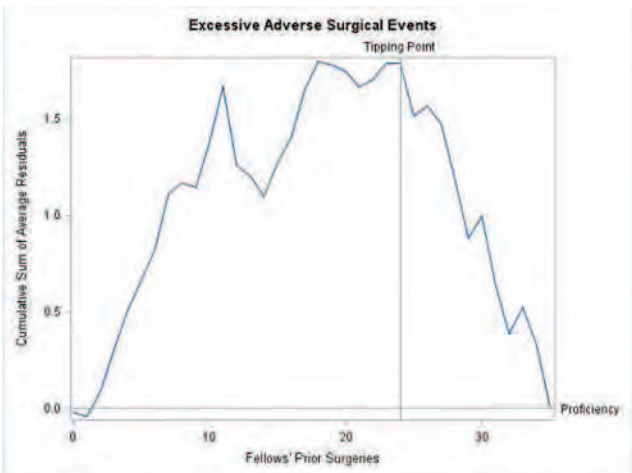

Figure 2. Learning curve for laparoscopic donor nephrectomy during abdominal transplant surgery fellowship.

Results: During our study time period, 970 LDN procedures were performed (791 performed by jrTSF; 179 performed by srTSF). The proportions of adverse surgical events were higher for jrTSF than for srTSF: high EBL (56% vs 43%; p=0.01), incidence of complication (6% vs 4.5%; p=0.54), and high ORT (58% vs 39%; p=0.0004). Incidence of high risk donor characteristics did not differ among patients in the jrTSF or srTSF cohorts: BMI>30, p=0.82; right nephrectomy, p=0.70; multiple renal arteries, p=0.73; prior abdominal surgery, p=0.43. Based on the risk-adjusted non-parametric analysis of the learning curves, there is a great deal of variability among trainees with a trend of improving OR time after 18 LDN procedures (Fig. 1a), EBL after 22 LDN procedures (Fig. 1b) and incidence of intraoperative complications after 24 LDN procedures (Fig. 1c). The comprehensive learning curve model for LDN during abdominal transplant surgery fellowship demonstrates a decrease in adverse surgical events after approximately 24 procedures, with proficiency achieved after 35 procedures (Figure 2).
Conclusion: Defining the learning curve of LDN during fellowship training has critical implications for surgical education, patient safety, and program credentialing. In the current era, where fundamental laparoscopy skills are mandated during residency training, TSF seem to acquire peak LDN performance in about 24 cases, with proficiency achieved after 35 procedures.

422.2

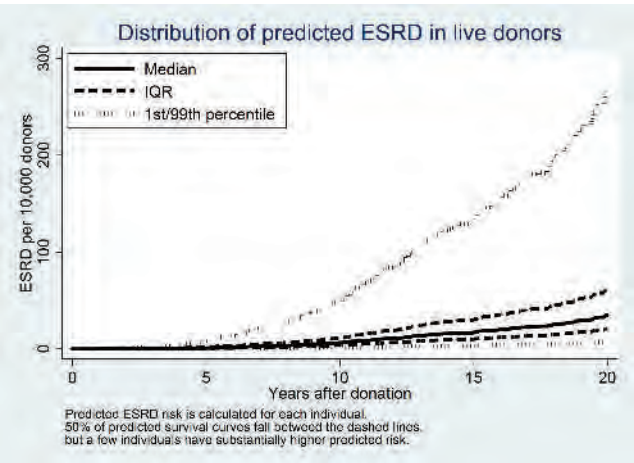
A prediction model for long-term risk of ESRD in living kidney donors based on individual characteristics

Allan B. Massie, Abimereki D. Muzaale, Xun Luo, Eric K.H. Chow, Dorry L. Segev.
Surgery, Johns Hopkins, Baltimore, United States.

In the face of recent evidence has suggested increased risk of ESRD in living kidney donors compared with healthy nondonors[1],[2], accurate communication of donor risk is required for informed consent. However, individual risk prediction is unavailable.

Materials and Methods: We modeled risk of ESRD in living donors in a cohort of all living donors in the United States 1987-2014 (N=128303) based on donor characteristics using Cox regression. ESRD outcomes were ascertained using linkage to CMS (national registry with mandatory reporting), with multiple imputation to account for missing BMI and eGFR. We used this model to produce individual predicted ESRD risk curves for each donor in the cohort.

Characteristic	Hazard ratio	p
Male sex	1.58 **2.02** 2.58	<0.001
Black race (at age 40)	2.32 **3.20** 4.41	<0.001
Age per 10y (non-black donors)	1.21 **1.42** 1.67	<0.001
Age per 10y (black donors)	0.61 **0.77** 0.98	0.03
BMI per 5 units	1.20 **1.56** 2.03	<0.001
Biologically related to recipient	0.43 **0.65** 0.97	0.03
eGFR per 10 mL/min/1.73 m^2	0.85 **0.97** 1.10	0.6



Results: Male sex was associated with twofold higher risk of ESRD in living kidney donors (HR=$_{1.58}$ 2.02 $_{2.58}$, p<0.001, Table). Older age was associated with increased risk (p<0.001), except among black donors, for whom age was associated with decreased risk (p=0.03). Lack of biological relationship to recipient was associated with decreased risk (HR=$_{0.43}$ 0.65 $_{0.97}$, p=0.03). Higher BMI was associated with increased risk (HR per 5 units = $_{1.20}$ 1.56 $_{2.03}$, p<0.001). There was no evidence of association between eGFR and risk after adjusting for other factors (p=0.6).

Median (IQR) predicted risk of ESRD was 6.0 (3.5-10.8) per 10,000 at 10 years post-donation, and 33.3 (19.5-59.2) per 10,000 at 20 years. However, the 99th percentile of risk was 49 per 10,000 at 10 years post-donation and 270 per 10,000 at 20 years post-donation. The C-statistic of the model was 0.704, indicating good predictive discrimination. The model can be found online at www.transplantmodels.com/donesrd/.

Discussion: The increased ESRD risk in black donors may reflect genetic risk due to high-risk alleles of APOL1, and/or discrimination and decreased access to health care in the US-based setting. The inverse association between age and ESRD risk in black donors may reflect selection, in that older potential donors with high-risk APOL1 alleles may be excluded from donation due to decreased kidney function.

Conclusion: In this US-based cohort, most individuals cleared for donation had very low long-term risk of ESRD. However, a few individuals had dramatically higher risk and should be counseled appropriately. Adequate lifetime access to health care should be ensured for all living kidney donors.

Where do living donors come from? A comparison of potential living liver and kidney donors at a high-volume U.S. center

Hillary Braun[1], John Feiner[3], Garrett RRoll[2].
[1]School of Medicine, University of California, San Francisco, San Francisco, CA, United States; [2]Department of Surgery, University of California, San Francisco, San Francisco, CA, United States; [3]Department of Anesthesia, University of California, San Francisco, San Francisco, CA, United States.

Introduction: Organs from living donors are an important component of the solution for the ongoing organ shortage. Understanding the potential donor pool is critical to recruitment efforts, and to date it is poorly defined. In 2013, UCSF implemented an online donor screening system to simplify the initial evaluation process for potential living kidney donors (BREEZE TRANSPLANT, MedSleuth, Inc.)[1],[2], and then expanded to include potential liver donors in 2015. Here we compare the demographics between potential kidney and potential liver donors who passed the initial screening process to identify characteristics that may help guide future efforts for recruiting living donors.

Methods: Using the web-based portal, potential living kidney and liver donors initiated the process of donation by completing an online questionnaire. This questionnaire gathers demographic information including gender, age, ethnicity, relationship to recipient, BMI, and health related behaviors including alcohol use, tobacco use, drug use, and exercise frequency. Potential donors are screened out for medical reasons such as current tobacco use without the desire to quit, diabetes, age, or simply failure to make it to the end of the survey. We included only those potential liver and kidney donors who passed the initial online screen in this analysis. Next we compared potential liver donors with potential kidney donors.

Results: 2306 potential living kidney donors passed the initial screen between 2013-2015, and 464 potential liver donors passed the initial screen in 2015. Comparison of basic demographic information is shown in (Figure 1- table). A greater percentage of potential kidney donors were female, older in age, related to their recipient, and had a higher BMI. Interestingly, a greater percentage of liver donors were unrelated to their intended recipient (24.1% vs. 10.6%). Among kidney donors alone, 11.9% (275/2306) went on to successfully donate. Interesting, only 1% of donors met through social media actually went on to organ donation.

	Kidney	Liver
N	2306	464
% Female	64.4%	62.7%
Age	41.1	38.5
BMI	26.3	25.2
Relationship to Recipient		
Parent	13.4%	12.3%
Child	5.3%	8.6%
Full Sibling	13.5%	9.3%
Unrelated	10.6%	24.1%
Other Relationships		
Community Member	4%	5.2%
Social Media	3.9%	2.8%
Acquaintance	5.1%	7.1%
Other	10.6%	7.8%
Ethnicity		
Asian	11.9%	6.9%
African American	6.5%	3.9%
Caucasian	52.5%	63.1%
Other	13.3%	1.7%
Alcohol Use		
Never	21.8%	24.6%
Occasional	25.2%	23.9%
Daily	6.7%	6.3%
Smoking Frequency		
Denies	69.3%	69.6%
Remote	19.5%	17.5%
Current	10.8%	7.1%
Exercise Frequency		
Infrequent	19.9%	16.4%
3x/week	27.8%	20%
>3x/week	36%	30%

Discussion and Conclusion: Understanding living donor demographics is essential to refining effective and efficient recruitment of donors. Our study of a large cohort of liver and kidney donors demonstrates subtle differences. Notably, unrelated donors were more prevalent in the population of potential liver donors. This study also demonstrates that many individuals who are recruited via social media fail to become successful donors even if they pass initial screening. Social media appears to be effective in generating interest but ineffective at attracting donor candidates who successfully donate.

Introduction: Transplantation from living donors (LD) comprises an increasing proportion of kidney(42%) and liver(18%) transplants worldwide. LD may suffer a range of psychosocial harms including coercion and impaired mental health and socioeconomic wellbeing. Global consensus recommends psychosocial evaluation (PE) of all prospective living liver donors (LLD) and living kidney donors (LKD) to identify and address risk factors. The Ethics Committee of The Transplantation Society(TTS) conducted this study to assess the extent to which PE is performed internationally and the features and goals of PE programs, and to evaluate needs for PE guidelines and educational resources.

Table 1: Information reportedly collected or verified during PE of LD

PE of LKD		PE of LLD	
Socioeconomic	**n (%)**	**Socioeconomic**	**n (%)**
Age	289/290 (99.7)	Age	33/33 (100)

Promise of Financial Reward	203/276 (73.6)	Promise of Financial Reward	21/27 (77.8)

Methods: Participants were recruited via email using TTS membership lists and other professional society networks. Professionals involved in LD transplant programs were invited to complete an anonymous online survey hosted on SurveyMonkey. The questionnaire was available in English, Spanish, Arabic and Chinese and included items concerning LD transplant activity and PE practices (e.g., goals; frequency; professionals involved and responsibilities for decision-making; information collected) at the participant's centre, as well as the duration of psychosocial follow-up after donation.
Results: 417 professionals from 83 countries completed the survey: 348 from centres performing LKD; 167 from centres performing LLD. Respondents were from Europe(31%), North America(24%), Latin America(14%), Western Pacific(10%), South East Asia(8%), Eastern Mediterranean(7%) and Africa(6%), and were mostly nephrologists (42%) but also surgeons, nurses, social workers, psychologists, psychiatrists and hepatologists.
Most participants reported PE was 'always' performed for LKD(82% n=293) and LLD(91% n=34), but national and regional differences were observed. Professionals involved in PE reportedly varied, however most respondents reported involvement of a mental health professional (85.2% for LKD; 90.9% for LLD). Participants identified goals of PE as: ensuring voluntariness of donation (97%); minimizing the risk of psychological (92% LKD; 100% LLD), physical (87%LKD; 91% LLD), or economic harm (50% LKD; 61% LLD); and ensuring altruistic donor motivations (85% LKD; 67% LLD). A range of information was solicited during PE (Table 1).
83% of respondents reported providing years or lifelong follow up of LKD physical health compared with 68% for LLD. Follow up of both LKD and LLD mental health, social wellbeing and financial wellbeing were less commonly reported, and was of shorter duration where provided. Guidelines for PE and more staff trained in PE were identified as resources that would improve PE by 58% and 59% of respondents respectively.
Conclusion: Despite international recommendations, PE of LKD and LLD is not consistently performed in many centres, possibly reflecting the lack of evidence-based standards for PE internationally and of resources required for PE in some countries.

422.5

Living kidney donor priorities for outcomes: a nominal group technique study

Camilla Hanson[1,2], John Kanellis[3,4], Steven J.Chadban[5,6], Jeremy R.Chapman[7], Jonathan C.Craig[1,2], Germaine Wong[1,2], Jule Pinter[2], Amit X.Garg[8], John S.Gill[9], Joshua R.Lewis[1,2], Allison Tong[1,2].
[1]Sydney School of Public Health, University of Sydney, Sydney, Australia; [2]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [3]Department of Medicine, Monash University, Clayton, Australia; [4]Department of Nephrology, Monash Medical Centre, Clayton, Australia; [5]Department of Renal Medicine, Royal Prince Alfred Hospital, Sydney, Australia; [6]Sydney Medical School, University of Sydney, Sydney, Australia; [7]Centre for Transplant and Renal Research, Westmead Institute for Medical Research, The University of Sydney , Sydney, Australia; [8]Division of Nephrology, Department of Medicine, Western University , London , Canada; [9]Division of Nephrology, University of British Columbia, Vancouver, Canada.

Background: Living kidney donors must accept risks associated with nephrectomy. While this is ethically justified with informed consent, screening and access to follow up, the outcomes that are most important to donors are yet to be established. We aimed to identify living kidney donor's priorities for outcomes and describe the reasons for their choices.
Methods: Living kidney donors were purposively sampled from two Australian transplant centres. Participants identified important outcomes of kidney donation, ranked the importance of the outcomes, and discussed reasons for their priorities. For each outcome, we calculated a mean rank score from zero (least important) to 10 (most important) and analysed the transcripts thematically.
Results: Across eight nominal groups, 67 participants aged 27-78 years identified 32 outcomes. The highest ranked outcomes were: time to recovery (mean rank score 5.39, SD =3.77), family life (5.24, SD = 4.02), donor-recipient relationship (4.25, SD = 4.07), diet and lifestyle restrictions (3.90, SD = 3.55), and kidney function (3.76, SD = 3.50). Kidney failure and mortality ranked 10th and 13th respectively. Women ranked the donor-recipient relationship, life satisfaction, and family life higher than men; whilst men ranked kidney failure, physical function (fitness), mortality and kidney function higher. The themes underpinning participants' priorities included: overriding concern for recipient wellbeing, undeterred by low risks, heightened susceptibility and unfulfilled expectations.
Conclusions: Living kidney donors prioritised outcomes that could potentially disrupt their lifestyle and relationships, were unexpected, or caused fear and anxiety about their health. Donor assessment and follow up should address expectations regarding recovery time, relationship challenges and possible constraints on vocational and recreational activities; and donors may be more empowered with advice about diet, exercise and other healthy lifestyle practices to prevent long-term health problems. This may increase donor satisfaction and improve outcomes that matter to donors.

Peri-operative events and complications in minimally-invasive live donor nephrectomy: What should we tell potential donors? A systematic review and meta-analysis

Kirsten Kortram, Jan N.M.Ijzermans, Frank J.M.F.Dor.
Surgery, Erasmus MC University Medical Center, Rotterdam, Netherlands.

Background: There are many different techniques for live donor nephrectomy, preferences vary per center. A small number of randomized controlled trials have been performed comparing these different techniques with regard to complications and adverse events. Donors have to be educated about all risks and details during the informed consent process. For this to be successful, more information regarding short-term outcome is necessary.
Methods: A literature search was performed; all studies discussing short-term complications after minimally-invasive live donor nephrectomy were included. Outcomes evaluated were intra- and postoperative complications, conversions, operative and warm ischemia times, blood loss, length of hospital stay, pain score, convalescence, quality of life and costs. Overall results of the minimally-invasive live donor nephrectomy were described in a systematic review. A meta-analysis was performed comparing the individual techniques currently employed, with regards to conversion rate, intra-operative events and post-operative complications.
Results: 174 Articles were included in the systematic review, 37 in the meta-analysis. Mortality was reported in 128 articles (74%), and three fatalities were described (0.02%). Mean operative time was 197.4 minutes (range 78-320), warm ischemia time was 3.6 minutes (0.7-8.7) and average blood loss was 148.9 milliliters (15-545). Overall conversion rate was 1.3% (n=306), of which 181 emergency (0.8%). Intraoperative complication rate was 2.4%, most frequently bleeding (1.6%). Postoperative complications occurred in 6.8% of donors. Ileus (6.3%), infectious complications (2.6%), wound infection (1.6%), and bleeding (1.1%) were encountered most. The average length of stay was 4.2 days (range 0.6-13), the average pain score on discharge was 2.7 (2-5). Mean duration of convalescence was 23.2 days (range 4-60), and the average quality of life as measured by the Short-Form 36 questionnaire was 66.3 (34.5-88). None of the minimally-invasive techniques was superior to another with regard to complication or conversion rate. However, intra-operative bleeding was more often encountered in hand-assisted procedures (3.9 vs 3.7%, p=0.04), as was postoperative ileus (1.7 vs 0.3%, p=0.06). When compared to mini-open procedures, intra-operative events occurred more often in laparoscopic procedures: 10.2 vs 4.2%, p=0.02, but postoperative infections were more common after mini-open procedures; 18% versus 7.9%, p=0.03. This was mainly attributed to an increased incidence of pneumonia after mini-open procedures: 7.9 versus 4.3%, p=0.04.
Conclusions: Minimally-invasive live donor nephrectomy is safe, and associated with low complication rates and an even lower risk of mortality. These data, combined with further analysis of donor comprehension and satisfaction will assist us in developing a standardized, donor-tailored informed consent procedure for live donor nephrectomy.

Evolution of living donor nephrectomy at a single center: long-term outcomes with 4 different techniques in > 4,000 donors for over half-century

Oscar Serrano[1], Varvara Kirchner[1], Ananta Bangdiwala[2], David Vock[3], Ty B.Dunn[1], Erik B.Finger[1], William D.Payne[1], Timothy L.Pruett[1], David E.R.Sutherland[1], John S.Najarian[1], Arthur J.Matas[1], Raja Kandaswamy[1].
[1]Surgery, University of Minnesota, Minneapolis, MN, United States; [2]Biostatistics and Bioinformatics Core, University of Minnesota, Minneapolis, MN, United States; [3]Biostatistics, University of Minnesota, Minneapolis, MN, United States.

Introduction: The development of minimally invasive approaches to donor nephrectomy (DN) has been primarily driven by the potential advantages for the donor. Questions remain about long-term outcomes, for the donor as well as the recipient, with the newer minimally invasive techniques versus traditional open DN.
Methods: In this study, we reviewed all donor and recipient records related to DNs performed from June 1963 through December 2014 at our center. We analyzed donor and recipient demographic characteristics, intraoperative parameters, complications, and short- and long-term outcomes.
Results: During our 51.5-year study period, we performed 4,296 DNs: 2,638 open (ODNs), 1,183 hand-assisted laparoscopic DNs (HA-LDNs), 200 pure LDNs (P-LDNs), and 94 robot-assisted LDNs (RA-LDNs). For donors, we found that LDNs (versus ODNs) made donation more accessible to an older and heavier ($p<0.001$) population. LDNs were associated with a higher probability of left kidney procurement ($p<0.001$). All 3 LDN modalities required a longer operative time ($p<0.001$); RA-LDNs took significantly longer than HA-LDNs or P-LDNs ($p<0.001$). LDNs decreased the need for intraoperative blood transfusion ($p<0.001$) and reduced both the incidence of intraoperative complications ($p<0.001$) and hospital length of stay ($p<0.001$). However, LDNs (versus ODNs) led to a significantly higher rate of short-term ($p<0.001$) and long-term ($p<0.001$) readmissions. Undergoing HA-LDNs (versus all other modalities) was an independent risk factor for an incisional hernia ($p<0.001$). For recipients, LDNs (versus ODNs) seemed to be associated with a lower rate of graft failure at 1 year ($p<0.001$). However, the rate of delayed graft function was unaffected.
Conclusion: LDNs have made kidney donation more accessible to a greater number of donors, decreasing their intraoperative complications and hospital length of stay. But LDNs were also associated with a higher readmission rate and long-term complications.

Table 1. Outcomes Between ODN, HA-LDN, P-LDN, and RA-LDN

	ODN	HA-LDN	P-LDN	RA-LDN
Age (yrs)	37±12	42±11 (p<0.001)	41±10 (p<0.001)	40±11 (p<0.001)
BMI (kg/m^2)	25±5	27±4 (p<0.001)	26±4 (p<0.001)	25±4 (p=0.70)
Left Kidney (%)	68%	78% (p<0.001)	87% (p<0.001)	94% (p<0.001)
OR time (hrs)	4.4	4.6 (p<0.001)	4.9 (p<0.001)	5.0 (p<0.001)
Blood transfusion (%)	3%	0.3% (p<0.001)	1% (p<0.001)	0 (p<0.001)
Intraoperative complications (%)	6%	3% (p<0.001)	5% (p=0.54)	3% (p=0.25)
LOS (days)	5±2	3.1±1 (p<0.001)	3.4±2 (p<0.001)	3.0±1 (p<0.001)
Readmission				
Short-term (%)	1%	4% (p<0.001)	2% (p=0.30)	4% (p=0.03)
Long-term (%)	1%	5% (p<0.001)	3% (p=0.19)	4% (p=0.04)
Incisional hernia (%)	1%	4% (p<0.001)	3% (p=0.19)	1% (p=1)
DGF (%)	4%	5% (p=0.12)	6% (p=0.19)	4% (p=0.80)
Graft failure, 1-year (%)	17%	20% (p=0.03)	17% (p=0.99)	22% (p=0.18)

Psychosocial long impact of living kidney donation: Evaluation of donors satisfaction

Ana Menjivar[1], Josep M.Peri[1], Xavier Torres[1], Eva Oliver[2], Núria Masnou[3], Teresa Rangil[4], Maribel Delgado[5], Anton Fernandez[6], Montserrat Martinez[7], Anna Vila[8], Ignacio Revuelta[1], Fritz Diekmann[1], Entela Kondo[9], Nuria Avinyo[1], Chloë Ballesté-Delpierre[9], Jaume Grau[1], Laura Cañas[4], Ricardo Lauzurica[4], Amado Andres[5], Marti Manyalich[1].
[1]Hospital Clinic of Barcelona, Barcelona, Spain; [2]Bellvitge Hospital, Barcelona, Spain; [3]Hospital Universitari Josep Trueta, Girona, Spain; [4]Hospital Universitari Germans Trias i Pujol, Badalona, Spain; [5]Hospital Universitario 12 de Octubre, Madrid, Spain; [6]Complexo Hospitalio Universitario A Coruña, A Coruña, Spain; [7]Fundació Puigvert, Barcelona, Spain; [8]Hospital Sant Joan de Deú, Barcelona, Spain; [9]Universitat de Barcelona, Barcelona, Spain.

Introduction: Living Donation has a positive impact on Kidney Living Donors (KLDs) in terms of their self-estimation and social value. However, an evaluated risk on their physical and psychosocial outcome is presented. Such risk appears to be linearly increased for a longer post donation time. This study, co-founded by European Regional Development Fund (FEDER) 2011-14, intend to assess some aspects of the presumed risk.
Objective: To analyze the long term impact of donation process on KLDs and to evaluate the level of satisfaction they received.
Methodology: The participants of the study were KLDs who donated in nine Spanish transplant centers during the year 2000 till 2010. The satisfaction level the donors received was assessed retrospectively by means of a satisfaction survey; a new version of the one designed during EULID (European Living Donation and Public Health) project. An analogical- visual scale was used to improve the survey. The centers adapted the methodology to their characteristics and resources.
The questions were addressed to explore perception and acceptance of the donation process in terms of information received, decision making and impact of donation on economics, life opportunities, job and donor recipient relationship.
Results: 240 KLDs were included in the study. Socio demographically described the most frequent donor is female, 51 years-old, genetically related with the recipient, full-time employed. The mean time between the donation process and the survey was 5.2 years. A Pearson correlation was calculated to verify that the KLDs opinions do not depend of the donors' age neither of the elapsed time form donation. The donors perception about the recipient status was good, pointed 8.1 in a scale from zero to10. Pre-donation KLDs experiences more uncertainty than fear ($p<0.0005$) and more happiness than responsibility ($p<0.0005$). Information given: KLDs feel that they have been informed in details about the medical assessment before donation 9.5 (scale from 0 to 10). Donation impact: median time to return to their normal life was 58 days. KLDs reports full recovery 9.4 (scale from 0 to 10). The Donor-recipient relationship was rated with 7.4 (scale from 0-worse to 10-better).
Conclusion: The Living Donors satisfaction is key point to ensure the overall quality and security of donation procedures and the key to detect the potential negative consequences of becoming Living Organ Donor.

422.9

A 5-year analysis after live donor nephrectomy within the era of extended criteria donors – identifying factors for decline of kidney function

Shiromani Janki[1], Leonienke F.C. Dols[1], Evalyn E.A.P. Mulder[1], Khe T.C. Tran[1], Michiel G.H. Betjes[2], Ine M.M.Dooper[3], Jan N.M. IJzermans[1].
[1]Department of Surgery, Division of HPB and Transplant Surgery, Erasmus MC, University Medical Center, Rotterdam, Netherlands; [2]Department of Nephrology, Erasmus MC, University Medical Center, Rotterdam, Netherlands; [3]Department of Nephrology, Radboud University Medical Center, Nijmegen, Netherlands.

Background: Recently some studies have reported less favorable results after live kidney donation. We investigated therefore which donors will possibly be at risk for progressive kidney function decline and chronic kidney disease.
Methods: A 5-year follow-up on renal function, hypertension, quality of life, and survival was performed of a prospective cohort of 190 donors who were part of a randomized controlled trial comparing lapascopic versus hand-assisted donor nephrectomy. A creatinine based estimated glomerular filtration rate (eGFR) was measured with the CKD-EPI formula. Quality of life was assessed by the physical (PCS) and mental component score (MCS) of the Short Form 12.
Results: Data was available for 94% of the donors. The mean age at baseline was 52.8 (range 21-77) years, of whom 15.7% had pre-existent hypertension. The mean follow-up of the population was 5.1±0.9 years. Eight donors died during follow-up due to causes unrelated to donation, and four donors were lost to follow-up.
There was a mean decrease of 33.7% in kidney function as compared with predonation levels from a mean of 90.1 to 60.2 ml/min/1.73m^2 ($p<0.001$) after 5-years of follow-up; at least 93 donors (48.9%) had an eGFR of <60 ml/min/1.73m^2. The 5-year follow-up measurements of the eGFR of all donors were also different compared to the 1-year measurements, mean 60.1±12.1 and 58.5±11.8 ml/min/1.73m^2 ($p<0.001$) respectively.
Donors with a current eGFR of <60 ml/min/1.73m^2 were older at the time of donation (58.3 versus 47.5 years, $p<0.001$) and had a lower eGFR (82.3 versus 101.0 ml/min/1.73m^2, $p<0.001$) compared with donors with a current eGFR of ≥60 ml/min/1.73m^2. In addition, their eGFR decline was higher (mean 36.9±8.6 versus 30.0±7.8 percent, $p<0.001$ respectively). However, there was no difference in gender ($p=0.152$), BMI ($p=0.920$), proteinuria in urine samples ($p=0.745$), or PCS and MCS scores ($p=0.993$ and $p=0.754$). No donors were found at risk for end-stage renal disease or renal replacement therapy.
Thirty donors (16.9%) developed new-onset hypertension. Their mean eGFR at follow-up was 55.0±10.5 ml/min/1.73m^2. New-onset hypertensive donors were older at the time of donation (58.9 versus 50.4 years, $p<0.001$) with a higher BMI (27.7 versus 25.9, $p=0.036$), and had a higher systolic (144.1 versus 130.9 mmHg, $p<0.001$) and diastolic (85.2 versus 79.2 mmHg, $p<0.001$) blood pressure at follow-up compared to non-hypertensive donors. Furthermore, donors with an eGFR <60 ml/min/1.73m^2 had a higher incidence of new-onset hypertension (44.9 versus 22.1%, $p=0.004$) compared with donors with a current eGFR of ≥60 ml/min/1.73m2. However, there was no significant difference in the percentage of eGFR decline between these groups, 34.5 versus 33.5 % ($p=0.465$), respectively. Also, there was no significant difference in the use of diuretics between donors with different eGFR classifications ($p=0.288$).
Conclusion: These results indicate a plea for surveillance of new-onset high blood pressure after kidney donation and yearly monitoring of renal function. Future studies are indicated to identify those individuals at risk for a progressive loss of renal function after kidney donation.

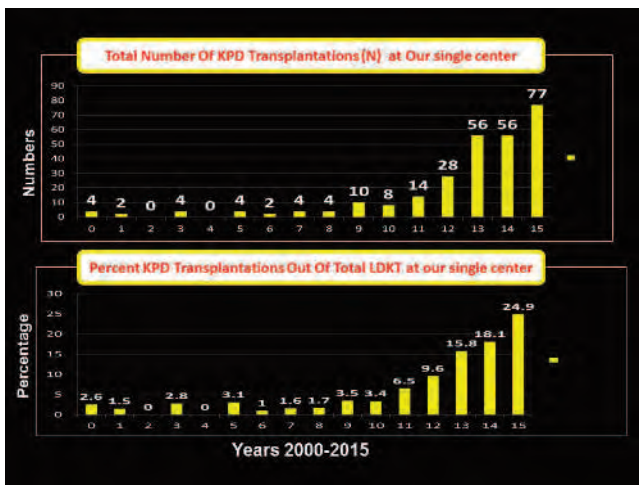
422.10

impact of single center kidney paired donation transplantation to increase donor pool in India

Vivek B. Kute, H.V. Patel, P.R. Shah, A.V. Vanikar, P.R. Modi, V.R. Shah, S.J. Rizvi, B.C. Pal, P.S. Shah, U.T. Varyani, P.S. Wakhare, V.A. Ghodela, S.G. Shinde, V.B. Trivedi, G.S. Kasat, M.V. Patil, J.C. Patel, D.P. Kumar, H.L. Trivedi.
IKDRCITS, Ahmedabad, India.

Background: As per Indian chronic kidney disease (CKD) registry only 2% CKD patients received kidney transplantation. The majority of kidney donors in India are living donors (90%). ABO incompatibility is most common reason (40%) to reject the healthy willing living donors. The deceased donor kidney transplantation (DDKT) is in infantile stage and living donor kidney transplantation (LDKT) with desensitization protocols and ABO incompatible transplantation could not be expanded due to high costs and increased risk of infections from more intense immunosuppression and inferior long term survival in India. Kidney paired donation (KPD) transplantation can be done without additional cost and infrastructure at any center that does LDKT. KPD outcomes are just like any other ABO compatible transplants and long-term management also just like any other transplant.
Material and Methods: We present a government and institutional ethical review board approved study of 275 end stage renal disease patients who consented to participate in KPD transplantation at our single center between 2000 to 2016. All patients had anatomic, functional, and immunologically comparable donors. KPD was performed to avoid blood group incompatibility (n = 201) or positive cross-match (n = 59) and for getting better HLA matching/donor age (n=15). Mean age of patients (230 males, 45 females) and donors (60 males, 215 females) were 39.3 and 42.9 years. Patient ABO type was A (n=101), B (n=113), AB (n=11) and O (n=50). Donor ABO blood group type was A (n=98), B (n=113), AB (n=3) and O (n=61).
Results: Out of 275 patients, 230 patients had two-way exchange and 39 patients had three-way exchange and one domino chain of 6 pairs. 179 patients were from Gujarat and 96 from other states. The majority of the donors were spouse (n=177) and parents (n=81).The waiting time in KPD was short as compared to DDKT. Laparoscopic donor nephrectomy was performed in 89.7% donors. Graft survival was 95% and 15.2% had biopsy-proven acute rejection. Mean serum creatinine was 1.3 mg/dl at last follow-up. With dedicated team work, mandatory counseling and awareness about KPD, there is significant growth and progress in KPD transplantation in the last 4 years (Figure 1 and 2).



Conclusion: KPD is legal and rapidly growing modality for facilitating LDKT for patients who are incompatible with their healthy, willing living donor. KPD has increased LDKT rate by 25 % in the year 2015

in our single center. We have performed the largest number of KPD Transplantations in our single center in 2015 and to the best of our knowledge this is largest number for KPD transplants in single center in one year in the World. KPD has the potential to decrease commercial transplantation and it should be promoted in centers with low DDKT rates.

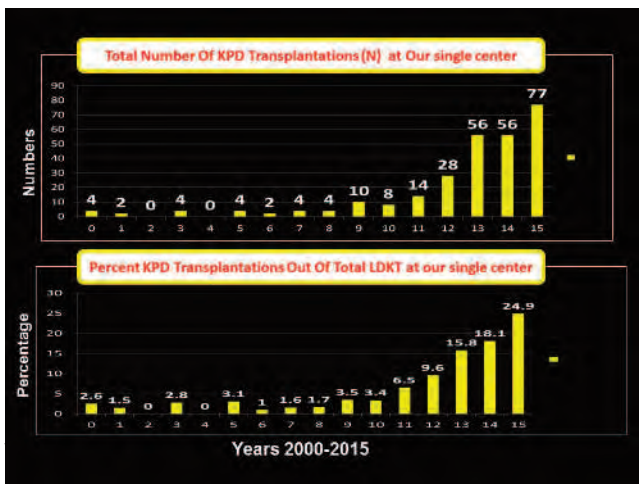
Milestones : Single center KPD transplantation in India	
1st June 2000	First two-way KPD transplantation
2000-2011	56 KPD transplantations (2.5 % of LDKT)
13th Feb 2013	First three-way KPD transplantation
14th March 2013	Ten KPD transplantations on world kidney day 2013
2013	56 KPD transplantations (15.8% of LDKT)
6th May 2014	First 3-way KPD transplantation in combination with desensitization protocol
2014	56 KPD transplantations (18.1 % of LDKT)
17th Feb 2015	First international 2-way KPD transplant between patients from Portugal and India
August 2015	First non-simultaneous domino chain transplant of 6 ESRD patients and 6 donors
2015	77 KPD transplantations (25 % of LDKT)

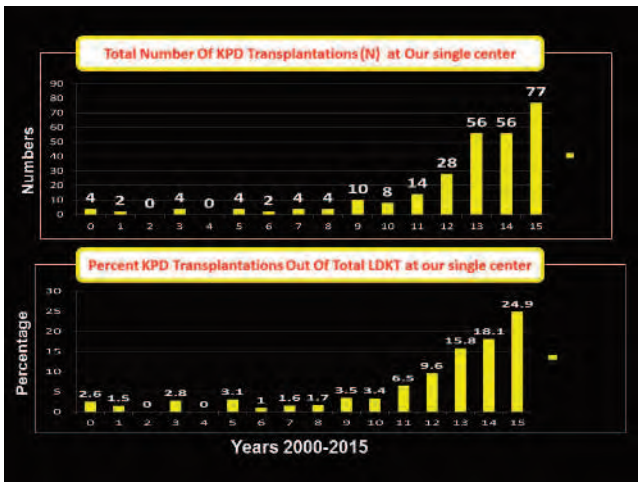
422.11

World record: 77 kidney paired donation transplantation in year 2015 at one transplant center in India: a model for the developing world to prevent commercial transplantation

VivekB. Kute, H. V.Patel, P. R.Shah, A. V.Vanikar, P. R.Modi, V. R.Shah, S. J.Rizvi, B. C.Pal, P. S.Shah, U. T.Varyani, P. S.Wakhare, V. A.Ghodela, S. G.Shinde, V. B.Trivedi, G. S.Kasat, M. V.Patil, J. C.Patel, D. P.Kumar, H. L.Trivedi.
IKDRCITS, Ahmedabad, India.

Introduction: Indian is having living donor kidney transplantation(LDKT) program(90%).Desensitization protocols, ABO incompatible kidney transplantation(KT),deceased donor kidney transplant(DDKT) could not be expanded.Kidney paired donation (KPD) promises hope to ESRD patients because of best outcome.
Methods: We have performed 380 KT from 1January 2015-1 January 2016(71 DDKT, 309 LDKT). 77 were KPD transplantation [25 two-way and 7 three-way pairs and one domino chain of 6 pairs]. This included first international KPD Transplantation and first non-simultaneous domino chain transplant(n=6), combination of KPD with desensitization in sensitized patient(n=1).
Patient ABO type was A(n=24), B(n=31), AB(n=4) and O(n=18). Donor ABO blood type was A(n=21), B(n=35), AB(n=0) and O(n=21). Number of transplants for each blood group were AtoA(n=21), BtoB(n=30), OtoO(n=18), OtoA(n=3), OtoB(n=1), AtoAB(n=1), BtoAB(n=3). Reason for joining KPD was ABO incompatibility(n = 45),sensitisation(n=26) and for better HLA matching(6 O group donor). Out of 26 sensitised patients 16 patients joined KPD without desensitization and 10 after failure of desensitization. All patients had anatomic, functional, and immunologically comparable donors.12 patients underwent non-simultaneous KT
Key to success of our single center KPD program are formation of registry to maintain database about ABO incompatible /sensitized patients, awareness and mandatory counseling about KPD, expert transplant coordinator ,dedicated KPD team . Figure 1 and 2 showed growth of KPD and KT in our single center.





Results: 158 pairs were registered and 77 transplants were completed. 13.2 %(n=21) are waiting for documents and permission from authorization committee(AC) despite having KPD donor (9 sensitized and 8 O group patients). Eight patients were not willing for KPD and underwent ABO incompatible KT due to low ABO titer . Four and 2 patients underwent LDKT with alternative donors and desensitization protocol respectively, 2 underwent DDKT. We Facilitated KPD transplant in 65.3%(98/150) and KPD Transplant completd in 51.3%(77 /150)

Waiting time in KPD was short as compared to DDKT(median 2 vs24 months). Donor relationships were spousal(n = 48), parental(n = 24), and others(n =5). Outcomes of KPD transplants are comparable to that of directed LDKT. Graft survival was 100%. Two patients died with functioning graft due to ischemic heart disease(n=1) and pneumonia(n=1). 14.2%(n=11) had biopsy-proven acute rejection. Mean serum creatinine was 1.1 mg/dl at last follow up. Donor survival is 100% and all underwent lapascopic donor nephrectomy. Transplant match rates among sensitized patients(n=60) was 58.3%(n=35) of which 43.3%(n=26) KT were completed and 15%(n=9) waiting for permission from AC. Transplant match rates among O group of patients(n=62) was 41.9%(n=26) of which 29%(n=18) KT were completed and 12.9%(n=8) waiting for permission from AC.

Conclusion: Our single center KPD has increased LDKT by 24.9% in 2015. This is largest number of KPD transplantations in single center in one year(2015) in World. IKPD should be promoted to overcome organ crisis and shortage of DDKT to prevent commercial KT.

422.12

Simulation of international kidney exchange between Saudi Arabia and the United States using actual incompatible pair data

Abdulnaser Alabadi[1], Khalid B.Akkari[1], Fahad Alotaibi[1], Khaled Hamawi[1], Meteb Albugami[1], Alvin E.Roth[2], Jonathan E.Kopke[3], Michael A.Rees[3,4].
[1]Multi Organ Transplant Center, King Fahad Specialist Hospital, Dammam, Saudi Arabia; [2]Economics, Stanford University, Palo Alto, United States; [3]Alliance for Paired Donation, Perrysburg, United States; [4]Urology, University of Toleod Medical Center, Toledo, United States.

Background: Kidney paired donation (KPD) has become a common method of increasing living kidney donation in many nations, but it has not become common practice in the Middle East. Recently, one Saudi transplant center began using KPD matching software from an American KPD non-profit organization.

Methods: Multiple transplant centers in the United States participated in a KPD program leading to a pool of 160 incompatible pairs for whom no opportunities for kidney exchange were identified. Using the same KPD matching software on a different server, a single Saudi transplant program enrolled 30 incompatible pairs and identified one 3-way exchange. The remaining 27 incompatible Saudi pairs were found no opportunity for kidney exchange. The 160 unmatched US pairs and the 27 unmatched Saudi pairs were placed into a common pool and a match run was performed to look for opportunities for international kidney exchange.

Results: From 187 incompatible pairs composed of 160 unmatched US pairs and 27 unmatched Saudi pairs, 25 potential kidney exchanges were identified. Of the 25 matched pairs, fourteen were from the USA (8.8% of 160) and 11 were from Saudi Arabia (40.7% of 27). More than 600 potential 1-way exchanges were evaluated by the matching software to identify the single, maximal cardinality optimized solution allowing 25 potential kidney transplants. If exchanges were limited to exchanges and chains of length ≤2 transplants, 11 transplants were possible; if limited to length ≤3 transplants, 15 transplants were possible; if limited to length ≤4 transplants, 19 transplants were possible; and when exchanges were allowed to be unlimited in length, 25 transplants were possible in a 12-way and 13-way chain. In these two chains, 17 patients were highly sensitized and 14 had blood type O. Mechanisms to overcome logistical, financial, legal, cultural, and governmental challenges are currently being explored to provide additional transplant opportunities for these highly sensitized, hard-to-match patients.

Conclusion: International kidney exchange is a promising strategy to increase the opportunity for living donor kidney transplantation for patients with willing, but immunologically incompatible living kidney donors. We hypothesize that differences in HLA antigen prevalence across different ethnicities may synergize KPD matching in pools that combine international incompatible pairs due to differential donor specific antibody specificities in candidates and available HLA antigens in donors.

Increasing deceased donor transplant activity in India: the Rajasthan story

Manoj Maloo, Dilip Jain, ML Swarankar, Christopher Taylor Barry.
Liver Transplant and hepatobiliary Surgery, Mahatma Gandhi University of Medical Sciences and Technology, Jaipur, India.

Deceased donor transplantation and organ donation in India have only recently become accepted by the Indian public and medical fraternity. Southern states have led the way to acceptance and sustainability of deceased donor transplant programs since 2008, but most other states in the nation have lagged behind in this regard. Rajasthan has only very recently begun to show success. The keys to Rajasthan's success involve strong political support from the State Government and cooperation between various NGOs, hospital administrators and dedicated transplant professionals.

In November 2014, a combination of State Government support, transplant NGOs, and transplant professionals trained in donor management and organ retrieval together helped to establish the first deceased donor transplant program in Rajasthan within 4 months. During this period, the Rajasthan Network for Organ Sharing (RNOS) was established, employing allocation rules agreed upon by the government and stakeholder institutions that would allow for equitable sharing of available donor organs.

On 6 February 2015, the first multiorgan recovery surgery from a brain dead declared, family consented organ donor was performed at Mahatma Gandhi University Hospital, Jaipur (MGH). Since then, a total of 8 multiorgan recoveries have been performed in Rajasthan, with 5 kidney transplants, 1 heart transplant and 2 liver transplants at MGH, all with successful outcomes to date. In addition, 8 deceased donor kidney transplants have been performed at Sawai Man Singh Government Hospital in Jaipur.

Conclusions: 1) The rapidity of establishing successful and sustainable deceased donor transplantation programs in Rajasthan was only possible because of the cooperation between government officials, NGOs, transplant professionals understanding donor management and organ recovery and interested nontransplant medical professionals, as well as hospital administrative support from existing transplant institutions, 2) well coordinated efforts have led to public acceptance of organ donation in Rajasthan at much higher than expected levels thanks to well trained transplant coordinators and dedicated multidisciplinary transplant teams, and 3) establishment of a fair and transparent allocation system (RNOS) has allowed for further increased trust among the public and the nontransplant medical fraternity that deceased donor transplantation in India can be conducted fairly, transparently and sustainably.

Date	Hospital	Organs Recovered	Organs Transplanted
5 February 2015	MGH	kidneys, liver	kidneys (pediatric en bloc) at MGH, liver to ILBS
25 February 2015	SMS	kidneys, liver	2 kidneys at SMS, liver to Army R&R
31 March 2015	SMS	liver	liver to Apollo Delhi
23 July 2015	MGH	kidneys	1 kidney at SMS, 1 kidney at MGH
25 July 2015	SMS	kidneys, liver	2 kidneys at SMS, liver to ILBS
2 August 2015	MGH	kidneys, liver, heart	1 kidney at MGH, 1 kidney at SMS, heart at MGH
28 November 2015	MGH	kidneys, liver	Liver and 1 kidney at MGH, 1 kidney at SMS
5 December 2015	MGH	Kidneys, liver	Liver and 1 kidney at MGH, 1 kidney at SMS

423.1

Efficient PRA monitoring strategy for cost reduction and improved waitlist management

Lourdes Robles[1], Yoshitsugu Obi[2], Jon Le[1], Eric Belen[1], Clarence Foster[1], Hirohito Ichii[1].
[1]Surgery, University of California Irvine, Orange, CA, United States; [2]Division of Nephrology and Hypertension, University of California Irvine, Orange, CA, United States.

Introduction: The kidney waiting list is increasing at a 20% per year rate. Donor-specific antibodies against human leukocyte antigen contribute to hyperacute rejection, accelerated acute rejection, and antibody-mediated rejection, and longer term complications. Periodical Panel Reactive Antibody (PRA) testing using the Luminex single antigen bead assay is one of the major expenses for pre-transplant evaluation.

The aim of this study is to develop and validate a novel PRA monitoring strategy for waitlisted renal transplant candidates to efficiently reduce the frequency of the PRA test without compromising the safety against all organ offers.

Methods: We retrospectively reviewed all 2,509 deceased kidney offers from 1/ 2011 to 3/2012. We concomitantly utilized the same approach for identifying those patients that would be most likely to receive an organ offer. Those patients were determined to require PRA testing. All other patients had annual status reviews.

Based on the reviewed data, we developed and started a new strategy where quarterly PRA testing was performed in those who met the following conditions:

1. Top 20% of blood group A, B and O - utilizing dialysis time.
2. 100% of blood group AB - which accounts for 1.8% of total waitlisted patients.
3. 100% of kidney/pancreas and pancreas waitlisted patients- less than 10 patients in our waitlist
4. Any patient with a CPRA of > of 10%

We then calculated the estimated annual savings comparing the periods on the old system.

Results: In retrospectively review, among a total of 2,509 organ offers during 1/2011 to 3/2012, 88 % (2,201) of offers were determined to be within the selected quarterly PRA testing group while the remaining 12 % (308) were either zero mismatch (0.08%, n=2) or organ offers which were turned down (99%, n=306). Blood groups A, B and O accounted for 96% of all patients in the waitlist. During this review period, all organ donations were offered to transplant candidates who had the AB blood group or who were wait-listed for the kidney/pancreas and pancreas transplantation were offered organs. Contrary, kidney transplant candidates with the other blood groups were offered only when they were within the top 20% of the waitlist.

We then started the PRA testing strategy from 4/2012. This new strategy excluded 77% of the waitlisted candidates from PRA testing and no organ donation was offered to those in the annual review period except zero mismatch and direct donation to the recipient from donor's family. Analysis of this new selective testing strategy contrasted to the old method resulted in a significant savings of $551,864/year. This model has been in use at our program from 4/2012 to 3/2014 with the benefits of annual cost savings and no reported detrimental effects.

Conclusion: More than 65% of waitlisted candidates did not require quarterly PRA testing. Our new PRA testing strategy saved substantial medical cost without compromising the safety against all organ offers.

423.2

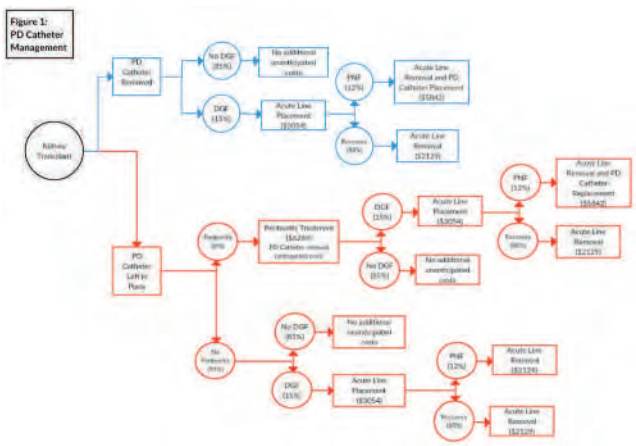
Financial implications of peritoneal dialysis catheter removal at the time of kidney transplantation

Meredith Barrett[1], Andrew M.Rizzi[1], Stephen D.Riutta[1], Joshua M.Peterson[1], Galina Gagin[1], Danielle M.Fritze[1], Kristen A.Schaedig[1,2], Randall S.Sung[1], Yee Lu[1], Kenneth J.Woodside[1]. [1]Transplant Center, University of Michigan, Ann Arbor, MI, United States; [2]Clinical Financial Planning and Analysis, University of Michigan, Ann Arbor, MI, United States.

Introduction: Peritoneal dialysis (PD) is increasingly used as a means for dialysis access for those with end stage renal disease. Management of PD catheters at time of kidney transplant has yet to be well standardized, although many centers are reluctant to utilize them for several weeks post-engraftment. Given this heterogeneity of practice, we sought to investigate the cost ramifications of PD catheter removal at time of transplant.

Methods: PD patients undergoing kidney transplantation at the University of Michigan from 2000-2015 were included for analysis (n=329). Outcomes data, with particular attention to management of PD catheters at time of transplant, was collected via chart review. Financial data was obtained from institutional finance officers and costs per procedure were established. Peritonitis treatment ranged from outpatient antibiotics to admission in a critical care unit, therefore an average cost of both inpatient and outpatient treatment was established and synthesized into a weighted average peritonitis cost. Differences in unanticipated costs—costs associated with delayed graft function (DGF), primary nonfunction (PNF), and peritonitis—were compared to assess which treatment practice was less costly at our institution.

Results: During the study period, 16 (5%) had their PD catheters removed at time of engraftment. The DGF rate was 15%, with 12% of DGF patients (1.2% of the total population) progressing to PNF. Of those with planned delayed PD catheter removal, 19 (6%) developed peritonitis. Treatment varied with the wide range of clinical presentation—from abdominal pain to ICU admission. Seven of 19 (37%) required outpatient oral or IV antibiotics, five (26%) had delayed discharge from transplant admission, and seven (37%) were readmitted (2-20 days) for treatment. With this wide range in treatment, outpatient and inpatient costs were quite variable therefore a conservative cost of $6269 per episode was used for analysis. To determine the cost of PD removal at transplant vs. post procedurally a model of 1000 patients per treatment arm was developed (Figure 1, Table 1). Utilizing the DGF, PNF, and peritonitis rates, we estimated unanticipated (excluding planned PD catheter removal) costs. Delayed PD catheter removal resulted in higher unanticipated costs ($1157/patient) when compared to PD catheter removal at kidney engraftment ($844/patient).



Conclusion: With our DGF and PNF rates, removal of the PD catheters at the time of kidney transplantation was cost effective. Institutions should take into account nephrology policy on PD catheter use immediately postoperatively, along with institutional DGF and PNF rates, when developing peri-transplant PD catheter management policies.

TABLE 1.				
Clinical Outcome	**Treatment**	**Percentage**	**Cost per procedure**	**Cost***
A. PD Catheter Removed at Transplant				
DGF	Acute line placement	15% (150)	$3,054	$458,100
-PNF	Acute line removal and PD cath replacement	12% of DGF (18)	$5,842	$105,156
-DGF Recovery	Acute line removal	88% of DGF (132)	$2,129	$281,028
No DGF	No further treatment	85% (850)	no additional unanticipated costs	
			Total:	**$844,284**
			Cost per patient:	**$844.28**
B. PD Catheter Removed after Transplant Recovery				
Peritonitis	PD removal and treatment of peritonitis	6% (60)	$6,269	$376,140
DGF	Acute line placement	15% of peritonitis (9)	$3,054	$27,486
-PNF	Acute line removal and PD cath placement	12% of DGF and peritonitis (1)	$5,842	$5,842
-DGF Recovery	Acute line removal	88% of DGF and peritonitis (8)	$2,129	$17,032
Recovery with DGF	No further treatment		no additional unanticipated costs	
No Peritonitis		94%(940)		
DGF	Acute line placement	15% of no peritonitis (141)	$3,054	$430,614
-PNF	Acute line removal	12% of no peritonitis and DGF (17)	$2,129	$36,193
-DGF Recovery	Acute line removal	88% of no peritonitis and DGF (124)	$2,129	$263,996
No Complications	Anticipated PD Cath Removal	85% of no peritonitis (799)	no additional unanticipated costs	
			Total:	**$1,157,303**
*Based on 1000pt/treatment arm			**Cost per patient:**	**$1,157.30**

Table 1: Unanticipated post transplant cost for 1000 patients undergoing PD catheter removal at transplant (A) versus after tranplant recovery (B). The percentages are derived from our intitution's clinical data and the numbers within parenthesis are the number of patients that would be in each subgroup based on a model of 1000 patients per treatment arm.

423.3

Low access of highly-sensitized patients to kidney transplantation associated with virtual crossmatch using standard MFI threshold: data from Northern Portugal

Jorge Malheiro[1], Sandra Tafulo[2], Leonidio Dias[1], La Salete Martins[1], Idalina Beirão[1], António Castro-Henriques[1].
[1]Nephrology & Kidney Transplantation, Centro Hospitalar do Porto, Porto, Portugal; [2]Histocompatibility Lab, Centro do Sangue e Transplantação do Porto, Porto, Portugal.

Introduction: In the Portuguese allocation system, at each deceased donor (DD) organ offer, points are attributed, considering candidate-donor age difference, HLA mismatches, and candidate time on dialysis, to all candidates AB0-identical with the donor. Candidates with cytotoxic PRA ≥50% receive extra-points, but no national prioritization program for highly-sensitized (HS) candidates exists. Since the first step in the allocation algorithm is to perform a virtual crossmatch that excludes every candidate with donor-specific anti-HLA antibodies (DSA) at a MFI threshold of ≥1000 automatically (before the cytotoxic crossmatch), HS candidates transplantability is curtailed. Previously, we published data showing that no antibody-mediated rejection occurred in non-desensitized patients with preformed DSA with a MFI below 3000[1]. In order to investigate the consequences of this allocation policy, we analyzed the access of HS candidates to kidney transplantation (KT).

Materials and Methods: Analysis of 987 adult candidates from North Portugal wait-listed with regular priority for DD KT between 2009 and 2011 was performed. The rate of DD organ offers and transplant cumulative incidence, considering candidates AB0 group and calculated PRA (cPRA), were assessed. For the analysis of cumulative incidence of KT, in order to control for competitive events, we excluded candidates that received a kidney graft from a living-donor (n=45), those removed from the waiting-list (n=136) or that died (n=30) during follow-up, with 776 candidates remaining for this analysis, with time being defined between the date of admission on the waiting-list and the date of DD transplantation or end of follow-up (31/December/2015).

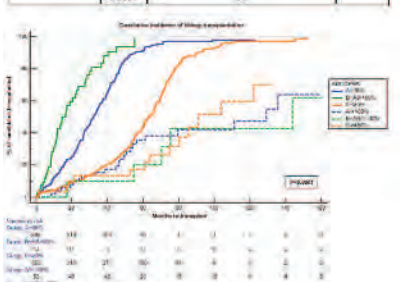
Results:

Candidates characteristics by cPRA

	cPRA<80% (n=863)	cPRA≥80% (n=124)	P
Age, mean	49	46	0.006
Female gender, %	33	62	<0.001
Previous KT, %	11	55	<0.001
AB0 blood group, %			<0.001
A	42	57	
B+AB	5	12	
0	53	32	
Cytotoxic PRA≥50%, %	2	35	<0.001
Years on dialysis, mean	2.9	6.5	<0.001
Years on the waiting-list, mean	2.4	5.7	<0.001

DD organ offer rate (Poisson regression)

Blood group	cPRA	Months until one DD offer	P
A	<80%	5	<0.001
	≥80%	16	
B+AB	<80%	4	<0.001
	≥80%	15	
0	<80%	10	<0.001
	≥80%	30	



Median waiting-time for DD kidney transplantation

Blood group	cPRA	% of candidates transplanted	Median waiting-time (months)	Log-rank P
A	<80%	91	32	<0.001
	≥80%	42	129	
B+AB	<80%	95	14	<0.001
	≥80%	50	144	
0	<80%	72	63	<0.001
	≥80%	43	91	

Conclusions: HS candidates had a reduced access to cytotoxic crossmatch during the allocation algorithm, since the time until one DD offer was 3 times higher than in non-HS candidates, independently from the AB0 group. Median waiting-time for a KT was also clearly higher in HS candidates, particularly in A and B+AB blood groups. Considering a higher DSA MFI threshold in the virtual crossmatch of HS candidates (particularly those wait-listed longer), would allow them to have a better chance of undergoing cytotoxic crossmatch with a potential donor. If negative and together with the eventual use of desensitization protocols according with the degree of immunological risk involved, this could allow for more HS candidates to be transplanted.

423.4

The new kidney allocation system: early impact at one of the most active transplant centers in the US

Franco Cabeza[1], Adriana Dejman[2], Aldo Torres[3], Jeffrey Gaynor[1], Analucia Schneegans[1], David Roth[1], Warren Kupin[1], Adela Mattiazzi[1], George Burke[1], Gaetano Ciancio[1], Linda Chen[1], Rodrigo Vianna[1], Giselle Guerra[1].
[1]Kidney Transplant, Miami Transplant Institute, Miami, United States; [2]Nephrology and Hypertension, University of Miami, Miami, United States; [3]Internal Medicine, Hospital San Jose Tec de Monterrey, Monterrey, Mexico.

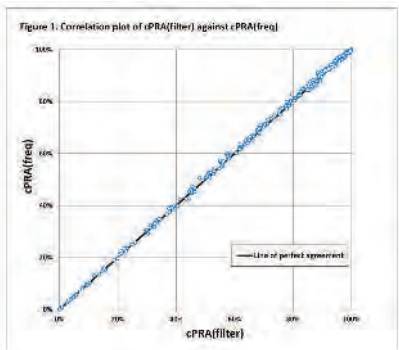
Background: The new kidney allocation system (KAS) was implemented in December 2014 to improve the graft-recipient longevity matching, to facilitate transplantation of harder to match recipients and to decrease discard rates. As one of the most actives centers in the US, we evaluated the early impact of the new KAS compared to recipients transplanted prior.
Methods: We performed a retrospective analysis of 269 kidney recipients transplanted between 1/1/2013-4/30/2015; 190 pre-KAS (control group= C) vs 79 recipients (new KAS group= KAS). Pearson (uncorrected) chi-squared tests of association were performed between selected baseline characteristics and group status (C vs. KAS) as well as between group status and selected outcome variables (%DGF, % biopsy proven acute rejection (BPAR)). Treatment regimens were similar for both groups with induction consisting in a combination of basiliximab, thymoglobulin and steroids. Maintenance immunosuppression was mainly based in tacrolimus and mychophenolic acid with the addition of steroids for the highly sensitized patients.
Results: *Baseline characteristics:* The mean age was 52.6 years for both groups, p=0.12; male gender was 60% in the KAS vs. 56% C; 71% (56/79) of KAS were African-Americans vs. 45.8% (87/190) in C (p=0.0002). Dialysis time ≥ 10 years was found in 41% (32/79) in KAS vs 12 % (23/190) in C (p< 0.01). There were no statistical differences on KDPI scores between both groups.
Outcomes: Under the new KAS, there was a higher trend to transplant very highly sensitized patients (cPRA ≥ 98%), 10.1% (8/79) compared to the 4.2% (8/190) in the C group (p= 0.07). Imported kidneys represented 32.9% of KAS (26/79) vs. 12.1% (23/190) C (P<0.001). Cold ischemia time (CIT) was higher in the C group with CIT > 30hs of 22.8% (18/79) in KAS vs 56.3% (107/190) in C, p<0.001.
There was also a higher rate of recipients receiving donation after cardiac death (DCD) kidneys, 16.5% (13/79) vs 3.2% (6/190) in the C group; that correlated with a significant increase in delayed graft function (DGF), 32.9% (26/79) vs. 11.1% (21/190), respectively, p<0.001.
Dialysis time ≥ 10 years was associated with a significantly higher readmission rate, p=0.04. The frequency of BPAR during the first 6 months after transplantation between both groups were similar, 20.5% (39/190) in KAS vs. 19.0% (15/79) in C (p =0.77).
Conclusion: The new KAS is effectively changing the allograft and recipient characteristics allowing transplant center to favor variables such as prolonged time on dialysis, and higher sensitization state. More frequent use of import and DCD kidneys may occur adversely impacting graft outcomes over time and thus requiring future long-term analysis.
We reported a three times increase in DGF leading to greater economic burden. Transplant centers may be unevenly affected by the new KAS policies with larger centers such as ours absorbing the bulk of higher risk patients.

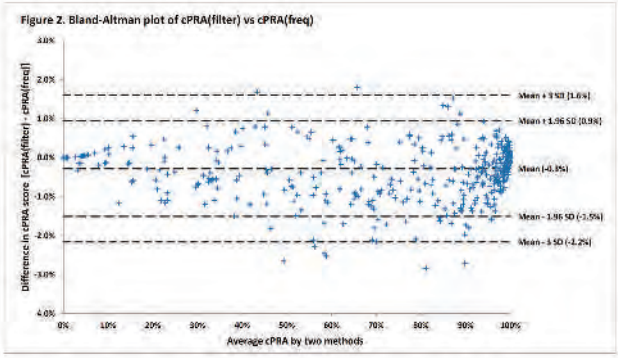
423.5

A simplified method of calculating cPRA for kidney allocation application in Hong Kong

Yuen Piu Chan[1], Monica Wing Kan Wong [1], Lydia Wing Mui Tang[1], Mengbiao Guo[2], Wanling Yang[2], Philip Kam Tao LI[3], Chi Bon Leung[3], Ka Foon Chau[4], Johnny Chi Kwong Lam[5], Nicholas Ka Ming Yeung[5], Janette Siu Yin Kwok[1].
[1]Division of Transplantation & Immunogenetics, Department of Pathology & Clinical Biochemistry, Queen Mary Hospital, Hong Kong, Hong Kong; [2]Department of Paediatrics and Adolescent Medicine, The University of Hong Kong, Hong Kong, Hong Kong; [3]Department of Medicine and Therapeutics, Prince of Wales Hospital, Hong Kong, Hong Kong; [4]Department of Medicine, Queen Elizabeth Hospital, Hong Kong, Hong Kong; [5]Information Technology and Health Informatics Division, Hospital Authority, Hong Kong, Hong Kong.

Introduction: Panel reactive antibody (PRA) has been used to assess the sensitisation level of renal patients in organ allocation program. In 2009 the Organ Procurement and Transplantation Network (OPTN) replaced PRA with Calculated PRA (cPRA) for US renal transplant candidates[1]. cPRA is defined as the percentage of donors expected to have HLA antigens that are unacceptable for a candidate. It is the probability for a patient to give a positive crossmatch and is based on Hardy-Weinberg equilibrium.
In view of no previous research of cPRA in Hong Kong, we embark on employing two methods of cPRA calculation on a renal transplant candidate cohort.
Materials and Methods: HLA-A, -B and -DR typing of 563 Chinese deceased donors in Hong Kong from February 1996 to July 2015 was included. Unacceptable antigens from 613 renal candidates were used for cPRA calculation.
Single locus HLA allele frequencies were counted from donor phenotype. Two and three loci haplotype frequencies were estimated from observed phenotype with Markov Chain Monte Carlo algorithm. cPRA(freq) was calculated based on the formula used by OPTN[2].
A computer script was written to compare listed unacceptable antigens of patients against HLA phenotype of each donor. Patients were filtered out once if they have at least one unacceptable antigen against a donor. cPRA(filter) was expressed as the percentage of filter out count over total number of donors.
cPRA(freq) and cPRA(filter) scores of 70 random selected renal candidates were compared with cPRAs obtained by OPTN and Eurotransplant PRA calculators[3],[4].
Agreement between cPRA calculation methods was analysed by Bland-Altman plot. Concordance correlation was assessed by Lin's correlation coefficient.
Results and Discussion: Both methods showed highly comparable cPRA scores. SD of bias is 0.6%. Limit of agreement is 0.9% to -1.5% difference between cPRA(filter) and cPRA(freq). Lin's correlation coefficient is 1.000, indicating an almost perfect agreement.





Lin's coefficients were 0.824 and 0.829 for cPRA(freq) against cPRA from OPTN, and cPRA(filter) against cPRA from Eurotransplant respectively. These reflected poor agreement and their calculators deemed not applicable in Hong Kong.

Conclusion: This is the first study on applying cPRA in Hong Kong. cPRA values calculated from allele frequencies and donor filtering method showed virtually perfect agreement.

The donor filtering method is more suitable for Hong Kong because the corresponding database and HLA matching function is already in place. cPRA(filter) incorporates existing and new donors in calculation instead of allele and haplotype frequencies captured at one time point. Real-time donor pool will reflect the population allele frequencies and also permits efficient periodic update for cPRA scores.

cPRA can be applied in allocation program for highly sensitised patients for renal and other organs such as heart or lung recipients. Inclusion of other HLA loci can be integrated easily in the future.

Comparison of Hong Kong cPRA results with results obtained from OPTN and Eurotransplant PRA online calculators

Yuen Piu Chan[1], Monica Wing Kan Wong[1], Lydia Wing Mui Tang[1], Mengbiao Guo[2], Wanling Yang[2], Philip Kam Tao LI[3], Chi Bon Leung[3], Ka Foon Chau[4], Johnny Chi Kwong Lam[5], Nicholas Ka Ming Yeung[5], Janette Siu Yin Kwok[1].

[1]Division of Transplantation & Immunogenetics, Department of Pathology & Clinical Biochemistry, Queen Mary Hospital, Hong Kong, Hong Kong; [2]Department of Paediatrics and Adolescent Medicine, The University of Hong Kong, Hong Kong, Hong Kong; [3]Department of Medicine and Therapeutics, Prince of Wales Hospital, Hong Kong, Hong Kong; [4]Department of Medicine, Queen Elizabeth Hospital, Hong Kong, Hong Kong; [5]Information Technology and Health Informatics Division, Hospital Authority, Hong Kong, Hong Kong.

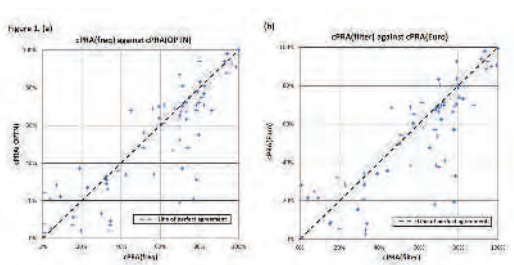
Introduction: Panel reactive antibody (PRA) has been used to assess the sensitisation level of renal patients in organ allocation program. In 2009 the Organ Procurement and Transplantation Network (OPTN) replaced PRA with Calculated PRA (cPRA) for US renal transplant candidates[1]. cPRA is defined as the percentage of donors expected to have HLA antigens that are unacceptable for a candidate. It is the probability for a patient to give a positive crossmatch. In view of no previous research of cPRA in Hong Kong, we set up the local cPRA calculation and compared them with OPTN and Eurotransplant PRA online calculators since HLA gene polymorphism is population specific.

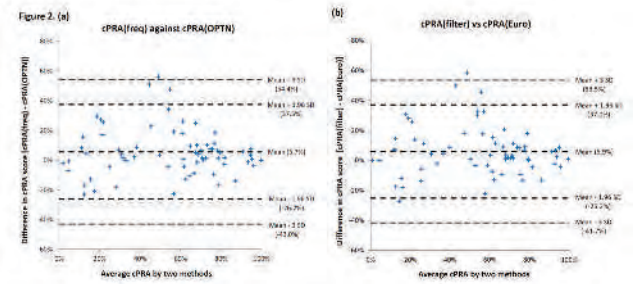
Methods: HLA-A, -B and -DR typing of 563 Chinese deceased donors in Hong Kong from February 1996 to July 2015 was included. Unacceptable antigens from 613 renal candidates were used for cPRA calculation. Single locus HLA allele frequencies were counted from donor phenotype. Two and three loci haplotype frequencies were estimated from observed phenotype with Markov Chain Monte Carlo algorithm. cPRA(freq) was calculated based on the formula used by OPTN[2]. A computer script was written to compare listed unacceptable antigens of patients against HLA phenotype of each donor. Patients were filtered out once if they have at least one unacceptable antigen against a donor. cPRA(filter) was expressed as the percentage of filter out count over total number of donors. cPRA(freq) and cPRA(filter) scores of 70 random selected renal candidates were compared with cPRAs obtained by OPTN cPRA(OPTN) and Eurotransplant PRA cPRA(Euro) calculators[3],[4].

Agreement between local cPRA results and results from overseas cPRA calculation were analysed by Bland-Altman plot. Concordance correlation was assessed by Lin's correlation coefficient.

Results and Discussion: For cPRA(freq) against cPRA(OPTN), SD of bias is 16.2%. Limit of agreement is 37.5% to -26.2%. For cPRA(filter) against cPRA(Euro), SD of bias is 15.9%. Limit of agreement is 37.0% to -25.2%.

Lin's coefficients were 0.824 and 0.829 for cPRA(freq) against cPRA(OPTN), and cPRA(filter) against cPRA(Euro) respectively. These reflected poor agreement and can be explained by the significant HLA allele frequency difference between Chinese and Caucasian population. The result indicates these calculators deemed not applicable in Hong Kong.





Conclusion: This is the first study on applying cPRA in Hong Kong. The poor agreement between our methods and online calculators indicates the necessity to use local population data for accurate cPRA calculation.

The donor filtering method is more suitable for Hong Kong because the corresponding database and HLA matching function is already in place. cPRA(filter) incorporates existing and new donors in calculation instead of allele and haplotype frequencies captured at one time point. Real-time donor pool will reflect the population allele frequencies and also permits efficient periodic update for cPRA scores.

cPRA can be applied in allocation program for highly sensitised patients for renal and other organs such as heart or lung recipients. Inclusion of other HLA loci can be integrated easily in future.

Access to kidney transplantation among HIV-infected waitlist candidates

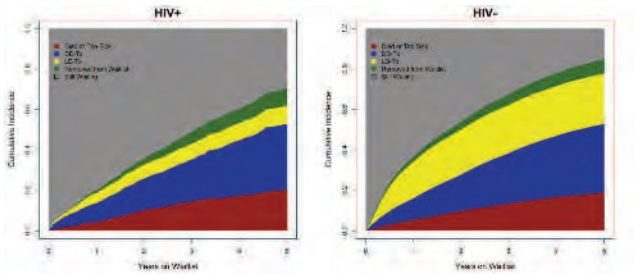
Jayme E. Locke[1], Shikha G.Mehta[1], Deirdre Sawinski[2], Sally Gustafson[3], Brittany Shelton[1], Rhiannon D. Reed[1], Paul A. MacLennan[1], Charolotte Bolch[3], Christine Durand[4], Allan Massie[4], Dorry L. Segev[4].

[1]Surgery, University of Alabama at Birmingham, Birmingham, AL, United States; [2]Medicine, University of Pennsylvania, Philadelphia, PA, United States; [3]Scientific Registry for Transplant Recipients, Minneapolis, MN, United States; [4]Johns Hopkins University, Baltimore, MD, United States.

Background: Kidney transplantation (KT) among HIV-infected ESRD patients confers a significant survival benefit over remaining on dialysis. Given the high mortality burden associated with dialysis, understanding access to KT after waitlisting among HIV+ candidates is warranted.

Methods: Data from SRTR were linked to IMS pharmacy fills (1/1/01-10/1/12) to identify and study 1,636 HIV+ and 72,297 HIV- KT candidates.

Results: Compared to HIV- waitlist candidates, HIV+ waitlist candidates were more often young (<50yrs: 37.5% vs. 62.7%, p<0.001), male (59.3% vs. 75.2%, p<0.001), African American (27.9% vs. 73.6%, p<0.001), > time on dialysis (Yrs: 2.3 vs. 3.8, p<0.001), co-infected with HCV (3.9% vs. 9.0%, p<0.001); and were less likely to remain active on the waiting list (always active: 49.4% vs 37.7%, p<0.001). Although likelihood of waitlist mortality among HIV+ candidates was similar compared to HIV- (aHR: 1.03, 95%CI: 0.89-1.20, p=0.67), likelihood of transplantation was 1.4-fold lower among HIV+ compared to HIV- candidates (aHR: 0.72, 95%CI: 0.64-0.82, p<0.001), and appeared related to an almost 2-fold lower likelihood of living donor kidney transplantation in HIV+ waitlist candidates (aHR: 0.53, 95%CI: 0.44-0.64, p<0.001).



Conclusions: While waitlist mortality has improved for HIV+ candidates, transplant rates remain lower than among HIV- candidates. These results suggest the need for further study to better understand disparities in access to transplantation among HIV+ kidney waitlist candidates, particularly access to living donor transplantation.

Prioritising renal transplantation based on clinical need: The role of an "urgent" kidney waiting list

Emma Aitken[1], Ann-Margaret Little[2], Marc Clancy[1].
[1]Department of Renal Surgery, Queen Elizabeth University Hospital, Glasgow, United Kingdom; [2]Histocompatability and Immunogenetics, Gartnavel General Hospital, Glasgow, United Kingdom.

Background: In the UK, cadaveric kidneys are allocated for transplantation according to the NHS-BT Deceased Donor Organ Allocation Policy. This complex matching algorithm attempts to provide equity of access by prioritising based on factors such as waiting time, HLA-match and age difference. Unlike liver transplantation however, the current system provides no opportunity to prioritise based on clinical need. There are a small, but significant, number of patients with end-stage vascular access (ESVA), who cannot wait 3 or 4 years for their "turn" and die from access loss on the waiting list for a cadaveric kidney.
Methodology: The current DCD donor sharing scheme permits local allocation of DCD kidneys. At our centre we have established an "expedited" list of patients with ESVA (bilateral central vein occlusion and survival, deemed by the MDT, to be <1 year on haemodialysis). It has been locally agreed that kidneys from DCD donors aged >50 years old will first be allocated to these patients if a match exists. We describe our early (4 year) experience of such a policy.
Results: 22 patients with ESVA were identified. 18 have been transplanted during the study period (9 via the "expedited" list, 6 via the national allocation policy, 3 live donors). The two patients with ESVA who remain on the "expedited transplant list" and have not yet been transplanted both have a cRF of 100% and match score of 1. Half of those who were transplanted also had cRF >95%. Mean age and waiting time for patients getting "expedited' transplantation (n=9) was comparable to the general transplant population (n=420) (46.3+/-10 vs 48.8+/-12.9 years; p=0.56 and 1305.4+/-925.5 days). 1-year patient and graft survival was 88.9%. 44.4% had DGF. Mean eGFR at 1 year was comparable to the general transplant cohort (62.0+/13.4 vs 58.4+/-20.9ml/min/1.73m2; p=0.71). In all but one case, the patient who would have been allocated the kidney according to the national algorithm, was transplanted within the subsequent year.
Conclusions: At our centre, priority allocation of DCD kidneys to patients with failing vascular access has proven effective with acceptable outcomes and minimal negative impact on the global transplant population.

423.9

Efficiency savings through reduction of red blood cell cross-match and transfusion in renal transplantation

Sarah-Jayne Edmondson, Irene Mosca, Ami Mehta, Neal Banga.
Department of Renal Transplantation, Royal Free Hosptial NHS Foundation Trust, London, United Kingdom.

Introduction: Blood products, including donated red blood cells (RBCs) are a valuable and limited resource. Transfusion of RBCs in transplant recipients is not only undesirable from an immunological perspective, but is also expensive. In the UK, each RBC unit costs £122 to produce and store, a recipient "group and save" sample costs £22 to process, while cross-matching and issuing a RBC unit costs between £22-160, depending upon the patient's antibody status. Our unit has recently switched from a policy of routine cross-match of 2 RBC units for renal transplantation to the use of "electronic issue", a process similar to virtual cross-match, where patients without red cell antibodies are allocated group-specific RBC units without a physical cross-match taking place. 90% of the general population are thought suitable for electronic issue. We aimed to quantify the use of RBC cross-match and transfusion in our unit, to assess the efficiency savings that could be achieved through electronic issue, and also identify variables that could predict the transplant recipient's transfusion requirement.
Methods: Transfusion data for all renal transplants performed in a one-year period (April 2014–March 2015) in our department were retrospectively analysed. Electronic issue was routinely performed for all recipients without red cell antibodies in the final four months of the study. Results collated included: initial number of RBC units cross-matched and transfused in the immediate peri-transplant period; total number of units cross-matched and transfused during index admission; proportion of patients receiving a transfusion; and the effect of admission haemoglobin on transfusion requirement.
Results: 140 kidney transplants were performed during the study period. 32/140 (23%) of grafts were from a living donor (LD) and 108/140 (77%) were from a cadaveric donor (CD). 62/140 (44.3%) patients required a RBC transfusion during their index admission. In the initial peri-transplant period, the mean number of units, cross-matched was 2.79 (range 0-10) and, transfused was 0.49 (range 0-4) per patient. There was no difference in transfusion requirements between LD and CD graft recipients. LD transplant recipients were more likely to require a RBC transfusion if their admission haemoglobin level was <100g/L (75.0% vs 20.8%, p=0.005). No similar association was seen in recipients of CD grafts. Following the introduction of electronic issue, 24/46 patients (56%) had electronic issue performed rather than a physical cross-match. This resulted in a £1056 cost saving, and could lead to a future 280 x 52% x £22 (£3,203) saving per annum.
Discussion: The blood transfusion requirement in patients undergoing renal transplantation during index admission is low. There is a clear benefit in optimising pre-operative haemoglobin in LD transplant recipients. Electronic issue has meant that patients no longer require multiple RBC cross-matches, which in turn will result in cost savings.

423.10

Kidney transplantation in the elderly: evaluation of effects of donor age on short- and long-term clinical outcome

Martin Ronaghi, Erik Berglund, Lars Wennberg.
Division of Transplant Surgery, Clinical Science, Intervention and Technology, Solna, Sweden.

Introduction: The population is continuously ageing, and the number of patients with end stage renal disease, and consequently, patients in need of a kidney transplant, are steadily growing. As organ shortage remains one of the main challenges in kidney transplant surgery, the use of elderly donors has become a common strategy to enlarge the donor pool. Herein, the short- and long-term effects of donor age on recipient and graft survival, and graft function, were determined at Karolinska University Hospital in Sweden.
Materials and Methods: Adult recipients of their first kidney allograft from either living or deceased donors, transplanted between the years 2001-2012, were included (n=548). The recipients were stratified and assessed separately depending on the donor's age: <60 (n=367), 60-64 (n=76), 65-69 (n=63), and ≥70 (n=42) years. Data on demographics, patient- and graft survival, as well as graft function was collected retrospectively from patient medical records. Survival was evaluated using Kaplan-Meier estimation and Cox regression analysis, adjusted for recipient age, and gender, as well as living contra deceased donor. Graft function was defined as estimated glomerular filtration rate according to CKD-EPI.
Results and Discussion: The recipients of grafts from donors aged <60 years experienced lower risk for death and graft loss (adjusted HR 0,4-0,7; p <0.05), and higher glomerular filtration rate compared to the other groups. The recipients of grafts from the eldest donors (≥70 years) experienced lower risk for graft loss and death compared to the recipients of grafts from donors aged 60-69 years. There was no significant difference in glomerular filtration rate between the three groups that received grafts from donors ≥60 years.
Conclusion: Recipients of kidneys from donors <60 years had significantly better outcomes compared to the other groups. However, progressively inferior outcomes with advancing donor age could not be shown in recipients of grafts from donors ≥60. These results indicate that utilization of older donors is likely to be a sustainable strategy to improve graft availability, and that no upper age-limit should be set for kidney donation. Our results also emphasize the necessity of further studies in Sweden, for a better understanding of how the donor source is best utilized.

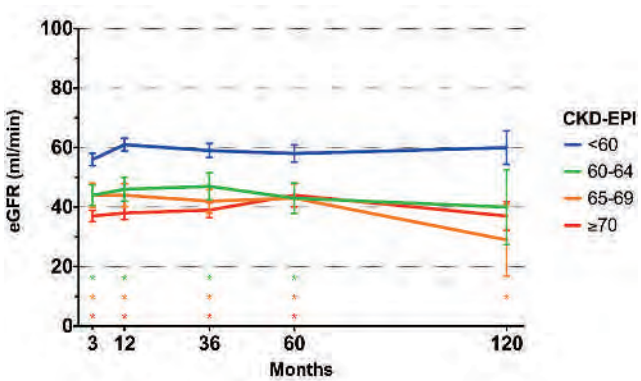

Figure 1. Estimated glomerular filtration rate during 10 years. Connected scatter plot showing estimated glomerular filtration rate over time from transplantation date, using Cockroft-Gault estimation. Error bars represent 95% CI. Subjects are grouped by donor age; <60, 60-64, 65-69, and ≥70. Asterisk denote significant (p<0.05) difference compared to the group <60.

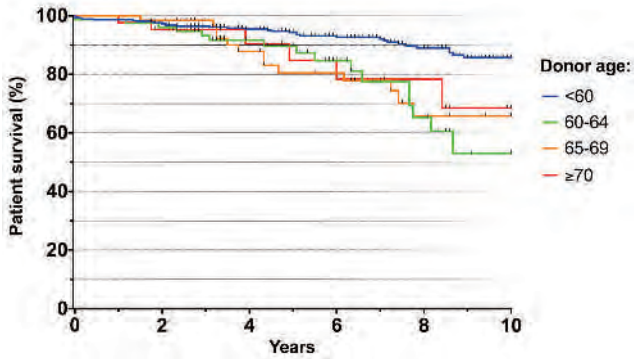

Figure 2. Patient survival. Kaplan-Meier plot showing the proportion of recipients alive expressed as function of time from transplantation. Recipients are stratified and grouped by donor age; <60, 60-64, 65-69, and ≥70.

423.11

Avoiding unnecessary healthcare utilization: The advantages of preemptive kidney transplantation

Patrick Dean[1,2], Kristi M.Swanson[3], James M.Naessens[3], Mark D.Stegall[1,2].
[1]Division of Transplantation Surgery, Mayo Clinic, Rochester, MN, United States; [2]William J. von Liebig Center for Transplantation and Regenerative Medicine, Mayo Clinic, Rochester, MN, United States; [3]Robert D. and Patricia E. Kern Center for the Science of Health Care Delivery, Mayo Clinic, Rochester, MN, United States.

Introduction: Delivering timely, definitive treatment can reduce healthcare costs. Performing a kidney transplant without ever undergoing dialysis (PreKTx) is associated with improved patient survival and quality of life and also might decrease health care utilization and costs. However, most patients—even those with living donors—do not undergo PreKTx. The goal of this study was to compare healthcare utilization in PreKTx vs. non-PreKTx.
Materials and Methods: We identified recipients of first kidney transplants from 2008-2014 utilizing the Optum Labs Data Warehouse, a database including administrative claims data on over 100 million privately insured and Medicare Advantage enrollees in the United States. Patients were identified as receiving a PreKTx vs. non-PreKTx based on claims indicating receipt of dialysis therapy. Healthcare utilization measures were compared across groups.
Results: Of 1334 KTx recipients, 595 (45%) received PreKTx [469 living donor (LD) + 126 deceased donor (DD)] and 739 (55%) received non-PreKTx (379 LD + 360 DD). In LD PreKTx, 20% (93/469) underwent 163 imaging or surgical procedures related to dialysis access, including 55 who underwent creation of an arteriovenous fistula. PreKTx was associated with fewer hospitalizations and emergency department visits before and after transplant (Table 1).

Table 1. Demographics and 90 Day Utilization Measures

	Preemptive (N=595)		Non-Preemptive (N=739)		
	Number or Mean (Median)	% or Std. Dev. (IQR)	Number or Mean (Median)	% or Std. Dev. (IQR)	P-Value
Age at transplant					0.018
≤ 18	36	6.1%	33	4.5%	
19 to 34	71	11.9%	70	9.5%	
35 to 44	103	17.3%	116	15.7%	
45 to 54	155	26.0%	192	26.0%	
55 to 64	172	28.9%	210	28.4%	
65+	58	9.8%	118	16.0%	
Race					0.015
White	291	48.9%	335	45.3%	
Black	21	3.5%	58	7.8%	
Hispanic	39	6.6%	51	6.9%	
Asian	16	2.7%	26	3.5%	
Unknown	228	38.3%	269	36.4%	
Office visits pre-transplant	25.7 (22.0)	15.1 (16)	23.6 (21.0)	14.7 (18)	0.004*
Office visits post-transplant	9.4 (9.0)	5.2 (6)	9.9 (9.0)	6.2 (8)	0.39*
ED visits pre-transplant	1.1 (0)	2.2 (2)	3.3 (2.0)	4.6 (4)	<0.0001*
ED visits post-transplant	0.4 (0)	0.9 (0)	0.6 (0)	1.2 (1)	0.03*
Hospitalizations pre-transplant	1.1 (0)	2.1 (1)	2.7 (2)	3.2 (2)	<0.0001*
Hospitalizations post-transplant	1.3 (2)	2.2 (2)	1.7 (1)	3.0 (2)	0.006*

Conclusions: PreKTx results in lower utilization of healthcare resources. These data suggest that "Transplant First" should be a priority rather than current Federal Government guidelines for "Fistula First"[1].

The end of the expanded criteria donor era: Lessons learned

Robert Stratta[1], Alan Farney[1], Giuseppe Orlando[1], Hany El-Hennawy[1], Muhammad Khan[1], Amber Reeves-Daniel[2], Amudha Palanisamy[2], Michael Gautreaux[3], Samy Iskandar[3], William Doares[4], Scott Kaczmorski[4], Jeffrey Rogers[1].
[1]Surgery, Wake Forest, Winston-Salem, NC, United States; [2]Internal Medicine, Wake Forest, Winston-Salem, NC, United States; [3]Pathology, Wake Forest, Winston-Salem, NC, United States; [4]Pharmacy, Wake Forest, Winston-Salem, NC, United States.

Introduction: Expanded criteria donor (ECD) kidneys increase the donor organ pool but their discard rate remains high and their value has been questioned because of expected lower long-term survival outcomes. With the development of the Kidney Donor Profile Index (KDPI) and a new allocation system in the US, the end of the ECD kidney era has occurred coincident with regional and national sharing of high KDPI (ECD) kidneys. The study purpose was to retrospectively review our single center experience with ECD kidney transplants (KT) prior to implementation of the new scoring and allocation systems.
Methods: All patients (pts) received antibody induction with tacrolimus/mycophenolate ± steroids. Standardized management algorithms were implemented to preserve nephron function (including machine preservation) and pt selection was based on low immunological risk (primary transplant, low panel reactive antibody [PRA] level) and predicted limited nephron need (older age, lower BMI).
Results: Over a 12.8 year period, we performed 497 ECD KTs including 247 local and 250 imported from other donor service areas. Mean KDPI was 82%. A total of 55 (11%) dual KTs were performed, including 31 (12.5%) from local and 24 (9.6%) from import ECDs. The import ECD group had more donors (16% vs 8.5%) and recipients (23% vs 16%) ≥ age 70, a higher recipient BMI (27.4 vs 25.4 kg/m^2), more zero HLA-mismatches (14% vs 2%), more pts with a PRA >20% (17% vs 9%), more KTs with a cold ischemia time >30 hours (46% vs 19%), fewer donation after cardio-circulatory death (DCD) ECDs (5% vs 9%), a shorter duration of pretransplant dialysis (mean 26 vs 34 months), higher pump resistance (mean 0.27 vs 0.20 mm Hg/ml/min) and fewer kidneys managed with pump preservation (78% vs 92%, all $p \leq 0.05$) compared to the local ECD group. With a mean follow-up of 5 years (minimum 1 year), actual pt and graft survival rates were 71% and 57.6% in import vs 76% and 57.9% in local ECD KTs, respectively. Death-censored graft survival rates were 70% in import vs 69% in local ECD KTs. Delayed graft function occurred in 28% import vs 23% (p=NS) local ECD KTs. There were no differences in other outcomes. One- and 2-year renal function (eGFR 42 ml/min/1.73 m^2) was similar in both groups. In 104 cases, right and left mate ECD kidney pairs were transplanted as single allografts into 208 pts at our center; outcomes were similar irrespective of kidney laterality.
Conclusions: In spite of a number of differences in donor, recipient, immunologic, and preservation characteristics, intermediate-term outcomes are remarkably similar for import vs local ECD KTs, suggesting that broader sharing of ECD kidneys may improve utilization without compromising outcomes. In addition, by appropriate donor and recipient profiling and the use of management algorithms to project and protect renal function, acceptable outcomes can be achieved with ECD kidney transplants irrespective of kidney laterality.

423.13

Financial cost of cold ischemia time in kidney transplantation

Oscar Serrano[1], David Vock[2], Ty B. Dunn[1], Srinath Chinnakotla[1], Raja Kandaswamy[1], Timothy L. Pruett[1], Arthur J. Matas[1], William D. Payne[1], Roger Feldman[3], Erik B. Finger[1].
[1]Surgery, University of Minnesota, Minneapolis, United States; [2]Biostatistics, University of Minnesota, Minneapolis, United States; [3]Health Policy & Management, University of Minnesota, Minneapolis, United States.

Purpose: A new kidney allocation system (KAS) was implemented in December 2014 using the kidney donor profile index (KDPI), which prioritizes historically-disadvantaged populations. While KAS aims to maximize the equitable sharing of kidney allografts, concerns remain that its implementation through wider geographical sharing may lead to increased cold ischemia time (CIT) and CIT-associated adverse effects, namely delayed graft function (DFG), and ultimately, transplant-related costs.
Methodology: Between 2006 and 2014, 1495 kidney transplants (KTx) were performed at our institution. Donor and recipient demographics, intraoperative parameters, short- and long-term outcomes and hospitalization cost data were collected. A linear regression model was constructed adjusting for recipient age, race, gender, pre-KTx hemodialysis (HD) status, KDPI, and donor type (DD, LD) to assess the impact of CIT on DGF, LOS (LOSTx) and cost (cTx) of transplant admission, and overall 1-year post-transplant in-hospital LOS (LOS1Y) and cost (c1Y).

Table 1. Effect of Cold Ischemia Time on Kidney Transplant Outcomes

Outcome	Expected Increase per 6 hr CIT [95% CI]	*p*-value
DGF	32% Odds of DGF [12-55%]	<0.001
LOS (Tx admission)	0.58 days [0.34-0.81]	<0.001
Cost (Tx admission)	$2078 [$1057-3098]	<0.001
LOS (1-year)	1.06 days [0.33-1.79]	<0.01
Cost (1-year)	$3135 [$651-5619]	0.013

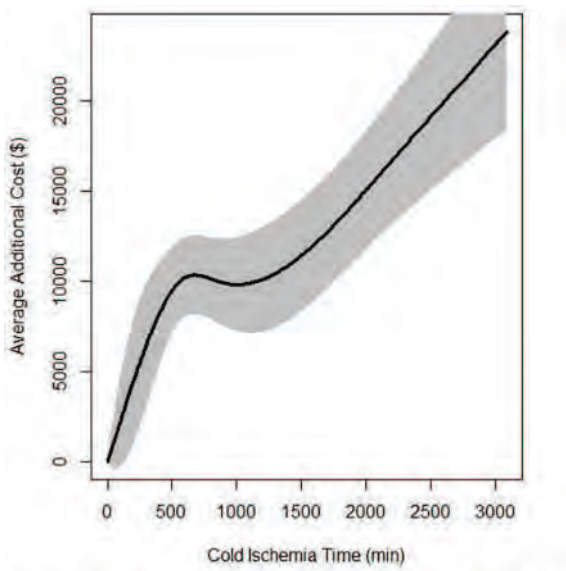

Figure 1. Average additional cost (±95% confidence interval) of transplant admission for each minute of cold ischemia time after adjusting for recipient age, gender, race, hemodialysis, donor type, year of transplant, and KDPI. A restricted cubic spline basis transformation was used to measure the effect of CIT on average cost.

Results: A total of 1200 KTx recipients had financial records available for analysis. Median age at transplant was 48.7 years (IQR 32.6, 59.7). The majority of our patients were male (62.5%), Caucasian (80.9%) and on pre-KTx HD (60%); 43% received a DD kidney. In multivariate analysis, CIT was associated with increased DGF ($p<0.001$), LOSTx ($p<0.001$), cTx ($p<0.001$), LOS1 ($p<0.01$) and c1Y ($p=0.013$). The incremental effect of CIT on KTx outcomes is listed in Table 1 and the average additional cost per minute of CIT is depicted in Figure 1. Further analysis of the cost breakdown revealed an incremental cost effect of CIT on direct, indirect, fixed and variable costs.
Conclusion: One of the unintended consequences of KAS is the prolongation of CIT, which has the potential to increase DGF rates. In turn, we have seen increased DGF rates, leading to increased LOS and overall hospital costs.

424.1

Kinetics of CMV-specific t-cells from pre-to-posttransplantation predict outcomes in CMV-seronegative kidney transplant recipients

Thomas Schachtner[1,2], Maik Stein[2], Pera Reinke[1,2].
[1]Nephrology and Internal Intensive Care, Charité Campus Virchow Clinic, Berlin, Germany; [2]Berlin-Brandenburg Center for Regenerative Therapies, Charité Campus Virchow Clinic, Berlin, Germany.

Introduction: CMV-seronegative kidney transplant recipients (KTRs) from CMV-seropositive donors are at highly increased risk of primary CMV-infection with associated inferior patient and allograft outcomes. Presence of preformed CMV-specific T-cells despite CMV-seronegativity, however, may result from absence of detectable circulating antibodies despite CMV-specific memory B-cells or cross-reactivity due to allogeneic presensitization.
Material and Methods: We studied all CMV-seronegative KTRs between 2008 and 2013 for the presence of CMV-specific T-cells pretransplantation. Among 87 CMV-seronegative KTRs, 49 KTRs (56%) received an allograft from a CMV-seropositive and 38 KTRs (44%) from a CMV-seronegative donor. Samples were collected pretransplantation, at +1, +2, and +3 months posttransplantation. CMV-specific T-cells to CMV-IE1, CMV-pp65, and alloreactive T-cells were measured using an interferon-γ Elispot assay.
Results and Discussion: Among 49 CMV-seronegative KTRs from CMV-seropositive donors, 11 KTRs (22%) showed detectable CMV-specific T-cells pretransplantation. Interestingly, no differences were observed for the incidence of CMV-replication between KTRs with preformed CMV-specific T-cells and those without ($p>0.05$). However, KTRs with preformed CMV-specific T-cells presented with shorter duration of CMV-replication, lower initial and peak CMV-loads, and less need for intravenous antiviral therapy ($p<0.05$). The loss of CMV-specific immunity from pre- to posttransplantation was highly associated with CMV-replication ($p<0.05$). KTRs with stable or increasing CMV-specific immunity from pre- to posttransplantation showed protection from CMV-replication. KTRs with no CMV-specific T-cells pretransplantation showed inferior patient survival and allograft function. We didn't observe an association between preformed CMV-specific T-cells and preformed alloreactive T-cells ($p>0.05$). However, KTRs developing CMV-replication showed a higher incidence of preformed alloreactive T-cells and acute cellular rejection episodes ($p<0.05$).
Conclusion: A relevant proportion of CMV-seronegative KTRs shows CMV-specific T-cells pretransplantation with less severe primary CMV-infection and superior allograft outcomes compared to KTRs without CMV-specific T-cells. However, not the presence of preformed CMV-specific immunity, but the kinetics of CMV-specific immunity from pre- to posttransplantation identifies KTRs at increased risk of CMV-replication. Higher frequencies of alloreactive T-cells may contribute to the higher incidence of acute cellular rejection in KTRs with CMV-replication.

[1]Infection Control Team, Hospital das Clínicas, School of Medicine, University of São Paulo, São Paulo, Brazil; [2]Kidney Transplantation Service, Hospital das Clínicas, School of Medicine, University of São Paulo, São Paulo, Brazil; [3]Laboratory Division of Microbiology, Hospital das Clínicas, School of Medicine, University of São Paulo, São Paulo, Brazil; [4]Infectious Diseases , Hospital das Clínicas, School of Medicine, University of São Paulo, São Paulo, Brazil.

Carbapenem resistant Enterobacteriaceae (CRE) is an emergence worldwide pathogen, with few therapeutic options. Treatment of CRE with reduced susceptibility to polymyxin (MIC ≥16) has been a further challenge, with no established gold standard therapy.
The aim of this study is described the treatment of infections with CRE with reduced susceptibility to polymyxin (MIC ≥16) (CREPR) in kidney transplant recipients (KTr). We included all cases of CREPR infection from Jan 2013 to Dec 2015 that have at least 48 hours of treatment with at least one antimicrobial agent having proven in vitro activity against the isolated strain. Treatment failure was defined as persistence or relapsed of infection within the first 30 days after the end of the initial treatment. Recurrence was defined as new signs or symptoms of infection at the same site, with a positive culture for CREPR of the same phenotype and no evidence of deep infection, after 30 days to the end of the initial treatment. Criteria for infection definitions were those outlines by NHSN.
Association between variables was performed by Chi-square or Fisher test for dichotomous variables and Mann-Whitney test for continuous ones. Multivariate analysis was performed by logistic regression.
We analyzed 21 CREPR infection episodes in 17 patients. The median time between the transplant to first infection episode by CREPR was 78 days (12-4613). Median age of KTr was 57 years (33-72). Two patients had combined transplant (pancreas-kidney and liver-kidney), 16 (94.1%) had a deceased donor, and 13 (76.5%) had induction therapy with ATG. All infections episodes were due to K. pneumoniae, except two patients which infections were caused by S. marcenscens. Sites of infection were urinary tract in 9 cases (42.9%), surgical site infection (SSI) in 11 (52.4%) and pneumonia in 1 (4.8%) case. Twelve infections (57.1%) had positive blood culture. All SSI evolved with deep collection and need surgical or radiological intervention for focus control. The median time from first positive culture to initial of effective therapy was 2 days (0-63). Combined therapy was used in 14 (66.7%) treatment, among those only 6 (28.6%) had more than one drug with in vitro susceptibility. Drugs used in treatment were: polymyxin in 5 cases (23.8%), aminoglycoside in 13 (61.9%), oral fosfomycin in 6 (28.6%), carbapenem in 11 (52.4%) and tigecycline in 7 (33.3%). Among infections treated with carbapenem, the MIC for this antibiotic was under 16mg/dl only in 3 cases. Median length of therapy was 14 days (7-30). Seven (33.3%) patients evolved with treatment failure: 4 (19.0%) died and 3 (14.3%) had relapsed of infection within first 30 days. One KTr had infection recurrence. Risk factors associated to treatment failure in univariate analysis were polymyxin used (P 0.001), higher SOFA score at diagnosis (P 0.002); protective factor was aminoglycoside used (P 0.05). In multivariate analysis, only higher SOFA score was associated to treatment failure. In conclusion infections with CREPR in KTr had high rate of treatment failure and the inclusion of aminoglycoside in therapy may be a protective effect.

VZV-specific T-cell memory responses after reactivation in transplant recipients and after vaccination in transplant candidates

Nicole M. van Besouw[1], Marcia M.L. Kho[1], Joke M. Zuijderwijk[1], Jeroen W.I. Jpelaar[1], Marieken J. Boer-Verschragen[1], Herold J. Metselaar[2], Rogier A.S. Hoek[3], Olivier C.Manintveld[4], Annemiek A. van der Eijk[5], Georges M.G.M. Verjans[5], Willem Weimar[1].
[1]Internal Medicine - Nephrology & Transplantation, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; [2]Gastroenterology & Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; [3]Respiratory Medicine, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; [4]Cardiology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; [5]Viroscience, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands.

Introduction: Primary varicella zoster virus (VZV) infection causes varicella and lifelong latent infection in neural ganglia from which it may reactivate leading to herpes zoster (HZ). Transplant patients are at high risk to develop HZ and severe clinical complications. In addition, we reported that VZV-reactive memory T-cells are significantly lower in transplant recipients compared to healthy controls (J Med Virol 2012). First, we investigated the incidence of HZ after organ transplantation. Second, we questioned whether HZ after transplantation leads to adequate VZV-reactive memory T-cell responses. Third, we studied the effect of a VZV booster vaccination on T-cell memory.
Methods: The medical records of 958 transplant recipients after first kidney (KTx: n=420), first liver (LTx: n=224), heart (HTx: n=195) and lung (LuTx: n=119) transplantation were analyzed for HZ. The VZV-specific T-cell memory responses before and after HZ (n=5) were compared to patients without HZ (n=5). The VZV-specific T-cell memory responses before and 1 year after Zostavax® vaccination were analysed in 19 patients, aged at least 50 years and older, awaiting renal transplantation. Twenty gender and aged-matched living donors served as controls.
Results: The overall incidence rate of HZ post-KTx (14.4 cases/1000 PY), LTx (24.5 cases/1000 PY), HTx (30.8 cases/1000 PY) and LuTx (38.2 cases/1000 PY) was significantly higher than in the general population of 50-70 years of age (7-8 cases/1000 PY). The percentage of both VZV-reactive CD4 and CD8 central (CM: p=0.06, p=0.02) and effector (EM: p=0.02, p=0.03) memory T-cells increased in all patients after HZ to significantly higher frequencies compared to those without HZ. One year after booster vaccination, the percentage of CD4 CM had increased in both patients (p=0.004) and donors (p=0.004) and the CD4 EM were increased in donors (p=0.009) compared to before vaccination.
Conclusion: HZ is a frequent complication after transplantation and increases VZV-specific T-cell memory responses. Boosting the VZV adaptive immune response by prophylactic VZV vaccination before transplantation may limit the incidence of HZ after transplantation.

424.4

Still an equal B-cell response to a VZV-booster in both renal transplant recipients and healthy individuals at one year post vaccination

Marcia Kho[1], Willem Weimar[1], Marieken J.Boer-Verschragen[1], Annemieke A.van der Eijk[2], Nicole M.van Besouw[1].
[1]Internal Medicine – Nephrology and Transplantation, Erasmus Medical Center, Rotterdam, Netherlands; [2]Viroscience, Erasmus Medical Center, Rotterdam, Netherlands.

Introduction: Herpes zoster incidence and complication rate is much higher in solid organ transplant recipients than in the general population of the same age. This reactivation of the varicella zoster virus could be prevented by booster vaccination. However, end stage renal disease (ESRD) patients are known to respond much poorer to vaccinations, e.g. against hepatitis B and influenza, than healthy individuals do. Therefore, we studied the effect of a VZV booster vaccine on B-cell response in patients with ESRD as well as in healthy individuals.
Methods: In a prospective study, 26 patients, aged at least 50 years, and awaiting renal transplantation were vaccinated with Zostavax®. Gender and age-matched living kidney donors were included as controls (n=27). Varicella Zoster Virus (VZV) specific IgG titres were measured before, at 1, 3 and 12 months post vaccination.
Results: All patients and donors reached month 3 after vaccination, 25 patients and 26 donors reached month 12 after vaccination. Both in patients and healthy individuals, VZV-specific IgG titers were significantly higher at all time points after vaccination compared to before (M1: $p<0.0001$, $p<0.0001$; M3: $p=0.0002$, $p<0.0001$; M12: $p=0.01$, $p=0.0005$; patients and controls, respectively). The patients' IgG titers were comparable to the donors' IgG titers at all time points (pre: $p=0.64$, M1: $p=0.94$, M3: $p=0.90$, M12: $p=0.84$). No difference was found between the patients who received a renal transplant within one year after vaccination and the patients who are still awaiting transplantation.
Discussion: VZV booster vaccination equally increases VZV-specific IgG titers for at least 1 year after vaccination in ESRD patients compared to healthy individuals. Prophylactic VZV vaccination before transplantation could reduce herpes zoster incidence and severity after transplantation.

424.5

Diagnostic potential of interferon gamma release assay to detect latent tuberculosis infection in kidney transplant recipients in endemic area

Hassan Aleid[1], Jameela Edathodu[2], Bright Varghese[3], Abdulrahman Alrajhi[2], Ahmad Nazmi[1], Mohammed Shoukri [4], Attia Ashraff[1], Hazem Elgamal[1], Ihab Mahmoud[1], Fahad Alrabiah[2], Sahal Al Hajoj[3]. [1]Department of Kidney and Pancreas Transplantation, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; [2]Medicine, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia; [3]Department of Infection and Immunity, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; [4]National Biotechnology Centre, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

Background: Latent tuberculosis infection (LTBI) is now being screened by using clinical assessment, tuberculin skin test (TST), and chest radiography. Interferon gamma release assays, which measure gamma interferon production by lymphocytes in response to exposure to Mycobacterium tuberculosis specific antigens, are now licensed to diagnose latent tuberculosis. The objective of this study was to evaluate the utility of QuantiFERON®-TB Gold in Tube (QFT) test for diagnosing LTBI in patients planned for kidney transplantation.
Methods: All adult patients with end-stage renal disease, evaluated for kidney transplantation in a referral center from August 2008 till May 2013, were enrolled, after consenting in a prospective, observational, non-interventional study. LTBI diagnosis was conducted by TST, chest X-ray and clinical assessment. Interferon Gamma Release Assay (IGRA) was carried out on all candidates by QuantiFERON®-TB Gold In-tube Test.
Results: Overall, 278 patients were enrolled and kidney transplantation was performed in 173 patients. Contributed follow-up was 836.5 patient-years, and tuberculosis-free transplant duration was 478.5 patient-years. By standard methods, latent tuberculosis was diagnosed in 14 patients. Peri-transplant chemoprophylaxis was given to 53 patients, including recipients of organs from all deceased donors and living donors with LTBI. QFT was positive in 70 patients, negative in 200 patients and indeterminate in 8. The agreement between latent tuberculosis diagnosis using standard methods and IGRA by QFT was poor (Kappa: 0.089 + 0.046, p-value = 0.017). 27 of the patients, who had positive QFT, were transplanted and none except one was given isoniazid preventive therapy. None of the transplant recipients developed tuberculosis after a median follow-up of 25 months (range 2-58 months, mean 27 months).
Conclusions: The agreement of the QuantiFERON®-TB Gold In-tube test with standard diagnosis of LTBI in kidney transplant recipients was poor.

Introduction: To evaluate the incidence and spectrum of etiologic agents of early bloodstream infections (BSI) among solid organ transplantation (SOT) recipients
Materials and Methods: This was the preliminary report of an ongoing prospective observational study (project no: KA14/120). The data of this report were collected from medical records for each SOT recipient from April 15th 2014 to December 31th 2015. BSI within the first month after SOT was defined as early BSI. Polymicrobial BSI was defined as the growth of more than one organism in blood culture, excluding coagulase-negative staphylococci, *Bacillus* spp. and *Corynebacterium* spp. The etiologic agents and antimicrobial resistance profiles of pathogens of bacteremia episodes were evaluated. Methicillin resistance in *Staphylococcus aureus* strains; extended-spectrum β-lactamase (ESBL) production both in *Escherichia coli* and in *Klebsiella pneumoniae* strains; and multidrug-resistance (MDR) and extensively drug-resistance (XDR) in *Acinetobacter baumannii*, *Pseudomonas aeruginosa* were evaluated. The interim standard definitions for MDR and XDR were used as appropriate[1]. SPSS version 11.0 was used and $p < 0.05$ was considered to be statistically significant. Pearson chi-square test was used as appropriate.

Table 1. Characteristics of the recipients of a SOT with early BSI

	Kidney	Liver	Heart	Total
Transplants performed	110	51	23	184
Living donor	80	37	0	117
Number of BSI episodes	13	20	6	39
Number of BSI episodes >1	1	3	0	4
Number of patients with BSI	12 (10%) (Cl_{95} 4.4-15.6)	17 (33%) (Cl_{95} 20.1-45.9)	6 (26%) (Cl_{95} 8.1-43.9)	35 (19%) (Cl_{95} 13.4-24.6)
Ratio BSI episodes/patients	1.1	1.2	1.0	1.1
Incidence by episodes	11.8%	39.2%	26.1%	21.2%
Incidence by patients	10.9%	33.3%	26.1%	19%
Microbiology of BSI				
Gram negative	11	14	4	29
Gram positive	2	9	0	11
Candidemia*	0	1	2	3
Polymicrobial	0	4	0	4
Leucopenia	5 (39%)	5 (25%)	0	10 (26%)
Crude mortality¶	1 (8%)	2 (10%)	1 (17%)	4 (10%)

Candida dubliniensis (1), Candida glabrata (1), Candida tropicalis (1)

¶Mortality within 30 days after the diagnosis of early BSI, number

Results: One hundred eighty five patients had 187 SOT (one patient had both liver and kidney transplantation, one patient had retransplantation) during the study period. As a total, 113 kidney, 51 liver and 23 heart transplantations were performed. Three SOT recipients living outside Turkey were exluded, as they were unlikely to return to Turkey for the treatment of BSI. The study population comprised of 182 patients with 184 SOT.
We diagnosed 39 early BSI episodes in 35 patients (19.2%). Four recipients had two episodes each: three liver recipients, one kidney recipient. The incidences of early BSI by type of transplantation were demonstrated in Table 1.
Early BSI was seen more in liver than kidney or heart transplantation (p= 0.001). Nine of 55 pediatric recipients had 11 early BSI episodes (28%, 11/39episodes). The median age of SOT recipients at the time of early BSI was 40 years (interquartile range: 11-49 years). The male gender (26/35, 74%) was prominent in the recipients with early BSI.
The source of early BSI episodes by type of transplantation was demonstrated in Table-2.

Table 2. The source of early BSI by type of transplantation

Source of early BSI	Kidney (N=13) N (%)	Liver (N=20) N (%)	Heart (N=6) N (%)	Total (N=39) N (%)
Catheter-related	0	3 (15%)	1 (17%)	4 (10%)
Urinary	7 (54%)	1	1 (17%)	9 (23%)
Biliary	0	3 (15%)	0	3 (8%)
Abdominal nonbiliary	4 (31%)	4 (20%)	0	8 (21%)
Surgical incisional wound	1 (8%)	0	0	1 (3%)
Mediastinitis	0	0	1 (17%)	1 (3%)
Unknown	1 (8%)	9 (45%)	3 (50%)	13 (33%)

Fourty three microorganisms (29 gram-negative, 11 gram-positive and three *Candida*) were isolated. The distribution of 29 gram-negative isolates were: 21 enteric (10 *K. pneumoniae*, 10 *E. coli*, 1 *Serratia* spp) and 8 nonfermentative (3 *A. baumannii*, 2 *Pseudomonas putida*, 1 *Pseudomonas aeruginosa*, 1 *Stenotrophomonas* and 1 *Burkholderia* spp.). ESBL production was 60% (6/10) in *K. pneumoniae* and 50% (5/10) in *E. coli*. One *P. aeruginosa* isolate was XDR. All three (100%) *A. baumannii* isolates were XDR. Among 11 gram-positive isolates; five methicillin resistant coagulase-negative staphylococci, two methicillin-sensitive *S. aureus*, four enterococci isolated.
Discussion: Liver transplant recipients are at the highest risk for developing early BSI after transplantation in accordance with previous studies[2],[3].
Conclusion: Prompt diagnosis and appropriate antimicrobial therapy are important in the management of BSI. Local antimicrobial resistance profiles are helpful in deciding empirical antibacterial therapy.

Efficacy of INH prophylaxis in renal transplant recipients: a follow up of 5 years

Anwar Naqvi[1], Rubina Naqvi[2], Sohail Akhtar[3], Tahir Aziz[2], Asma Naseem[4], Sunil Kumar[4].
[1]Urology and Transplantation, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [2]Nephrology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [3]Pulmonology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [4]Infectious Diseases, Sindh Institute of Urology and Transplantation, Karachi, Pakistan.

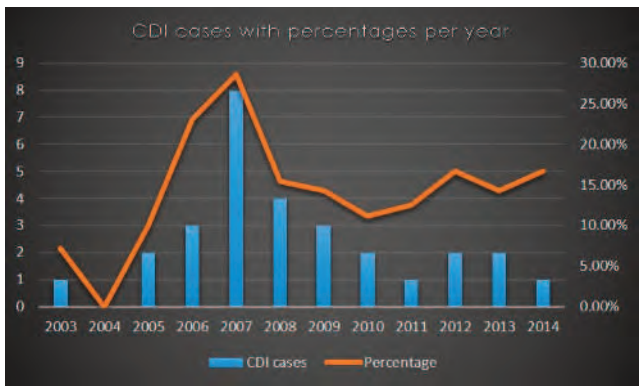
Introduction: Renal transplant recipients are at high risk of tuberculosis due to immunosuppressives they receive. The incidence of tuberculosis in transplant recipients is found to be 20 to 70 time more than in the general population. A prospective randomized study on Isoniazid (INH) prophylaxis at our center showed good efficacy. We have started INH prophylaxis in all renal transplant recipients from April 2009.
Objectives: We seek to follow up all patients on INH prophylaxis and will study the incidence of TB, tolerability of INH and INH resistance. Methods: This is a retrospective observational study. The files of renal transplant recipients from April 2009 to December 2011 were reviewed till June 2015. We noted the incidence of TB, INH resistance, and the tolerability of INH prophylaxis.
Results: A total of 910 patients were followed till June 2015. Eight hundred and twenty six (91%) completed INH prophylaxis successfully. Overall 1.42% had hepatotoxicity due to INH. Fortysix patients (5%) developed tuberculosis. Nearly half of the patients (43%) developed TB >2yrs post prophylaxis. Twenty two (48%) had Pulmonary tuberculosis and 12 (26%) had extrapulmonary TB. Out of 14 cultures only one isolate was INH resistant (7%). There was no significant effect of immunosuppression on the onset of tuberculosis. Thirty seven (84%) got cured and tolerated Rifampicin based regimen very well with no rejection episode.Six patients (13%) died, 3 (6.5%) died due to fulminant TB.
Conclusion: NH prophylaxis is well l tolerated with minimal side effects. The incident TB has significantly decreased during the first 2 years post prophylaxis. INH seems to be effective in curtailing TB in the first two years post transplant. However we should consider prolonging the duration of INH prophylaxis in countries where TB is endemic.

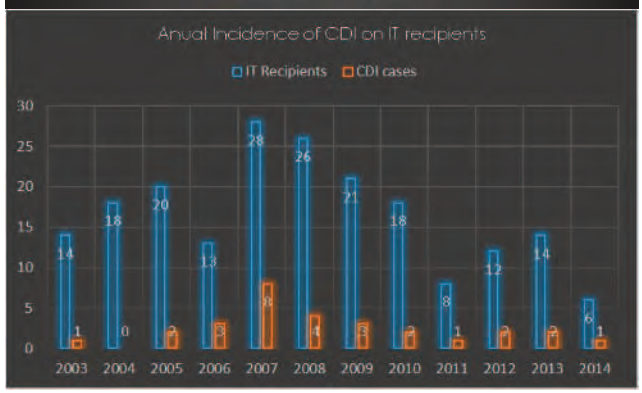
424.8

Epidemiology of Clostridium difficile infection (CDI) in Intestinal Transplant (IT) recipients

Luis F. Guzman Vinasco[1], Fang Qiu[3], Andre C. Kalil[1], David Mercer[2], Alan Langnas[2], Diana F. Florescu[1].
[1]Infectious Diseases, University of Nebraska Medical Center, Omaha, NE, United States; [2]Transplantation Surgery, University of Nebraska Medical Center, Omaha, NE, United States; [3]Department of Biostatistics, University of Nebraska Medical Center, Omaha, NE, United States.

Introduction: IT has become an alternative treatment option for patients with intestinal failure. C. difficile is the most common cause of healthcare-associated infectious diarrhea. One previous report estimated the prevalence of C difficile infection (CDI) in IT recipients at 8%[2]. The aim of our study was to describe the epidemiology of CDI in IT recipients during the first year post-transplantation.
Methods: We performed a retrospective cohort study in pediatric IT recipients who were transplanted at University of Nebraska Medical Center from January 2003 to June 2014. Recipients who developed CDI during the first year post-transplant were analyzed, and only the first episode was taken in consideration. Descriptive statistics are presented for categorical variables, and medians (range) for continuous variables.
Results: 198 patients were transplanted during the study period, with a median age at transplantation of 19 months (range 3 – 443 months); 92(46%) recipients were female, 104 (53%) were Caucasian. CMV sero-status: 27(14%) D+/R+, 54 (27%) D+/R-, 31(16%) D-/R+, 86(43%) D-/R-. Allograft type: 37(19%) patients underwent isolated IT, 155(78%) liver-IT and 6(3%) liver-kidney-IT. 197 recipients were induced with basiliximab and 1 with basiliximab-thymoglobulin. Maintenance immunosuppression: 198(100%) oral steroids, 188(95%) tacrolimus, 22(11%) mycophenolate, 7(3.5 %) sirolimus and 1(0.5 %) everolimus.
29(15%) recipients developed CDI. The graph describes the annual incidence of CDI.





Of the recipients with CDI: 13(44%) were exposed to antibiotics, 10(34%) had surgery, 23(79%) were on proton pump inhibitors, 2(6.9%) had jejunostomy, 23(79%) gastrostomy, 20(68%) ileostomy, 3(10%) received IVIG, 25(86%) were on tube feedings; median serum levels of tacrolimus during the month prior to diagnosis of CDI was 13.6 ng/mL (range 3.3 – 28.7). 25(86%) patients were treated with oral metronidazole; in 26(89%) patients the length of treatment was 14 days. There was only 1(3.3%) episode of recurrent CDI. Of the 29 patients with CDI, 7(24%) had an episode of rejection: 4 before and 3 after CDI. 6(20.6%) died during the first year post-transplant.
Conclusion: CDI is a frequent (15%) infectious etiology of diarrhea in IT recipients during the first year post-transplant.

424.9

Incidence and outcome of parasitic infection after kidney transplantation in Thailand

Siriorn Watcharananan[1], Kaenchai Pipatpannawong[2], Viroon Mavichak[2], Nattakan Naitook[2].
[1]Medicine, Ramathibodi hospital, Mahidol University, Bangkok, Thailand; [2]Kidney transplant institute, Praram 9 hospital, Bangkok, Thailand.

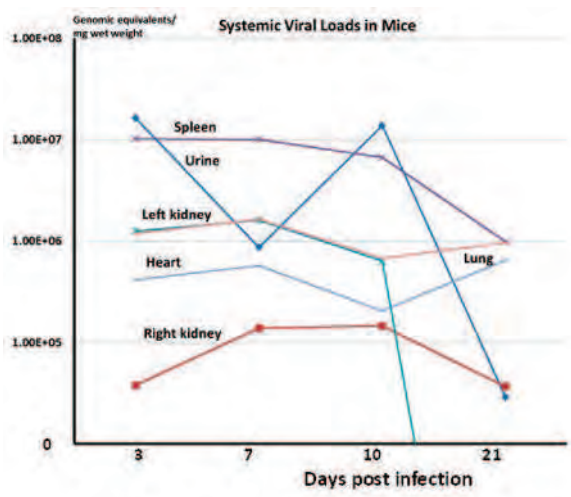
Background: Little is known about the parasitic infection among kidney transplant (KT) recipient.
Methods: We prospectively screened 374 adult (age >18 years old) KT candidates for pretransplant latent infections during 2006 and 2016. Majority of the patients were from Thailand (66.3%), Myanmar (26.2%), and Cambodian (4.3%). Parasitic screenings including blood serology for strongyloides and rapid screen for malaria for patients from endemic area. Endemic parasites (Gnathosomiasis spp., Angiostrongylus spp., Strongyloides spp.) were tested by serology and stool examination among the case with peripheral eosinophilia. Medical records of patients with parasitic infection before or after KT were reviewed for demographic characteristics, clinical presentation, laboratory findings, treatment and outcome.
Result: A total of 357 (95.45%) and 39 (10.43%) patients were tested for strongyloides antibody and rapid screen for malaria before KT, respectively. Only one (0.28%) was screened positive for strongyloides without notable peripheral eosinophilia, nor clinical symptoms. None were screened positive for malaria. Two (0.53%) had peripheral eosinophilia and were tested positive for gnathosomiasis. Patient with seropositive strongyloides received 2 courses of oral ivermectin (before and soon after transplantation). Long term (> 3 years) success was noted without repeated course of treatment. Of the 2 gnathosomiasis cases, one completed oral albendazole before transplantation and the long term follow up showed no relapse of eosinophila. Another received oral ivermectin plus albendazole within 2 weeks before transplantation, followed by the completion of albendazole course after KT. There was no relapse of eosinophila at 6 weeks follow up. After KT, there were 2 (0.53%) cases with clinically evident parasitic infections. Both were previously tested negative for strongyloides antibody before KT but they were diagnosed with strongyloides hyperinfection after transplantation. One had disseminated strongyloidiasis 5 months after KT. Despite the treatment with oral and parenteral ivermectin plus albendazole, he subsequently died from ARDS, sepsis with multiorgan failure. Another was diagnosed with eosinophilic appendicitis 4 years after KT. This patient initially presented with acute fever, abdominal pain and underwent appendectomy. A history of intermittent abdominal pain and chronic diarrhea was also noted. Stool examination showed viable larva of Strongyloises stercolaris which persisted despite 2 days of oral ivermectin. Extending the treatment to 1 more week resulted in resolution of the clinical symptoms. There was no relapse of parasites in the stool, nor eosinophilia at 3 months follow up.
Conclusion: Parasitic infection is uncommon among KT recipients in endemic area but the infection result in a significant complication after transplantation. Serology for strongyloides antibody might not be helpful to prevent infection after transplantation.

424.10

Pathogenesis of polyomavirus-associated nephropathy: insights from a mouse model

Gang Huang[1], Gang Zeng[2], Yuchen Huang[2], Parmjeet Randhawa[2].
[1]Department of Organ Transplantation, The First Affiliated Hospital, Sun Yat-sen University, Guangzhou, People's Republic of China; [2]Department of Pathology, University of Pittsburgh, School of Medicine, Pittsburgh, United States.

Background: Polyomavirus-associated nephropathy is an important cause of dysfunction and failure of renal transplants. Because it typically occurs in kidney transplant recipients, immunosuppression and renal ischemia-reperfusion injury are considered important factor in its pathogenesis. We sought to test this notion experimentally and develop an animal model that would facilitate development of novel therapies for this distressing disease.
Methods: 4 week old, 15-20 gram, male, C57BL/6J mice were used as kidney ischemia- reperfusion model. The left kidney pedicle was clamped for 3 hours and then released. Tacrolimus (0.2 mg/Kg) and Mycophenolate mofetil (200 mg/Kg) were given by the intragastric route daily. Mouse PyV (MPyV) LID -1 strain was propagated in NIH 3T3 cells and 3×109 genomic equivalents were used to infect mice by the intraperitoneal route 2 days after clamping of the renal artery. DNA was extracted using the Qiagen DNeasy Blood & Tissue Kit, QIAamp Fast DNA Stool Mini Kit, or QIAamp DNA Mini Kit (for urine samples). Viral load kinetics was studied in groups of 4-6 mice, sacrificed 3, 7, 10, 14, 21 and 28 days after infection. For quantitation of viral load, MPyV A2 large T antigen gene derived primers were used in a SyBrGreen based PCR run on the ABI Prism 7500 System using a MPyV-A3 plasmid based standard curve.
Results: Following infection, MPyV DNA was readily detected at virtually all time points with a peak observed on day 3, 7 or 10. MPV can replicate in many organs including not widely appreciated sites, namely the lung, aorta, heart, and liver. Viral loads were in the range of 105-107 genomic equivalents /mg wet weight. The two organs with the highest load were the spleen and aorta. Complete viral clearance occurred in the left kidney by 21 dpi, while clearance in other organs was partial with a 10-1000 fold decrease in viral load. Although some of the left kidneys with ischemic damage developed very high loads, there was considerable variability, and some organs showed no demonstrable infection, possibly because the tissue saved for viral DNA was not completely viable. Histopathologic examination did not produce the characteristic pathology of human polyomavirus nephropathy. There was also no viral cytopathic effect in any other organ.



Conclusion: A combination of ischemia and immunosuppression in the non-transplanted kidney failed to recapitulate human polyomavirus nephropathy. It appears that alloimmune mononuclear infiltrates provide a critically needed cytokine milieu that engenders viral replication and triggers the biochemical pathways that cause acute tubular injury and interstitial nephritis, which are the hallmark lesions of polyomavirus infection in the allograft kidney.

Pneumocystis pneumonia cluster outbreak at a Scottish Renal Transplant Centre

Andrew McClarey, Paul J.Phelan, Ian Laurenson, Dáire T.O'Shea, Lorna K.Henderson.
Royal Infirmary of Edinburgh, Edinburgh, United Kingdom.

Introduction: Pneumocystis Pneumonia (PCP) caused by Pneumocystis jirovecii is a potentially fatal opportunistic infection occurring primarily in immunocompromised hosts. Cluster outbreaks of PCP amongst renal transplant recipients have been documented worldwide. We describe a cluster of PCP diagnosed in nine renal transplant recipients from a single centre between November 2014 and January 2016.
Methods: A restrospective analysis of cases was carried out within our transplant centre, collating demographic and clinical data from the hospital database.
Results: During November 2014 to January 2016, nine renal transplant recipients (including one combined kidney pancreas recipient) were diagnosed with PCP, a notable rise in our centre. All suspected cases were confirmed by real time polymerase chain reaction testing of induced sputum (n=7) and bronchoalveolar lavage (n=2). All patients had radiological features consistent with PCP but two had no clinical symptoms initially other than pyrexia.
The median age at presentation was 65 years (range 24-77 years). All patients had a functioning graft (mean eGFR 30ml/min/1.73m2 (range 15-47ml/min/1.73m2). Median time to disease onset was 5.8 years post transplant (range 0.5-10.4 years). Eight patients were receiving tacrolimus or sirolimus based immunosuppression at diagnosis together with an anti-metabolite (n=7) and/or steroids (n=6). Mean MMF dose was 1.5 g (range 1-2 g). Mean tacrolimus trough was 6.6 ug/l (range 4-8 ug/l). Two patients received ATG therapy for vascular rejection within 12 months of presentation. All patients received pneumocystis prophylaxis for three months post transplantation and following ATG therapy but none were taking prophylaxis when diagnosed. Three patients had received treatment for CMV disease prior to index presentation, CMV viremia was simultaneously detected in a further three patients at presentation. All patients were lymphopenic at diagnosis (mean $0.2x10^9$/L) with six of nine demonstrating lymphopenia in the 12 months prior to diagnosis (mean $0.9 x10^9$/L).
Four patients required mechanical ventilation and two required dialysis. Four patients died within three months of presentation. Graft failure occurred in one further survivor.
Conclusion: This study characterises a heterogenous cluster of renal transplant patients developing PCP. Notable clinical features included a universal lymphopenia, low eGFR, high rates of co-morbidities (rejection episodes, CMV viremia) and several patients being a considerable time out from transplant. A number of the cases overlapped in time and place such that cross-transmission amongst susceptible hosts is suspected and further characterisation of this cluster by molecular typing of clinical specimens has been undertaken. This cluster illustrates the persistent risk of opportunistic infection, many years from transplantation, and represents a precedent in Scotland, and an emerging challenge to the long-term success of renal transplantation.

424.12

Neutrophil function assay in renal transplant recipients with bacterial and fungal infections

Sabiha Anis[1], Hafsa Tanwari[1], Mahjabeen Imam[1], Rana Muzaffar[1], Tahir Aziz[2], Anwar Naqvi[3], Adib Rizvi[3].
[1]Molecular Biology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [2]Nephrology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [3]Urology and Transplantation, Sindh Institute of Urology and Transplantation, Karachi, Pakistan.

Background: Neutrophils are the cells of the innate immune system that kill microorganisms by generating oxidative burst. This may be impaired in renal transplant recipients (RTx) due to immunosuppressive drugs and may predispose to develop bacterial and fungal infections. In this study we have evaluated the neutrophil functions in renal transplant recipients with bacterial and fungal infections by Nitro Blue Tetrazolium (NBT) slide test.
Methods: Neutrophil function was assessed in 41 RTx and 12 healthy controls. The neutrophils were stimulated with E. coli endotoxin and Candida extracts. The NBT scoring was done based on percentage of NBT positive cells from total neutrophils counted with or without formazan. Reference cut-off was taken from NBT scores of the control group. The data was analyzed using spss version 20. $P \leq 0.05$ was taken as significant difference between groups.
Results: The mean NBT score was significantly higher in unstimulated (US) and stimulated neutrophils RTx compared to control group (14.2 ± 8 vs. 7.3 ± 3.2; $P = 0.006$, 63.1 ± 17 vs. 54 ± 9.2; $P = 0.007$ and 42 ± 14.4 vs. 32 ± 6.2; $P = 0.020$ respectively)
There was a significant association of mean NBT scores of US neutrophils with the renal dysfunction compared to normal renal functions (16.4 ± 8.3 vs. 10 ± 6.0; $P = 0.013$). Rejection episodes were found in 11 recipients (42%). A high mean scores of NBT results was seen with Candida stimulation in patients with rejection compared to non-rejection (46 ± 12 vs. 25 ± 15.3; $P = 0.007$).
Conclusions: The neutrophil function assay has a major role in assessing the status of innate immune system in transplant recipients. A significant association of high NBT score in US neutrophils with active infections and renal dysfunction may indicate a need of aggressive treatment strategies in these patients. Low NBT positive results may signify considerable degree of immunosuppression, requiring drug modification. A prospective study with a larger sample size may help to elucidate these important findings in RTx.

424.13

Factors associated with clostridium difficile infection after heart and heart-lung transplantation

Jackrapong Bruminhent[1,2], Kelly A.Cawcutt[2], Charat Thongprayoon[5], Tanya M.Petterson[3], Walter K.Kremers[3], Raymund R.Razonable[2,4].
[1]Department of Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; [2]Division of Infectious Diseases, Mayo Clinic, Rochester, MN, United States; [3]Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN, United States; [4]William J. von Liebig Center for Transplantation and Clinical Regeneration, Mayo Clinic, Rochester, MN, United States; [5]Division of Critical Care, Mayo Clinic, Rochester, MN, United States.

Background: Clostridium difficile is a major cause of diarrhea in thoracic organ transplant recipients. We investigated risk factors of Clostridium difficile infection (CDI) in heart and heart-lung transplant (HT) recipients.
Materials and Methods: This is a retrospective study of HT recipients at a single US transplant center from 2004-2014. CDI was defined by diarrhea and a positive toxigenic Clostridium difficile in stool measured by toxin enzyme immunoassay (EIA) (2004-2006) or polymerase chain reaction (2007-2014). Cox proportional hazards regression was used to model the association of baseline risk factors and the time dependent variable, acute cellular rejection (ACR), with time to CDI following transplant.
Results: There were 254 (246 heart and 8 heart-lung) HT recipients, with a median age was 53 years (IQR, 45-60); 34% were female. During the median follow-up of 96 months (IQR, 40- 185), 22 (8.7%) patients developed CDI. In univariate analysis, CDI in HT recipients was associated with female sex, having combined heart-lung transplant, redo-transplantation, acute cellular rejection (ACR), and maintenance with tacrolimus and prednisone (Table 1). In multivariate analysis, ACR was associated with lower risk [HR=0.24; 95% CI, 0.09-0.69 (p=0.008)] while maintenance with prednisone was associated with higher risk [HR 10.60; 95% CI, 1.43-78.83 (p = 0.02)] of CDI after transplantation.
Conclusion: CDI after HT is less common among patients who have ACR and more common among those maintained on prednisone.

Table 1
Univariate analysis of risk factors for CDI after heart and heart-lung transplantation

Risk factors	HR	95%confidence interval	P-value
Recipient age (years)	0.98	0.95-1.01	0.16
Recipient female sex	3.07	1.31-7.18	0.01
Recipient BMI (kg/m^2)	0.93	0.84-1.03	0.15
Heart-lung transplant	6.26	1.85-21.21	0.003
CMV mismatch	0.75	0.31-1.85	0.54
Redo-transplant	5.92	1.34-26.12	0.02
Prior episode of CDI	2.43	0.56-10.58	0.24
Donor age (years)	1.00	0.97-1.04	0.87
Donor female sex	1.79	0.77-4.15	0.17
Ischemic time	1.00	0.99-1.01	0.91
Perioperative prophylaxis with cephalosporins	1.17	0.35-3.96	0.80
Induction with Anti-thymocyte globulin	1.61	0.60-4.32	0.35
Maintenance therapy			
-Cyclosporine	0.81	0.32-2.02	0.65
-Tacrolimus	3.63	1.54-8.53	0.003
-Azathioprine	0.85	0.32-2.22	0.73
-Mycophenolate mofetil	0.48	0.21-1.13	0.09
-Prednisone	10.13	1.36-75.33	0.02
Acute cellular rejection	0.26	0.09-0.74	0.01

425.1

Liver transplantation in the elderly: An increasing and appropriate indication

Luis Moulin, Andres Fraile, Diego Ramisch, Silvina Yantorno, Gabriel Gondolesi, Valeria Descalzi.
Multiorgan Transplant Institute, Favaloro's Foundation University Hospital, Ciudad Autonoma de Buenos Aires, Argentina.

Continues increase in general life expectancy and improvements achieved in medical therapies for cirrhotic patients (pts), have rise the age of potential candidates for Liver Transplantation (LT). Age is no longer an absolute contraindication for LT or donation. Previous presentations from our center have shown a progressive increase from 5% to 15% of elderly patients transplanted from 1995-2000 to the 2006-2009 periods.
Aim: To evaluate number and outcomes of LT performed on patients older (OP) than 65 years of age at a single center.
Methods: A retrospective study, based on a prospective database including 216 LT from 9/2009 to 12/2015. OP patients were compared to the younger population (YP). Demographics and transplant variables, ethiologies and outcomes were analyzed using SPSS v 17.0.
Results: Over the last 6 years, 45 OP (20.8%) and 171 YP were transplanted. Analyzed variables are presented in table 1. Actuarial patient survivals at 1 and 3 years were: OP group 84% and 77%, vs. YP group: 91 and 84% respectively (p: NS). Graft survivals were: 82 and 77% for the OP vs. 88 and 80% for the YP (Figure 1).

		OP 45 (20.8%)		YP 171 (79.2%)		p
Mean Age (years±SD)		68 ± 2.25		50 ± 11.4		<0.05
Sex	*Males (n; %)*	25	55%	101	59%	NS
MELD score (±SD)		21 ± 8.3		18 ± 7.1		<0.05
DRI (±SD)		1.50 ± 0.33		1.52 ± 0.29		NS
Ethiology (*)	*Alcohol(n; %)*	15	33%	57	33%	NS
	HCV(n; %)	12	27%	36	21%	NS
	Autoimmune (n; %)	1	2%	12	7%	<0.05
	Cryptog./NASH (n; %)	11	24%	21	12%	<0.05
	PBC (n; %)	2	4%	16	9%	NS
	ALF (n; %)	2	4%	21	12%	NS
	HCC (n; %)	19	43%	37	22%	<0.05

Table 1: Variables analyzed. Categorical variables were analyzed using: χ^2-test, Fischer exact test and t-test. (*) We included most frequent etiologies for both groups. *PBC*: primary biliary cirrhosis. *ALF*: acute liver failure. *HCC*: hepatocarcinoma.

425.2

Long term outcome results using predictive scores in liver re-transplantation

Andres Fraile, Nestor Pedraza Alonso, Maria Eugenia Serio, Victorio Cervera, Valeria Descalzi, Pablo Barros Schelotto, Gabriel E. Gondolesi.
Instituto de Trasplante Multiorgánico, Hospital Universitario Fundación Favaloro, Ciudad Autónoma de Buenos Aires, Argentina.

Liver re-transplantation (re-LT) is an infrequent indication for LT, with a reported prevalence close to 6% in different reported series. It is the unique therapeutic option when graft failure occurs. Although is a high risk population with poor prognosis, so a strict selection of candidates is mandatory.
Aims: 1) to evaluate the prevalence and outcome of re-LT at our centre, 2) To identify predictors of survival after re-LT. Patients and Methods: From 6/95 to 12/15, 876 consecutive adult liver transplantations were performed. Clinical, biochemical, and demographic variables, and survival prediction scores (Rosen, Markmann and UCLA) were retrospectively applied and analyzed from donors and receptors of re-LT. Statistical Analysis: Chi-square, T-Test, Actuarial Survival Rate by Kaplan Meier.
Results: 55 out of 876 were re-LT (6 %) and 4 received a 2nd re-LT (0.4 %). Median age of re-LT was 43±14 years, 57 % were males with median time between LT and re-LT of 2.2 years. Main causes for re-LT were recurrence disease (29%), biliary (22%),ductopenia (20%), vascular (18%) and primary non-function (8%). Causes for 2nd re-LT were: biliary 2 (50%), recurrence disease 1 (25%) and ductopenia 1 (25%). According to priority for re-LT, in 37 patients (72%) re-LT was elective (>60 days) and urgent in 14 (27%). From the 51 re-LT patients, 23 died, with an overall, elective and urgent survival rate at 3 months, 1, 5 and 10 years of 84-83-64%, 77-78-64%, 72-76-48%, 58-63-48% (p=ns). Among studied variables (donor and recipients age, gender, underling liver disease, time between LT and re-LT, bilirrubin, creatinine, DRI and survival prediction scores) only cold ischemia time (CIT) >495 minutes was associated with poor outcome (p=0.002). Markmann score was statistically significantly associated with 1 year mortality (p=0.015). Actuarial survival rate of 2nd re-LT at 3 months, 1 and 5 years were 50, 50 and 25% respectively. The re- LT scores did not predict early mortality in the 2nd re-LT.
Conclusions: 1) Re-LT represents a safety option for patients with graft failure, with survival rate over 70% at 5 year post re-LT 2) CIT > 495 minutes for re-LT was the only useful predictor of outcome in our series 3) Although Markmann score was associated with 1 year mortality, re-LT predictive scores when were applied individually, didn't show enough sensibility and specificity to predict poor outcome.

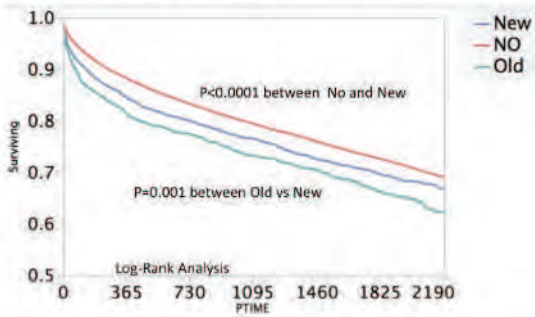
425.3

Patients on the liver transplant waiting list at risk for developing new onset portal vein thrombosis

Martin Montenovo, Jorge Reyes, James Perkins.
Surgery, University of Washington, Seattle, United States.

Introduction: Portal vein thrombosis (PVT) is quite common in patients with cirrhosis. The risks factors of developing PVT while on the waitlist and the impact on patient survival after liver transplantation are not well defined. The objective of this study was to determine risk factors for developing PTV while in the waitlist and the impact in patient survival after liver transplantation..
Methods: We conducted a retrospective cohort analysis using the United Network for Organ Sharing database from January 2002 through June 2014, including adults (³18 years old) who were listed and received a primary OLT. We looked at rate of PVT during the study period at the time of listing and at the time of transplant, and the effect of PVT on patient survival after the liver transplantation. Cox Proportional Hazards models were constructed to adjust for recipient characteristics in order to estimate the risk factors associated with development of PVT while in the waitlist.
Results: A total of 63.265 patients listed and transplanted for primary OLT were identified. 3,612 patients were listed without PVT but developed PVT by the time of transplant; 1,708 patients were listed with PVT and had PVT at the time of transplant; 57,945 patients never had PVT at listing or time of transplant. PVT at listing and at the time of transplant has a negative impact in patient survival after liver transplantation (fig 1).

Fig 1. Survival among patient with new, old and no PVT.



On the multivariate analysis several risk factors were independently associated with the development of PVT while in the waitlist (table 1).

Table 1. Logistic Regression Analysis of Factors Associated with the Development of PVT while in the waitlist.

Days Waiting	1.0008	1.0007	1.0009	<0.0001
Age	1.01	1.009	1.018	<0.0001
Prior Abd Surg	1.27	1.01	1.38	<0.0001
Exception for HCC	1.21	1.08	1.37	0.0009
Albumin at Listing	0.90	0.84	0.97	0.004
Slight Ascites	1.30	1.16	1.46	<0.0001
Moderate Ascites	1.5	1.31	1.71	<0.0001
Previous Malignancy	1.32	1.17	1.49	<0.0001
Variceal Bleeding Yes	1.4	1.14	1.7	0.001
SBP	1.23	1.04	1.44	0.02
INR at listing	0.90	0.84	0.96	0.001
Serum Creatine at Listing	0.95	0.91	0.98	0.05
Diabetes	1.28	1.16	1.4	<0.001

Conclusions: PVT has a significant negative impact in patient survival after liver transplantation. Patients at increased risk for PVT should undergo a more aggressive screening for early identification and potential treatment.

425.4

Determination of alcohol abstinence in transplant candidates by ethyl glucuronide hair analysis

Brigitta Globke[1], Christina Papachristou[2], Martin Hastedt[3], Franziska Krumbiegel[3], Johann Pratschke[1], Andreas Pascher[1].
[1]Department of General, Visceral and Transplantation Surgery, Charité - Universitaetsmedizin Berlin, Berlin, Germany; [2]Department of Psychosomatic Medicine, Charité - Universitaetsmedizin Berlin, Berlin, Germany; [3]Institute of Legal Medicine and Forensic Sciences, Charité - Universitaetsmedizin Berlin, Berlin, Germany.

Introduction: In the Eurotransplant region listing for liver transplantation requires abstinence of at least 6 months in patients with alcoholic liver disease. The assessment of alcohol abstinence is a complex process and so far comprised a thorough taking of the history of alcohol consumption as well as the presentation to the department of psychosomatic medicine. The use of biomarkers to objectify alcohol abstinence is an important addendum. Ethylglucuronide (EtG) is a direct alcohol metabolite, with a high sensitivity and specificity for detection of alcohol consumption for a period of a few days in urine samples and three months in hair samples, respectively. As of mid 2015 the german authorities implemented a testing for EtG in urine (uEtG) samples to the mandatory evaluation process, hair testing (hEtG) is an optional test.
Materials and Methods: In our patient collective EtG was determined using liquid chromatography-electrospray ionization-tandem mass spectrometry (LC-ESI-MS) in hair samples of transplant candidates referred to our hospital for alcoholic-, cryptogenic- or suspected alcohol abuse between 2012 and 2015. We analysed samples from 221 patients (m:f 149:72) and compared patients statements concerning their alcohol consumption habits, with EtG results and psychosomatic assessment.
Results: When the hair sample was taken 90% of patients claimed abstinence of at least three months time, but only in 76% of the samples the patients statement was confirmed by the test results. In a multivariate analysis "favourable psychosomatic assessment," a "long duration of abstinence" and "male gender" proofed to be predictors for negative hEtG results. In 147 cases the EtG test results matched the psychosomatic assessment, whereas in 35 cases we received contradictory results. Those cases were re-assessed individually.
Conclusion: EtG hair analysis is the only generally available method that allows detection of alcohol consumption over a period of time that comes close to the demanded period of abstinence for placement on the Eurotransplant list. Therefore, we are enabled to offer support to people who still need to overcome alcoholism before they become the transplant candidates. We also have a tool at hand that might enable patients with cryptogenic cirrhosis to fend off allegations of alcohol abuse. In our hospital we established an algorithm combining psychosomatic evaluation, mandatory uEtG analysis and optional hEtG analysis in the liver transplant evaluation process.

425.5

Influencing factors of fatigue in liver transplant recipients

Hongxia Liu, Xiaohong Lin, Sha Teng, Yabin Shang.
School of Nursing, Beijing University of Chinese Medicine, Beijing, People's Republic of China.

Aims and Objectives: The purpose of this study was to examine the intensity, interference, duration, and prevalence of fatigue in liver transplant recipients and to explore the influencing factors of post-transplantation fatigue.
Background: Fatigue is a highly prevalent symptom experienced by patients who underwent the liver transplantation. However, the influencing factors of fatigue are poorly understood. More studies are needed to document fatigue and its influencing factors in patients after liver transplantation. Design A cross-sectional design was used in this study.
Methods: A convenience sample of liver transplant recipients was recruited at an outpatient liver transplant clinic in Beijing, China. Self-report survey data were provided by liver transplant recipients using the Fatigue Symptom Inventory (FSI), the Hospital Anxiety and Depression Scale (HADS), the Perceived Social Support Scale (PSSS), and the Athens Insomnia Scale (AIS). Demographic, clinical, psychosocial parameters were evaluated as influencing factors of fatigue.
Results: Participants (n=285) included 69 women and 216 men. Fatigue was found in 87.02% of liver transplant recipients. Mean scores of fatigue intensity items were 4.47±2.85, 1.93±1.97, 3.15±2.13, 2.73±2.42 (most fatigue, least fatigue, average fatigue, fatigue now). Mean score of fatigue interference were 2.27±2.09. Number of days having fatigue in the previous week was 2.26±2.02 and the mean percentage of fatigue time each day was 2.75±2.44. Spearman Correlation Analysis showed that fatigue intensity was associated with anxiety, depression, and insomnia ($P<0.001$ for all), while fatigue interference was associated with gender, anxiety, depression, and insomnia ($P<0.05$ for all). In the multiple linear regression analysis, anxiety and insomnia were associated with fatigue intensity ($P<0.001$), and insomnia, depression and anxiety were associated with fatigue interference ($P<0.001$).
Conclusions: Fatigue is common and pervasive in liver transplant recipients, and it is strongly associated with insomnia, anxiety, and depression.
Relevance to Clinical Practice: Health professionals need to pay attention to fatigue in liver transplant recipients and take appropriate measures to reduce patients' fatigue.
This study was supported by Beijing Natural Science Foundation, grant number:7142098

425.6

Predictors of mortality in living donor liver transplantation

Shaimaa Elkholy, Sherif Mogawer, Mostafa Elshazli, Ula M.Al-Jarhi, Samah Abdel-Hamed, Adel Hosny, Ayman Salah, Noman El-Garem, Amany Abdel-Maksoud, Mona El-Amir, Mohamed S.Abdel-Aziz, Ahmed Nabil.
Liver Transplantation Unit, Faculty of Medicine, Cairo University, Cairo, Egypt.

Background: Liver transplantation had become now the definite treatment of patients with end stage liver disease (ESLD). Due to ethical and cultural background, living donor liver transplantation (LDLT) is the only available option for liver transplantation in some countries. Being the only source of donors it's of extreme importance to perform a detailed analysis for the whole process aiming to improve the overall outcome of LDLT. Minimizing the Mortality had been the target of this study.
Post-operative infection is a leading cause of morbidity and mortality in patients undergoing Living Donor Liver Transplantation (LDLT). This study aims to develop a practical and efficient prognostic index for possible predictors of post-transplant mortality using risk factors identified by multivariate analysis.
Materials and Methods: This study was done to analyze data from patients with post hepatitic cirrhosis, HCV positive, genotype 4, Child B, C or MELD score (13-25) undergoing LDLT. It included data from 100 Egyptian patients who had LDLT conducted at Kasr AlAiny Hospital, Liver Transplantation Department, Faculty of Medicine, Cairo University. The Study included 90 males and 10 females with ages ranging between 20 and 63 years.Patient management and decisions were independent from the study and totally subject to our centre protocol. More than 160 fields per patient were documented including pre-operative, operative and post-operative data. Data included patient history, clinical, laboratory, and sonographic information as well as complications and outcome. All potential predictors of mortality were analyzed by backward logistic regression. Cut-off values were obtained from ROC curve analysis.
Results: Sepsis was the main cause of death in the studied group. Early infectious complications were associated with a significantly higher mortality rate 34(50.7%) in patients who encountered post-operative infection versus 11(33.3%) in patients who did not (p-value < 0.005). TLC, total bilirubin, early biliary complications, fever and CRP were highly correlated to morbidity and mortality. By performing multivariate analysis (logistic regression) it was found that the presence of infection, fungal infection and HCC recurrence were the most prominent predictors of mortality.
Conclusion: Post LDLT infections remains on the top of the list as a cause of mortalitiy. Prompt initiation of risk-stratified management plans may improve the outcome of LDLT.

Liver transplantation in elderly recipients: when is old too old?

Nicholas Gilbo, Ina Jochmans, Mauricio Sainz, Jacques Pirenne, Diethard Monbaliu.
Abdominal Transplantation Surgery and Coordination, University Hospitals of Leuven, Leuven, Belgium.

Background: Recipient age is regarded a risk factor of inferior outcome after Liver Transplantation (LT) because of increased co-morbidities, including cardiovascular disease. Nevertheless, the average age of LT recipients is increasing. We therefore compared post-LT outcome between recipients younger and older than 70y.
Methods: We retrospectively compared donor and recipient demographics, transplant and outcome data between LT recipients >70y (R>70) and <70y (R<70) in a cohort of 643 consecutive LT in (01/2003-12/2014). The influence of recipient age on patient and graft survival was evaluated by means of multivariable regression. Data are presented as median and IQR.
Results: 30 LT and 3 ReLT out of 643 transplants (5%) were performed in R>70. Compared to R<70 [IQR 49-64y], all R>70 [IQR 72-74y] received grafts from brain dead donors (100% vs 87.2%, p:0.1), more frequently extended criteria donors (66.7% vs 48.2%, p=0.048) of older age [69y (53.5-79) vs 53y (43-63), p<0.0001] although with no difference in DRI [2.39 (1.99-2.61) vs 2.13 (1.8-2.51), p=0.08]. Recipients >70y had lower lab-MELD [12.5 (8.45-18.42) vs 15.6 (10.8-24), p=0.01] but higher BAR score [4 (4-4) vs 2 (2-4), p<0.0001] and were less frequently admitted in intensive care at the time of LT (6% vs 14%, p=0.1). R>70 were more frequently transplanted for HCC (54.5% vs 29.5%, p=0.004). Cold ischemia was shorter in R>70 [6.17h (5.3-7.55) vs 7.36h (5.65-8.9), p=0.02]. Peak AST post-LT [R>70 626IU/L (299-1058) vs R<70 693IU/L (365-1323), p=0.27], incidence of early allograft dysfunction (R>70 15% vs R<70 29.3%, p=0.1) or acute kidney injury (R>70 21.2% vs R<70 22.8%, p=1), permanence in intensive care and length of hospitalization did not differ amongst groups. The incidence of non-anastomotic biliary strictures within 1y post-LT was similar in both groups (R>70 15.2% vs R<70 12.1%, p=0.5). One and five year graft survival were similar between R>70 and R<70 (93.9% vs 87.6%, 75.4% vs 70.8% respectively, p=ns); likewise 1 and 5 y patient survival did not differ (100% vs 90.9%, 78.7% vs 75.8% respectively, p=ns). Multivariable Cox regression did not reveal an impact of recipient age when considered either as continuous or dichotomous variable on patient and graft survival (R>70 HR:0.84, 95%CI:0.42-1.7 and HR:1.01, 95%CI:0.99-1.04) in contrast to the presence of HCC which was independent risk factor of impaired recipient survival (HR:1.53, 95%CI:1.08-2.2, p=0.017).
Conclusion: In our experience, transplanting stable elderly recipients did not increase post-operative morbidity and achieved survival comparable to that one of younger patients. Patient selection for LT should therefore not be limited by age.

425.8

Extracorporeal membrane oxygenation support for critically Ill liver transplantation recipient

Kyo Won Lee[1], Min Jung Kim [2], Nuri Lee[1], Seounghyun Kim[1], Ji Soo Lee[1], Gyuseong Choi[1], Kyeong Sik Kim[1], Jae-Won Joh[1].
[1]Department of Surgery , Samsung Medical Center , Seoul, Korea; [2]Department of Surgery, Jeju National University Hospital , Jeju, Korea.

Introduction: After liver transplantation (LT), recipients occasionally come into cardiopulomonary dysfunction refractory to optimal medical management and ventilator care. Extracorporeal membrane oxygenation (ECMO) can provide life support in those cases. This study was designed to assess the outcome of the ECMO and predict the prognosis of those cases.
Methods: From February 2008 to October 2012, ECMO was used in 25 cases (24 patients) due to cardiogenic shock (n=5), septic shock (n=9), respiratory failure (n=10), hypovolemic shock (n=1). Laboratory values including lactate level just before starting ECMO were obtained and Sequential Organ Failure Assessment (SOFA) score, Acute Physiology and Chronic Health Evaluation (APATCH) II score and Simplified Acute Physiology Score (SAPS) II were calculated. Subsequent SOFA, APATCH II, SAPS II and lactate clearance (LC) after 24 hours of starting ECMO were also calculated. Comparisons were made between cases who did and did not succeed in weaning ECMO and between who did and did not survive.
Results: Successful weaning occurred in 8 cases (7 patients) and 4 cases (4 patients) were survived. APATCH II and SAPS II were significantly low($p = 0.011$, 0.016, respectively) and LC and Δ-SOFA(0-24) were significantly high in weaning success group ($p = 0.009$, 0.020, respectively). In survival group, SAPS II and APATCH II were low ($p = 0.047$, 0.038, respectively).
Conclusions: ECMO can be used for critically ill LT recipients who do not respond to conventional management. SAPS II and APATCH II could be good indicators of prognosis in terms of both weaning and survival.

Pre transplant recipient frailty combined with disease severity predicts post liver transplant (OLT) mortality

Dympna Kelly[1], Lisa Louwers[1], Kareem Eid[1], Shetal Shah[3], Pilar Bayona[3], Fouzeyah Ali[3], Kevin Chagin[2], Bijan Eghtesad[1], Nafatali Presser[1], Julia Muntean[1], Michael Kattan[2], Charles Miller[1], John Fung[1].
[1]General Surgery, Cleveland Clinic, Cleveland, United States; [2]Quantitative Health Sciences, Cleveland Clinic, Cleveland, United States; [3]Imaging, Cleveland Clinic, Cleveland, United States.

As we transplant sicker patients we are challenged in identifying patients with poor post OLT outcomes. This study aimed to identify pre-OLT parameters which can predict early post OLT mortality.
Methods: Data for all adult primary OLT recipients (01/10-08/14) was retrospectively reviewed (IRB 15-1443). Pre OLT parameters were identified in the frailty domains of: 1) Age 2) Functional status: Karnofsky score (KS), location at transplant 3) Cognition: encephalopathy, history of depression 4) Nutrition: BMI, albumin, Hct, refractory ascites, sarcopenia 5) Comorbidities: heart disease, diabetes, renal and thyroid disease, PVD, PUD, tobacco use) 6) Extrinsic frailty: support at home 7) Measures of disease severity: chemical MELD, PT, INR, creatinine, bilirubin. Sarcopenia was assessed using psoas and paraspinal muscle vol. (mean) and density (HU) (mean) on CT scans within 90 days prior to OLT on a Leonardo Workstation using Oncocare® software (Seimens Healthcare, Erlangen, Germany). Data was analyzed using multivariate logistic regression to identify predictors of in-hospital mortality (death during the OLT admission) and 1yr mortality. Two patients with graft failure were excluded from mortality analysis.
Results: 523 adult, liver only, recipients were transplanted. CT scans within 90 days of OLT were available in 278/523 (53%) patients. Data was analyzed for the entire population (n=523) without sarcopenia parameters, and all data, including sarcopenia, was analyzed for 278 patients with CT scans.
In-Hospital Mortality: 20/522 (4%) patients died in-hospital. Excluding sarcopenia the model predicting in-hospital mortality had a c-statistic of 0.757 (95% CI 0.66-0.85). 15/277 (5%) patients with all data including sarcopenia died in-hospital. The final model predicting in-hospital mortality with the inclusion of sarcopenia (n=277) had c-statistic of 0.875 (95% CI 0.81-0.93).

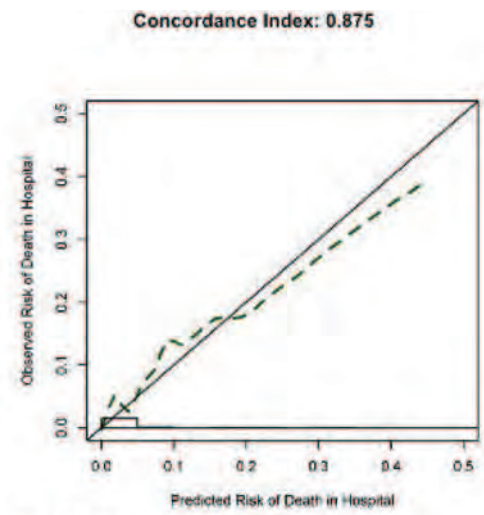

Fig. 1: In Hospital Mortality.

Variables with the highest predicting value were MELD (Odds Ratio 1.12), KS (OR 0.94), Bilirubin (OR 0.92), Psoas vol. (0.44), Paraspinal vol. (OR 1.3)

One Year Mortality: 52/521 (10%) patients 52 died within 1yr. The c-statistic was 0.688 (95% CI 0.62-0.77). 31/276 (11%) patients with all data including sarcopenia died within 1yr. The final model predicting 1yr mortality with the inclusion of sarcopenia (n=276) had c-statistic of 0.823 (95% CI 0.76 and 0.89). Variables predicting 1yr mortality were male gender (OR 2.8), KS (OR 1.1), depression (OR 2.9), BMI (OR 0.9), Living alone (OR 0.1), Psoas density (OR 1.1), Psoas vol. (OR 0.4).
Conclusion: The sub group of patients with sarcopenia data (n=278) is representative of the entire cohort including mortality rates. Frailty parameters, including sarcopenia, combined with disease severity significantly improves our ability to predict post OLT mortality, with a C Index of 0.877 for in-hospital mortality and 0.823 for 1yr mortality. This model has the potential to identify poor risk patients prior to proceeding to OLT.

A nationwide analysis of reoperation after liver transplant

Zhobin Moghadamyeghaneh[1], Gennaro Selvaggi [1], Seigo Nishida [1], Linda Chen[1], Rodrigo Vianna [1], Giselle Guerra[2].
[1]Miami Transplant Institute, University of Miami/ Jackson Memorial Hospital, Miami, United States; [2]Transplant Surgery, Miami Transplant Institute, Miami, FL, United States.

Objectives: This study aimed to report the rate and short-term outcomes of patients underwent reoperation following liver transplant in the United States.
Methods: The NIS database was used to examine the clinical data of patients underwent liver transplant and reoperation during same hospitalization during 2002-2012. Multivariate regression analysis was performed to compare outcomes of patients with and without reoperation.
Results: We sampled a total of 59,166 patients who underwent liver transplant. Of these, 7373 (12.5%) had reoperation during the same hospitalization. The most common day of reoperation was the first day after transplant (Figure 1). Hemorrhagic complication with 68% was the most common reason of reoperation followed by biliary tract anastomosis complications (14.8%) and vascular complications (10%). Also, 3.6% of patient underwent reoperation for wound disruption. Patients with reoperation had a significantly higher mortality (11.6% vs. 3.8%, AOR: 3.01, P<0.01). Preoperative coagulopathy (AOR: 1.71, P<0.01) and renal failure (AOR: 1.57, P<0.01) were associated with hemorrhagic complications. Also, preoperative peripheral vascular disorders (AOR: 2.15, P<0.01) and coagulopathy (AOR: 1.32, P<0.01) were significantly associated with vascular complications. Risk of wound disruption was significantly higher in patients with chronic pulmonary disease (AOR: 1.50, P<0.01).
Conclusion: Reoperation after liver transplant occurs in 12.5% of cases. However, it is associated with a significantly increased mortality. The first day after transplant and hemorrhagic complication are the most common day and reason of reoperation respectively. Controlling coagulation disorders preoperatively may decrease hemorrhagic and vascular complication. Patients with chronic pulmonary disease are at risk of wound disruption.

Effect of graft weight to recipient body weight ratio on hemodynamic and metabolic parameters in pediatric liver transplantation: A retrospective analysis

Zeynep Ersoy[1], Şerife Kaplan[1], Aycan Özdemirkıran[1], Adnan Torgay[1], Gülnaz Arslan[1], Arash Pirat[1], Mehmet Haberal[2].
[1]Anesthesiology and Reanimation, Baskent University Hospital, Ankara, Turkey; [2]General Surgery, Baskent University Hospital, Ankara, Turkey.

Background: The ratio of graft weight to the recipient body weight (G/R ratio) in liver transplantation (LT) is one of the major risk factors affecting patient outcome. We hypothesize that a high G/R ratio (>4%) in pediatric LT adversely affects the intra and early postoperative hemodynamic and metabolic parameters.
Methods: In this retrospective study, we screened data of children who underwent LT between 2005 and 2015 at Ankara Baskent University Hospital. LT recipients were divided into two groups based on their G/R ratio: liver transplant recipients with a G/R > 4% (large for size) and those with a G/R ≤ 4% (normal for size). Collected parameters included demographic data, preoperative laboratory findings, intraoperative metabolic and hemodynamic parameters, and intensive care unit follow-up parameters.
Results: A total of 130 pediatric liver transplant recipients' data were included in the analyses. The median Child and PELD scores were 9.0 and 17.0, respectively. Child and PELD scores were significantly different between two groups (9.6±1.3 and 8.5±2.1, p=0.013; 27.8±11.3 and 14.5±15.2, p<0.001).
When we compared the two groups the patients in group G/R > 4% received higher amounts of colloid solutions (57.7±20.1 ml/kg and 45.1±21.9 ml/kg, p=0.08) and higher doses of furosemide (0.7±0.6 mg/kg and 0.4±0.7 mg/kg, p= 0.018).
Patients in group G/R > 4% had lower mean pH and pO2 values during newhepatic phase than those in group G/R ≤ 4% (7.1±0.1 and 7.2±0.1, p=0.004; 115.4±44.6 mmHg and 147.6±49.3 mmHg, p=0.004). Compared to group G/R ≤ 4%, recipients in group G/R > 4% had higher values of blood glucose (352.8±96.9 mg/dl and 262.8±88.2 mg/dl, p<0.001) and lower mean body temperature during newhepatic phase (34.8±0.7oC and 35.2±0.6oC, p=0.016). Compared to group G/R ≤ 4%, group G/R > 4% received higher amounts of packed red blood cell transfusion during both anhepatic and newhepatic phases (30.3±24.3 ml/kg and 18.8±21.8 ml/kg, p=0.013; 17.7±20.4 ml/kg and 10.3±15.5 ml/kg, p=0.031, respectively) and received higher amounts of fresh frozen plasma during newhepatic phase (13.6±17.6ml/kg and 6.2±10.2ml/kg, p=0.012).
Recipients in group G/R > 4% were more likely to be hypotensive in terms of systolic and diastolic blood pressures intraoperatively and also more hypothermic during all phases (p<0.05).
Recipients in group G/R > 4% more commonly received norepinefrine infusion intraoperatively (44% and 22%, p <0.05) . More patients in group G/R > 4% compared to group G/R ≤ 4 were mechanically ventilated in ICU (56% vs 31%, p=0.035). There were no significant differences between two groups in terms of postoperative acute renal dysfunction, graft rejection or lost, infections, length of ICU stay, and mortality (p>0.05).
Conclusion: The high G/R are associated with adverse metabolic and hemodynamic changes during LT and early postoperative period. These results emphasize the importance of using an appropriate size of the graft in liver transplantation.

The role of curative intent surgical resection for the recurrent hepatocellular carcinoma after liver transplantation

Seung Hwan Song[1], Jee Youn Lee[1], Su-Kyung Kwon[1], Jae Geun Lee[1], Juhan Lee[1], Dai Hoon Han[1], Kyu Ha Huh[1], Gi Hong Choi[1], Myoung Soo Kim[1], Yu Seun Kim[1], Jin Sub Choi[1], Soon Il Kim[1], Dong Jin Joo[1].
[1]Department of Surgery and The Research Institute for Transplantation, 1Department of Surgery and 2 The Research Institute for Transplantation, Seoul, Korea.

Introduction: Liver transplantation (LT) is one of the best treatment for hepatocellular carcinoma (HCC). However, there could be HCC recurrence in around 10-20% of the transplant patients. The Recurrent HCC after LT remains one of the major causes to graft failure and patient death. Because HCC recurrence is known for systemic disease, systemic therapy may be considered. However the optimal treatment of recurrent HCC is not established. The aim of this study is to evaluate the difference of graft survival rate between palliative therapy and curative intent surgical therapy after LT.
Methods: A total 292 recipients with HCC who underwent LT between January 2007 and April 2015 in Severance hospital were retrospectively reviewed. Among 292 patients, 41 patients developed hepatic or extra-hepatic recurrent HCC. We compared the outcomes of the recurred patients according to the therapeutic approaches.
The Results: The mean age of the HCC recurrence group was younger than non-recurrence group (51.4 ± 6.3 vs 54.8 ± 6.9, p<0.003). There was no significant difference of the etiology of HCC between the groups. The patients above Milan criteria showed a higher tumor recurrence rate than those within Milan criteria(Odd ratio 4.717, p<0.001). The curative intent surgical therapy was performed in 13 patients. Among them, resection only in 2, adjuvant chemotherapy after resection in 4, adjuvant radiation therapy (RT) in 4, adjuvant transarterial chemoembolization (TACE) and chemotherapy in 1, adjuvant TACE and RT in 1, and adjuvant TACE and RFA in 1 case. The palliative therapy was consisted of TACE, chemotherapy, or RT. Among the patients received curative intent surgical therapy, 3 patients had intrahepatic recurrence and 10 patients had extrahepatic recurrence. The 5 year graft survival was higher in curative intent surgical therapy group than in palliative therapy group (51.1% vs 306%, P=0. 026)
Conclusion: The curative intent surgical therapy showed the superior graft survival than palliative therapy. The curative intent surgical therapy is not applicable in every recurrent case. However the patient received curative intent therapy if possible, it is increased with the graft survival significantly.

Intraoperative blood loss is an independent promoter of tumor recurrence in liver transplant patients with advanced hepatocellular carcinoma

Arno Kornberg[1], Ulrike Witt[1], Jennifer Kornberg[2], Hemut Friess[1], Katharina Thrum[3].
[1]Surgery, Technical University, Munich, Germany; [2]Anesthesiology, LMU, Munich, Germany; [3]Pathology, Helios Klinikum , Berlin, Germany.

Introduction: Mechanisms of ischemia-reperfusion (I/R) injury were shown to promote the risk of hepatocellular carcinoma (HCC) recurrence after liver transplantation (LT). Along with ischemia times, intraoperative blood loss (IOBL) is a major trigger of I/R damage to the liver graft. The aim of this trial was to analyze the impact of IOBL on risk of tumor recurrence in liver transplant patients with HCC.
Material and Methods: A total of 108 liver transplant patients with HCC were included. Prior to LT, 18F-fluoro-D-glucose (18F-FDG) positron emission tomography (PET) was performed in all of them to identify PET-positive (18F-FDG-avid) and PET-negative (18F-FDG-non-avid) HCC. According to final pretransplant radiographic staging, tumors were classified as Milan In (meeting the Milan criteria) and Milan Out (exceeding the Milan criteria). The impact of IOBL on tumor-specific outcome was analyzed by uni- and multivariate analysis, along with other established prognostic variables.
Results: Mean IOBL was 1500 ml (median: 1493 ml). Twenty-six patients (24.1%) developed HCC recurrence. IOBL was significantly higher in patients with HCC relapse (2196 ml) than in patients without tumor recurrence (1270 ml; $P < 0.001$). Increased IOBL was associated with a significantly higher post-LT C-reactive protein level (4.7 versus 3.5 mg/dl; $P < 0.05$). In multivariate analysis, IOBL $\leq$ 1500 proved to be an independent promoter of recurrence-free long-term survival (Hazard ratio [HR] 3.3; $P = 0.013$), along with negative PET-status (HR 6.15; $P < 0.001$), alpha-fetoprotein level $\leq$ 400 ng/ml (HR 4.13; $P = 0.001$) and well/moderate tumor grading (HR 2.91; $P = 0.014$). Five-year recurrence-free survival was 91.9% in patients with low, but only 37.1% in those with increased IOBL (log rank < 0.001). Blood loss had no independent prognostic impact in patients with HCC meeting the Milan criteria. In contrast, IOBL $\leq$ 1500 ml was identified as an independent promoter of recurrence-free survival in Milan In patients (HR 9.08; $P = 0.003$), along with tumor grading (HR 36.12; $P < 0.001$), PET-status (HR 15.58; $P = 0.002$) and red blood transfusion (HR 4.83; $P = 0.022$). Five-year recurrence-free survival rates were comparable between Milan In recipients and Milan Out patients with low IOBL (86.2% versus 79.2%; log rank = 0.433) and, thus, significantly better than in Milan Out patients with IOBL exceeding 1500 ml (26.9%, log rank = 0.001).
Discussion: IOBL is an independent promoter of HCC recurrence following LT, possibly by inducing pro-inflammatory and pro-cancerogenic proccesses. Particularly in patients with advanced HCC, IOBL should be significantly restricted in order to improve oncological outcome post-LT. Our results suggest that monitoring and considering IOBL might be useful to improve posttransplant follow-up surveillance.

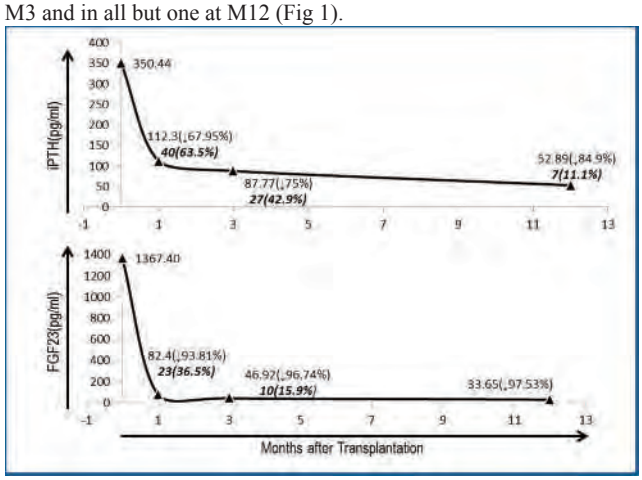
Biointact FGF-23 normalizes faster and correlates better with inorganic phosphorus as compared to intact PTH in living donor renal allograft recipients

Narayan Prasad[1], Akhilesh Jaiswal[1], Vikas Agarwal [2], Shashi Kumar[1], R. K. Sharma[1], Shaurabh Chaturbedi[2], Dharmendra S.Bhadauria[1].
[1]Nephrology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [2]Clinical Immunology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India.

Introduction: Fibroblast growth factor-23 (FGF23) and Parathyroid hormone (PTH), are phosphaturic hormones and both are usually elevated in end stage renal failure (ESRF) patients to maintain homeostasis of serum phosphorus and calcium level. Hypophosphatemia is not uncommon in post transplant period. There is paucity of data on serial changes in these parameters particularly FGF-23 level in living donor post renal transplant period.
Aims: We aimed this study to analyze the serial changes in iFGF-23, iPTH, serum calcium and inorganic phosphate level in renal transplant patients.
Materials and Methods: Biointact PTH(iPTH), calcidiol, biointact FGF-23, albumin corrected calcium, and inorganic phosphorus (iP) were analyzed in 63 ESRD (Male 58, mean age 35.65±11.79 years) patients who underwent living donor renal transplantation with average eGFR 9.58±4.01 ml/min before transplantation (preTx) and month 1 (M1), 3 (M3) and 12 (M12) of transplantation. The native kidney diseases of these patients were chronic glomerulonephritis (n=36), interstitial nephropathy (n=20), diabetic nephropathy (n=6) and polycystic kidney disease (n=1). The upper normal cutoff value of iPTH was considered as >65 pg/ml, and iFGF23 >50 pg/mL, hypo and hyperphosphatemia was defined with iP <2.5 and >5.5mg/dl respectively, hypo and hypercalcemia with corrected for serum albumin <8.5 and >10.8 mg/dL, respectively.
Results: Pre-tx eGFR was inversely correlated with logFGF23 (r=-0.668, p=0.001) and log PTH (r=-0.516, p=0.001). Compared to pre-tx level FGF23 decreased at M1 by 94%, 16.6 fold and PTH by 68%, 3.1 fold; at M3 FGF23 decreased by 97%, 29.1 fold and PTH by 75%, 4 fold; and at M12 FGF deceased by 98%, 40.6 fold, and PTH by 85%, 6.6 fold respectively. FGF23 level normalized in 64% at M1, 84% at M3 and in all but one at M12 (Fig 1).



However, prevalence of hyperparathyroidism was 63%, 43%, 11% at M1, M3 and M12 respectively. At M1, 17(27%) hypophosphatemic patients had higher FGF23 (pre-tx, p<0.01, M1, p<0.001) and iPTH (pre-tx, p<0.048, M1, p=0.002) compared to normophosphatemic. At pre-tx, 26(41%) hypocalcemic patients had higher values of iPTH(p=0.016), and FGF23(p=0.008) as compared to values in normocalcemics. Serum calcium normalized in all except one patient at M1 and in all at M12. On linear regression using a backward stepwise

model, serum iP was significantly correlated with FGF23 levels and eGFR in pre-tx and M1, not with iPTH (Fig 2).

variable	Pre-Tx	Month 1	Month 3	Month 12	Friedman Test (p)
iPTH (pg/ml)	350.44±235.16	112.3±84.38	87.77±65.92	52.89±22.17	0.001
Hyperparathyroidism (>65 pg/ml)	63(100%)	40 (63.5%)	27 (42.9%)	7(11.1%)	
FGF23 (pg/ml)	1367.4±807.24	82.40±79.78	46.92±33.63	33.65±15.32	0.001
FGF23 (>50 pg/ml)	58(92%)	23(36.5%)	10(15.9%)	0	
25(OH) Vit D (ng/ml)	27.29±12.35	23.54±9.56	27.22±7.60+	28.17±6.29	0.002
eGFR (ml/min)	9.58±4.01	81.02±48.64	84.86±64.90	95.71±49.3	0.001
Inorganic phosphate (mg/dl)	6.42±2.12	2.92±0.85	3.19±0.71	3.18±0.51	0.001
Hypophosphatemia (<2.5mg/dl)		17(27%)	5(8%)	0	
creatinine (mg/dl)	7.49±1.93	1.19±0.25	1.20±0.25	1.21±0.26	0.001
BUN (mg/dl)	53.54±22.51	23.26±9.14	19.64±7.91	18.53±7.05	0.001
uric acid ()	6.76±1.99	4.33±1.32	4.21±1.20	4.24±1.37	0.001
calcium (mg/dl)	8.62±0.82	9.24±0.50	9.45±0.50	9.42±0.49	0.001
Hypocalcemia (<8.5mg/dl)	26(41.3%)				
alkaline phosphatase (U/l)	182.02±97.75	99.86±50.27	83.22±48.34	82.87±33.42	0.001

Conclusions: In conclusion, our data indicate that FGF23 normalizes faster than iPTH after successful renal transplantation.iPTH remains high in 11% of patients at end of one year while FGF23 normalizes in all. FGF23 is better correlated with hypophophatemia as compared to iPTH at one month post-transplantation in living donor renal allograft recipients.

We acknowledge Sanofi Synthelabo (India) Ltd. to support FGF23 kit for this study

426.2

Are there risks to fathering pregnancies after solid organ transplantation?

Serban Constantinescu[1,2], Lisa Coscia[2], Dawn P.Armenti[2], Michael J.Moritz[2,3].
[1]Medicine, Temple University, Philadelphia, PA, United States; [2]National Transplantation Pregnancy Registry (NTPR), Gift of Life Institute, Philadelphia, PA, United States; [3]Surgery, Lehigh Valley Health Network, Allentown, PA, United States.

The purpose of this study was to analyze 1343 pregnancy outcomes fathered by 870 male solid organ transplant recipients with emphasis on exposure to mycophenolic acid products (MPA) and sirolimus. Data were collected by the National Transplantation Pregnancy Registry (NTPR) via telephone interviews and review of medical records. Overall pregnancy outcomes are similar to the general population (Table 1).

Table 1. NTPR Fathered Pregnancies

Organ(s)	Recipients	Pregnancies/ Outcomes[1]	Fetal loss[2] (%)	Live births (%)	Mean Gestational Age (wks)	Mean Birthweight (g)	Birth defects (%)
Kidney	619	968/987	6.5	93	39±2.4	3320±659	2.7
Kidney-Pancreas	33	43/45	9	91	38.7±2.4	3321±589	2.4
Liver/Multi-organ	91	147/154	11	88	39±1.9	3326±611	4.4
Thoracic organs	127	185/190	8.4	89	38.8±2.4	3380±614	1.8
General Population			16-21		39	3389	4-6

[1]includes multiple births; [2]miscarriages and stillbirths

Females are advised to avoid MPA during pregnancy due to higher fetal loss rate and the increased incidence and pattern of malformations in maternal MPA exposures. Between 11/1996-6/2015, 268 pregnancies (278 outcomes) fathered by male recipients taking MPA (exposed) were compared to 251 pregnancies (263 outcomes) fathered by male recipients not taking MPA (unexposed) during the same time period. In the exposed group, the fetal loss rate was 10%, and the birth defect rate was 2.8% with no observed pattern of malformations. These rates are similar to the general population. There was no significant difference in live births, fetal loss and birth defect rates between the exposed and unexposed groups (Table 2).

Table 2. NTPR Fathered Pregnancies: MPA Exposed vs. Unexposed

	Exposed	%	Unexposed	%	p-value (Fisher's exact test)
Pregnancies	268		251		
Outcomes	278		263		
Live births	250	89.9	244	92.8	0.29
Fetal loss rate	28	10	18	6.8	0.22
Birth defect rate	7	2.8	6	2.5	1

There were 16 (18 outcomes) fathered pregnancies with exposure to sirolimus; all resulted in live births with no reported birth defects.

Conclusions: The outcomes of pregnancies fathered by male transplant recipients are comparable to the general population. The results of this study do not support the avoidance of MPA for male recipients considering parenthood. Data regarding sirolimus remains limited, however, to date there does not appear to be increased risks for pregnancies fathered while taking sirolimus.

The NTPR is supported by grants from Astellas Pharma, US Inc., Bristol-Myers Squibb Co. and Pfizer Inc.

Impact of induction therapy on incident cardiovascular events in kidney transplant recipients

Shaifali Sandal[1], Sunjae Bae[2], Allan Massie[2], Marcelo Cantarovich[1], Dorry Segev[2].
[1]Medicine, McGill University Health Center, Montreal, Canada; [2]Surgery, Johns Hopkins University, Baltimore, United States.

Cardiovascular events (CVE) are one of leading causes of mortality in kidney transplant (KT) recipients and ATG use is hypothesized as a risk factor. To better understand the relationship between induction and post-KT CVE, we compared CVE incidence among patients who received no induction, alemtuzumab (ALM), anti-thymocyte globulin (ATG) and IL-2 receptor antagonist (IL-2RA).

Methods: Medicare-primary KT recipients from 1999 -2010 were studied using USRDS data. The outcome of interest was time to first post-KT CVE hospitalization, ascertained using validated ICD-9 codes for myocardial infarction, congestive heart failure, stroke and transient ischemic attack. We used Cox regression to model the association between induction therapy and CVE, adjusting for recipient, donor and transplant characteristics.

Results: A total of 86,541 first-time KT recipients were eligible for analysis. Compared with the no induction group, ATG and IL2 were at a similar risk for CVE [table1]. However, KT recipients who received ALM as induction therapy had 18% higher CVE. When stratified by donor type, this association was only found among recipients of kidneys from deceased donors (22% higher CVE).

Conclusion: Deceased donor recipients receiving alemtuzumab, particularly those with high baseline cardiovascular risk profile, should be closely monitored for CVE and/or should receive other induction agents. No other induction agent appears to be associated with post-KT CVE.

Adjusted hazard of CVD-related readmission (Ref: No induction)

	aHR	95% CI	p value

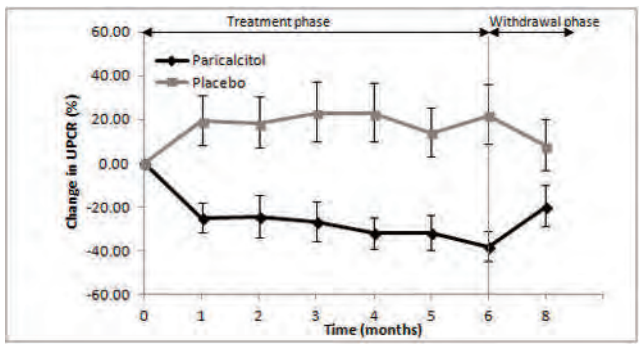
Paricalcitol versus placebo for reduction of proteinuria in kidney transplant recipients: A double-blind, randomized controlled trial

Miha Arnol[1,2], Manca Oblak[1], Gregor Mlinšek[1], Jadranka Buturović-Ponikvar[1,2], Aljoša Kandus[1].
[1]Department of Nephrology, University Medical Centre Ljubljana, Ljubljana, Slovenia; [2]Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia.

Introduction: Kidney transplant recipients with proteinuria have an increased risk of allograft failure[1]. We aimed to assess whether paricalcitol could be used to reduce proteinuria in patients with increased urinary protein excretion despite treatment with renin-angiotensin-aldosteron system (RAAS) inhibitors.

Materials and Methods: In this single-center, placebo-controlled, double-blind trial, we enrolled a national cohort of kidney transplant recipients at least 3 months' post-transplant with urinary protein-to-creatinine ratio (UPCR) ≥20 mg/mmol despite optimization of the RAAS blockade during the run-in phase. Patients were randomly assigned to receive 24 weeks' treatment with 2 µg/day paricalcitol or placebo. The primary endpoint was the percent change in geometric mean UPCR, and secondary endpoints were the percent change in geometric mean urinary albumin-to-creatinine ratio (UACR) and mean 24-hour proteinuria from baseline to last measurement during treatment. Analysis was by intention to treat. This trial is registered with ClinicalTrials.gov, number NCT01436747.

Results: After completion of the run-in phase in 2012, 190 of 572 prevalent kidney transplant recipients (33%) had UPCR ≥20 mg/mmol. Of 168 patients who consented to undergo randomization, 83 were allocated to paricalcitol, and 85 were allocated to placebo; all patients on paricalcitol and placebo received at least one dose of study drug and had UPCR data at baseline and at least one timepoint during treatment. Change in UPCR was -38% (from 74 to 46 mg/mmol; 95% CI -45% to -31%) in the paricalcitol group and 21% (from 52 to 63 mg/mmol; 95% CI 9% to 36%) in the placebo group, with a between-group difference *vs.* placebo of -28% (95% CI -45% to -4%; $P<0.001$). Patients on 2 µg paricalcitol showed a sustained reduction in UPCR, ranging from -25% to -39% ($P<0.001$ *vs.* placebo, Figure).



Change in UACR and 24-hour proteinuria was -47% (95% CI -54% to -38%) and -35% (95% CI -42% to -28%) in the paricalcitol group, and 11% (95% CI -5% to 29%) and 19% (95% CI 8% to 30%) in the placebo group, respectively. Significant reduction in IL-6 and TGF-beta plasma concentrations were recorded in the paricalcitol group. Incidences of hypercalcemia, adverse events, and serious adverse events were similar between both patient groups.

Discussion: We have shown that 24 weeks' treatment with 2 µg paricalcitol daily reduced proteinuria in kidney transplant recipients who were on stable doses of RAAS inhibitors. The effect occurred within 4 weeks and then progressively increased during treatment, and returned towards baseline after drug withdrawal, indicating that the effect was real. Biomarker analysis suggested that renoprotection may be caused by antiproliferative and antifibrotic effects.

Conclusion: In kidney transplant recipients, addition of 2 µg/day paricalcitol to RAAS inhibition safely lowers proteinuria, and could be used as an effective approach to lower allograft failure risk.

The study has been supported by University Medical Centre Ljubljana (research grant 20110090), Slovenian Research Agency (research grant P3-0323), and AbbVie.

Effect of the RANKL inhibitor denosumab on early loss of bone mineral density and skeletal microstructure in first-year kidney transplant recipients

Rudolf Wuthrich[1], Diana Frey[2], Thomas Mueller[1], Nicole Graf[3], Marco Bonani[1].
[1]Division of Nephrology, University Hospital, Zurich, Switzerland; [2]Division of Rheumatology, University Hospital, Zurich, Switzerland; [3]Graf, Biostatistics, Winterthur, Switzerland.

We performed a randomized controlled clinical trial in kidney transplant recipients (NCT01377467) to examine whether RANKL inhibition with denosumab improved areal and volumetric bone mineral density (aBMD, vBMD) and skeletal microstructure when given during the first year after renal transplantation.

We randomly assigned 90 kidney transplant recipients (age 49 ± 13 yrs, 63% male, all on CNI, mycophenolate, steroids, and calcium/vitamin D supplementation) 16 ± 6 days after surgery in a 1:1 ratio to receive 60 mg denosumab s.c. at baseline and after 6 months, or no treatment. At baseline and after 6 and 12 months, aBMD was measured at the lumbar spine and the hip by DXA (n=90). Cortical and trabecular vBMD (Ct.vBMD, Tb.vBMD), and cortical thickness and porosity (Ct.Th, Ct.Po) were assessed at the distal tibia and radius by HR-pQCT (XtremeCT®) at baseline and after 12 months (n=24).

The denosumab group (n=46) had significantly increased bone mineral density at the lumbar spine (+5.1%; 95% CI 3.1-7.0%; P<0.001) and at the hip (+1.9%; 95% CI 0.1-3.7%; P=0.035) over that in the control group (n=44) at 12 months. Biomarkers of bone resorption (beta-CTX) and bone formation (P1NP) markedly decreased with denosumab (P<0.001). Treatment with denosumab led to a significant increase of the vBMD and the Ct.Th at the distal tibia and radius, but did not change Tb.vBMD and Ct.Po. The Ct.vBMD, bone stiffness and failure load showed significant improvements at the tibia. Denosumab was well tolerated, except for more frequent episodes of cystitis and asymptomatic hypocalcemia, whereas graft function, rate of rejections and incidence of opportunistic infections were similar in the denosumab and control groups. Three-year safety follow-up showed excellent graft function in both groups.

In summary, denosumab improved bone density and bone quality in first-year kidney transplant recipients at risk to develop osteoporosis.

Arteriovenous fistula (AVF) maturation among prevalent hemodialysis patients with failed kidney transplants: Results from the united states renal data system (USRDS)

Kenneth Woodside[1], Sarah Bell[1], Brett W.Plattner[1], Douglas E.Schaubel[1], Sudipta Dasmunshi[1], Purna Mukhopadhyay[2], Jeffrey Pearson[2], Ronald L.Pisoni[2], Rajiv Saran[1].
[1]Kidney Epidemiology and Cost Center, University of Michigan, Ann Arbor, MI, United States; [2]Arbor Research Collaborative for Health, Ann Arbor, MI, United States.

Kidney transplant patients with failed allografts who have returned to dialysis have more difficulty establishing access and are more likely to suffer from central venous catheter (CVC)-related complications. The recent addition of Consolidated Renal Operations in a Web-Enabled Network (CROWNWeb) data to the USRDS allows more granular analysis of dialysis care, including vascular access use. We sought to describe AVF maturation from placement until time to first use for prevalent hemodialysis patients with failed kidney transplants in the US.
Methods: We examined prevalent hemodialysis patients with previous failed kidney transplants who had new AVF placements during 2013 using Medicare claims. Failure of maturation was identified by non-use following placement using CROWNWeb, where patient access use is reported monthly by the facility. Patients were followed until end 2014. We assessed the relationship between patient characteristics and time-to-first-use of AVF with a Cox model (HR < 1.0 indicating longer time to first use).
Results: In 2013, a total of 1353 AVF were placed among 1186 failed kidney transplant patients followed through 2014. No subsequent evidence of use occurred in 34.4% of the placements. Of successfully used AVF, median time to first use was 108 days (IQR 70 – 209). AVF in females were associated with longer time to AVF use (HR 0.68, 95%CI 0.59-0.79), as were AVF in black patients (HR 0.84, 95%CI 0.71-0.98). Comorbidities including cardiovascular disease (HR 0.83, 95%CI 0.70-0.98), diabetes (HR 0.85, 95%CI 0.72-0.99), tobacco use (HR 0.69, 95%CI 0.51-0.94), and needing assistance (HR 0.57, 95%CI 0.40-0.82) had similar association with increased time to AVF use. Patient age, dialysis vintage, hypertensive history, and ESRD Network Region associations with AVF maturation were mostly non-significant, as was previous dialysis access history.
Conclusions: We have characterized AVF maturation in the subset of failed kidney transplant patients in a national sample and identified important associations with multiple patient-level factors. Patients who were female, black, frail, smokers, or had cardiovascular or diabetic disease required additional time for maturation, suggesting that such patients may require earlier referral as part of their access placement plan. Research is urgently required into the importance of patient, region, and practice factors that could improve AVF placement and maturation, decrease CVC use, and improve outcomes in patients with failed kidney transplants.

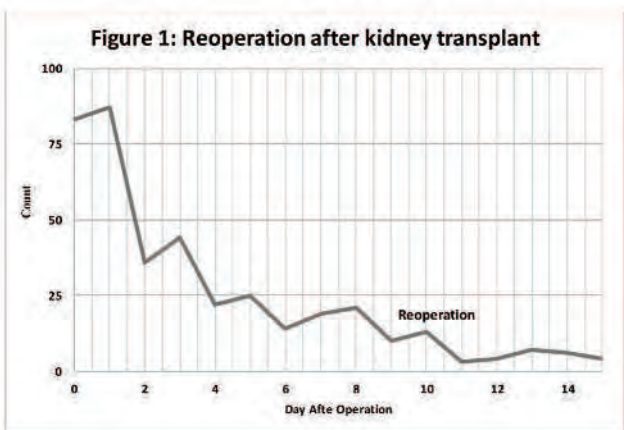
A nationwide analysis of reoperation after kidney transplant

Zhobin Moghadamyeghaneh, Mahmoud Alameddine, George Burke, Gaetano Ciancio, Linda Chen.
Miami Transplant Institute, University of Miami/ Jackson Memorial Hospital, Miami, United States.

Objectives: We aim to report the rate and short-term outcomes of patients undergoing reoperation following kidney transplant in the United States.
Methods: The NIS database was used to examine the clinical data of patients undergoing kidney transplant and reoperation during same the hospitalization from 2002-2012. Multivariate regression analysis was performed to compare outcomes of patients with and without reoperation.
Results: We sampled a total of 172,586 patients who underwent kidney transplant. Of these, 3802 (2.2%) had reoperation during the same hospitalization. Reoperation was associated with a significant increase in mortality (3.1% vs. 0.4%, AOR: 5.40, P<0.01), mean total hospital charges ($249425 vs. $145403, P<0.01), and mean hospitalization length of patients (18 days vs. 7 days, P<0.01). The most common day of reoperation was POD 1 (Figure 1). Hemorrhagic complication (64.1%) was the most common reason for reoperation followed by urinary tract complications (8.9%). Renal vein complications needing reoperation was more than seven times higher than renal artery complications (2.9% vs. 0.4%, P<0.01). Preoperative coagulopathy (AOR: 3.65, P<0.01) was the strongest predictor of need for reoperation and renal artery (AOR: 1.50, P=0.04) and renal vein complications (AOR: 3.62, P<0.01). Also, diabetes (AOR: 1.26, P<0.01) and hypertension (AOR: 1.88, P<0.01) had associations with need for reoperation.
Conclusion: Reoperation after kidney transplant occurs in 2.2% of cases. However, it is associated with a significantly increased mortality, hospitalization length, and total hospital charges. The first day after transplant and hemorrhagic complication are the most common day and reason of reoperation respectively. Preoperative coagulopathy was the strongest factor in prediction of need for reoperation, renal artery complications, and renal vein complications. Controlling coagulation disorders preoperatively may decrease need for reoperation, hospitalization length, and total hospital charges.



426.8

Efficacy of using FloSeal to prevent post renal transplantation lymphocele formation

Yiu Chung Lam, Chun Ki Chan, Chi Man Ng, Yi Chiu, Kwok Leung Ho, Tin Yu Chu, Fu Keung Cheung.
Surgery, Princess Margaret Hospital, Hong Kong, Hong Kong.

Introduction: Preliminary data suggests the use of FloSeal® hemostatic matrix can reduce lymphocele formation after pelvic lymphadenopathy for prostate cancer. We investigate the efficacy of using FloSeal® to reduce the incidence of post renal transplantation lymphocele.
Materials and Methods: We retrospectively reviewed the data of renal transplantation performed from June 2002 to January 2016 in our center. From May 2013 onwards, FloSeal® was applied over graft kidney hilum and segment of iliac artery dissection. Patients' demographics and peri-operative parameters were analysed. Symptomatic lymphocele was defined as those causing either mass effect, impaired renal function or infection requiring intervention. Chi-square and t-test were used for statistical analysis of categorical and continuous variables respectively.
Results: Total 238 patients (203 cadaveric and 35 living-related renal transplantation) were included in this 15 years review. The mean age was 36.6 years old (range 4-69 years old) and FloSeal® was applied in 62 (26.1%) patients. There was no significant difference in patients' demographics such as age, gender and duration of renal replacement therapy between the FloSeal® and non-FloSeal® groups. The incidence of lymphocele formation was significantly reduced in FloSeal® group (9.7% vs 22.2%, p=0.031). Also, the incidence of symptomatic lymphocele formation was lower in FloSeal® group as well (4.8% vs 14.2%, p=0.049). Total drain output was significant less in FloSeal® group (464ml vs 890ml, p=0.004) and drains could be removed earlier (4.3 days vs 6.2 days, p=0.000). No adverse effect associated with the usage of FloSeal® occurred.
Discussion: FloSeal® is a hemostatic matrix using in both open and laparoscopic procedures. It consists of bovine-derived gelatin matrix mixed with human-derived thrombin before usage. The effectiveness of FloSeal® in lymphocele prevention may come from several hypotheses. Firstly, the swelling of gelatin granules by up to 20% after local application may offer a local tamponade effect resulting in occlusion of leaky lymphatic channel. Moreover, as lymph contains a limited amount of fibrinogen, it may form a fibrin clot with the thrombin solution leading to further blockage of the disrupted lymphatic chain. Lastly, the cross-linked gelatin granules facilitates conformation to irregular wound geometries. Thereby it maintains contiguous contact of tissue with the active site of lymphorrhea so that leakage site of lymphatic channel is minimized and tissue healing is promoted. The promising result of FloSeal® in preventing post renal transplantation lymphocele formation is strongly back up these hypotheses.
Conclusion: The results of this study suggest FloSeal® can reduce lymphocele formation after renal transplantation and associated intervention. It also helps decrease drain output and earlier drain removal. This findings warrant a randomized controlled study to further confirm the use of FloSeal® in such aspect.

External ureteral stenting in kidney transplantation; does the type of stent matter?

Liselotte Ooms[1], Laura G.Spaans[1], Michiel G.H.Betjes[2], Jan N.M.IJzermans[1], Turkan Terkivatan[1], Robert Minnee[1].
[1]Transplant Surgery, Erasmus University Medical Center, Rotterdam, Netherlands; [2]Nephrology, Erasmus University Medical Center, Rotterdam, Netherlands.

Introduction: In our center, we prefer the use of external stents over double J stents to prevent urological complications after kidney transplantation. we think external stents have several advantages like the possibility of monitoring the grafts urine production and the simplicity of stent removal without a cystoscopy. The aim of this study was to evaluate the effect of two types of external ureteral stents on the number of urological complications after kidney transplantation.
Materials and Methods: Data were retrospectively collected from 366 consecutive transplantations performed between January 2013 and January 2015 in our hospital, in which an external ureteral stent was placed during surgery. A urological complication was defined as urinary leakage or ureteral stricture requiring percutaneous nephrostomy (PCN) placement.. PCN placement was indicated when the post-operative ultrasound revealed hydronephrosis in combination with a rising serum creatinine level or a peri-renal urinoma indicating urine leakage, confirmed by ultrasonography or MAG-3 scanning.
Results and Discussion: A total of 197 patients received a straight stent with two larger side holes (type A; 8 Fr 'Covidien' tube) and 169 patients received a single J stent with 7 smaller side holes (type B; 7 Fr 'Teleflex' single J stent). In total 50/366 patients (14%) required PCN placement, of whom 37 patients (10%) underwent a PCN placement due to hydronephrosis and 13 patients (4%) due to urinary leakage. We found a significant higher number PCN placements in type A stenting: 34 (17%) PCN interventions versus 16 (9%) in type B stenting (p= 0.030). Reason for PCN placement, stent dysfunction and early removal (< 8 days) was equally distributed in both groups (p= 0.397) while incidence of rejection and urinary tract infection were higher in type B stenting. The 3 months, 6 months and 1 year graft survival rate in the type A stenting group was respectively 97%, 96% and 95% and in the type B stenting group 98%, 97% and 95% (p= 0.781). The 3 months, 6 months and 1 year patient survival rate in the type A stenting group was respectively 99%, 98% and 98% and in the type B stenting group 99%, 98% and 95% (p= 0.093).
Conclusion: 'Stent type B' is associated with less urological complications compared to 'stent type A'. The type of stent does not affect patient and graft survival.

426.10

Standardized intraoperative application of HaemoCer(trademark) may reduce the incidence of lymphocele after kidney transplantation

Christopher Burghuber[1], Daniela Kandioler[1], Stephanie Strobl[1], Martina Mittlböck[3], Georg Böhmig[2], Thomas Soliman[1], Gabriela Berlakovich[1].
[1]Surgery, Division of Transplantation, Medical University Vienna, Vienna, Austria; [2]Nephrology, Medical University Vienna, Vienna, Austria; [3]Medical Statistics, Medical University Vienna, Vienna, Austria.

Introduction: Lymphoceles can occur after kidney transplantation with a reported frequency of around 20% in the literature. Aim of this prospective, non-randomized academic study was to assess whether the standardized application of HaemoCer™ absorbable polysaccharide hemostatic powder (BioCer Entwicklungs-GmbH CE1275), available at our center for facilitating hemostasis, has an effect on the lymphocele rate.
Materials and Methods: The center specific lymphocele rate after kidney transplantation was retrospectively assessed at Vienna University Hospital, Division of Transplantation, over a defined period of one year (April 2011- April 2012). Lymphoceles were diagnosed via routine ultrasound assessment. During this time frame the lymphocele rate in 183 consecutively transplanted patients was 20.3%. We proposed a reduction of 50% in lymphocele rate to be a significant result. In order to detect this difference using a 1-group $\chi 2$ test with a two-sided significance level of 5% and a power of 80% we calculated the number of patients to treat to be at least 108. For one year HaemoCer™ was prospectively used intraoperatively in all patients undergoing kidney transplantation. The study was approved by the ethics committee of the Medical University of Vienna; EK 1125/2013).
Results and Discussion: In the study period 156 patients were transplanted and included into the prospective evaluation. Two patients did not receive HaemoCer™. Of the remaining 154 patients, 19 developed a lymphocele (12.3 %, 95 % CI: 8.0-18.5 %). Compared to the earlier assessed center specific lymphocele rate after kidney transplantation of 20.3%, this represents a significant reduction (p= 0.0174).
Conclusion: Lymphoceles after kidney transplantation seemed to be significantly reduced in a period of time when Haemocer™ was applied intraoperatively compared to a period without standardized use. The magnitude of the effect warrants randomized evaluation.

426.11

Pregnancy after renal transplantation: A single-center experience

Toyofumi Abe[1], Yukito Kokado[2], Nariaki Nakazawa[1], Kazuaki Yamanaka[1], Yoichi Kakuta[1], Ryoichi Imamura[1], Naotsugu Ichimaru[3], Shiro Takahara[3], Norio Nonomura[1].
[1]Department of Urology, Osaka University Hospital, Suita, Japan; [2]Takahashi Clinic, Toyonaka, Japan; [3]Department of Advanced Technology for Transplantation, Osaka University Hospital, Suita, Japan.

Background: Pregnant women with renal allografts often face several complications such as chronic deterioration of graft function and increased risk of preterm delivery. We examined women with renal transplants who became pregnant and delivered at our hospital.
Methods: Of 36 women who underwent renal transplantation and became pregnant and delivered at Osaka University Hospital between 1977 and 2014, 28 women with complete data served as subjects.
Results: Mean recipient age at the time of transplantation was 27.4 (19-38) years. Mean duration from transplantation to delivery was 5.9 years. The 28 recipients became pregnant a total of 40 times after renal transplantation, and neonates were delivered in 32 of the 40 pregnancies. Four recipients delivered twice and 2 recipients delivered twins. As a result, 34 neonates were delivered. Mean gestational period was 36.3 (27-41) weeks, and mean birth weight was 2423 (724-3544) g. Intrauterine growth retardation was observed in 3. One child was born with a double-outlet right ventricle and another child had congenital unilateral hydronephrosis. In 7 of the 32 deliveries (22%), renal function worsened after delivery. Rates of graft survival for the 28 recipients at 1, 5 and 10 years after delivery were 100%, 86% and 74%, respectively. Prognosis for renal transplantation was significantly poorer for recipients with hypertension prior to pregnancy than for recipients without hypertension (log-rank test, p=0.0008).
Conclusions: Rates of graft survival after delivery were mostly favorable. In patients with drug-treated hypertension prior to pregnancy, subsequent renal function may be adversely affected.

A multidisciplinary approach to reviewing patient care in abdominal transplantation

Susan Lerner, Vinay Nair, Morgan Resta-Flarer, Ron Shapiro, Sander Florman, Leona Kim-Schluger.
Recanati Miller Transplantation Institute, Mount Sinai, New York, NY, United States.

Purpose: Unbiased review of patient care in solid organ transplantation is essential for improving patient safety. In October 2013 we created a process by which select events were reviewed by a multidisciplinary team which then determined if standard of care (SOC) was met, and if a corrective action plan (CAP) needed to be implemented. We present results of 694 reviewed cases from our abdominal transplant program.
Methods: All cases presented for review between 10/2013 and 12/2015 were included. Cases came from adult and pediatric kidney, pancreas, liver, small bowel transplantation and hepatobiliary surgery. Cases were selected based on the following criteria: unexpected death, 1 year graft failure, operative complication, unplanned reoperation, medical complication, adverse event, near miss, reported medical event, 30 day readmission, donor disease transmission, and living organ donor adverse event. Members of the review committee include program leadership, director of quality, social worker, and physicians from the transplant department. After review cases are graded as SOC met, SOC not met, or SOC met with room for improvement.
Results: We reviewed 694 cases since 10/2013. Adult liver service (liver transplant, pre and post, and hepatobiliary surgery) accounted for 426 cases and kidney/pancreas, small bowel and pediatric liver accounted for 198, 58 and 12 cases respectively. Death within 1 year of transplant, other death (on the waiting list, while on service, or more than 1 year post-transplant), 30 day readmissions, unplanned reoperations, graft failure within one year, operative/procedural complications, medical complications, adverse events, near misses, reported medical events, donor disease transmissions, and living donor adverse events represent 5.2, 39.9, 28.1, 13.83, 1.59, 6.63, 3.03, 0.14, 0.29, 0.29, 0.72, and 0.29 percent of the cases, respectively. SOC was met in 95.1% of adult liver cases; 91.9% of kidney cases; 94.8% of small bowel cases; 83.3% of pediatric liver cases. Cases where SOC was not met led to the creation and implementation of 43 CAPs.
Conclusions: We have created a process for multidisciplinary review of problematic clinical cases in abdominal transplantation. This has led to the discovery of patient safety problems and the creation of CAPs to prevent recurrence. We believe our approach can help guide other centers in quality and process improvement with benefits in both patient safety and long term clinical outcomes.

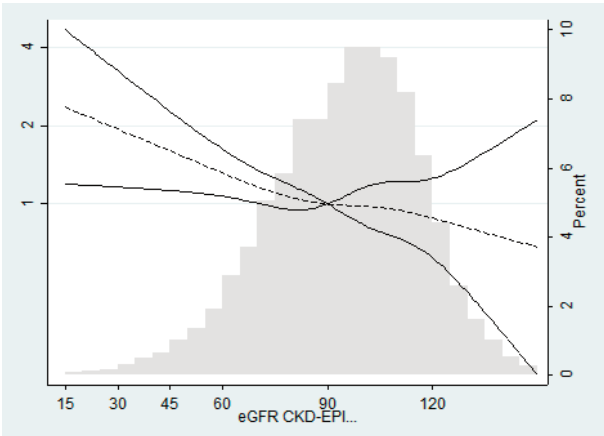
The impact of renal function on post-operative respiratory complications in bariatric surgery

Akihiro Shimomura[1], Yoshitsugu Obi[2,3], Reza Fazl Alizadeh[1], Shiri Li[1], Clarence EFoster[1], Hirohito Ichii[1].
[1]Department of Surgery, Division of Transplantation, University of California, Irvine, Orange, CA, United States; [2]Harold Simmons Center for Kidney Disease Research and Epidemiology, University of California, Irvine, Orange, CA, United States; [3]Division of Nephrology & Hypertension, University of California, Irvine, Orange, CA, United States.

Introduction: As the obesity epidemic in the United States has spread to encompass almost a third of adults older than 20 years, the prevalence of obesity is also increasing among patients with chronic kidney disease. Kidney transplant candidates, most of whom have severely impaired kidney function, often undergo a bariatric surgery in order to lose their weight before transplantation because morbidly obese patients are at greater risk for postoperative complications. However, the prevalence of restrictive spirometric abnormalities is common among dialysis patients, and little is known about the risk of respiratory complications after bariatric surgery among patients with decreased kidney function.
Subjects and Methods: From the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) database, we identified patients who underwent laparoscopic bariatric surgery between 2005 and 2013. We calculated estimated glomerular filtration rate (eGFR) by the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula using preoperative serum creatinine concentrations. We then conducted multivariate logistic regression analyses with restricted cubic spline functions to examine the association of eGFR with the development of post-operative respiratory complications including pneumonia, being on ventilator >48 hours, or unplanned re-intubation after extubation.
Results: Patients were 45±12 years old, 79% female, 15% non-Hispanic Black, and 27% diabetic. Median eGFR and body mass index were 97 (IQR, 81 to 110) mL/min/1.73m^2 and 44.5 (IQR, 40.5 to 49.7) kg/m^2, respectively. Among 112,844 patients who underwent laparoscopic bariatric surgery, 744 (0.7%) experienced respiratory complications during the post-operative period. The incidence of respiratory complications was 0.5%, 0.7%, 1.7%, and 2.5% in patients with eGFR ≥90, 60 to <90, 30 to <60, and 15 to <30 mL/min/1.73m^2, respectively (P for trend = 0.000). Lower eGFR showed higher likelihood of respiratory complication rates after adjustment for demographics, comorbidities, and laboratory variables; 60, 30, and 15 mL/min/1.73m^2 in eGFR showed adjusted odds ratios (95%CIs) of 1.32 (1.07-1.62), 1.95 (1.16-3.25), and 2.36 (1.20-4.66), respectively (reference: 90 mL/min/1.73m^2).



Conclusion: These data demonstrated higher risks of respiratory complications after bariatric surgery among patients with decreased kidney function. The involved mechanisms have yet to be examined, careful perioperative evaluation and management of cardiovascular and respiratory functions may be necessary when obese kidney transplant candidates are undergoing bariatric surgery.

Imbalance of t helper 17 cells and T regulatory cells is associated with chronic active antibody mediated rejection in renal allograft recipients

Brijesh Yadav[1], Narayan Prasad[1], Vikas Agarwal [2], Vinita Agarwal [3], R. K. Sharma[1].
[1]Nephrology and Renal Transplantation, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [2]Clinical Immunology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [3]Pathology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India.

Introduction: Chronic antibody mediated rejection (CABMR) poses challenges for the clinicians and researchers as well. The link between Th17 and antibody formation has been explored. IL-17 deficient mice exhibit impaired T-dependent antibody production.Th17 cells can function as B-cell helpers and IL-17 alone or in combination with B cell-activating factor control the survival and proliferation of human B cells and their differentiation into immunoglobulin-secreting cells.Tregs and Th17 cells share a differentiation pathway involving TGFβ with IL-6 serving as a switch favoring Th17 differentiation.
Aim: To study the frequency of Th1, Th2, Th17 and Tregs; soluble and biointact cytokines in peripheral blood and PBMCs culture supernatant, their mRNA transcript (T-bet, GATA-3, RORC and FoxP3) expression in allograft tissue of patient with CABMR and stable graft function (SGF).
Methods: Total 42 recipients, 10 SGF patients (age 40.90±12.67) with SGF for 6 months without proteinuria and <10% cortical surface area with IF/TA on biopsy; and 32 (age 37.93±12.78 year) in CABMR group as per defined Banff 2013 criteria. Frequency of Th1, Th2, Th17 and Treg was analyzed by flow cytometry and IFN-γ, IL-4, IL-17A, IL-6 and IL-10 level was analyzed from Serum and PBMC by ELISA and mRNA transcript expression by Taqman Real time PCR from graft specimen. Fold change was calculated by 2^^-ct method relative to SGF.
Result: Mean post-transplant interval at biopsy in CABMR Versus SGF was (70.18±34.4 and 49.70±22.71) months. Serum creatinine (2.40±0.8 and 1.23±0.18; P=0.001) mg/dl; daily urine protein (2.94±1.53 and 0.13±0.10; P<0.001) g/day respectively.
Circulating frequency in CABMR Versus SGF of Th1 cell was 23.65±5.93 and 22.2±8.79; P=0.55; Th2 2.28±1.0 and 2.51±0.80; P=0.52;, CD4+Th17 7.84±1.99 and 4.73±1.22; P<0.001; and CD4+CD25+FoxP3+ Treg was 2.25±1.02 and 3.70±1.55; P<0.001,respectively. Ratio of circulating Th17/Treg was higher in CABMR (4.30±2.30) than SGF patients (1.80±1.65; p<0.001).
Soluble cytokines level (pg/ml) in CABMR Versus SGF of IFN-γ 109.8±23.7 and 82.36±24.97; P=0.003; IL-17 ,66.97±18.27 and 42.09±15.9; P<0.001; and IL-6, 57.11±12.92 and 42.94±12.20; P=0.004 ; and IL-10 , 98.91±17.0 and 149.85±22.51, P<0.001respectively. However, IL-4 level was similar in both groups. Similarly, Bio-intact soluble IFN-γ level in patients of CABMR Versus SGF was 161.1±37.34 and 110.68±13.21; P=0.003; IL-17A 66.97±18.27 and 45.65±14.5; P<0.001; IL-6, 63.91±18.97 and 44.41±11.20; P=0.004), IL-10, 163.53±32.56 and 197.62±20.18; P=0.003 repectively. Intragraft mRNA transcript expression in CABMR Versus SGF of T-bet was 2.79±1.62 and 1.03±0.05 a.u; P<0.002; RORc 2.53±0.98 and 1.02±0.076 a.u; P<0.001; FoxP3 1.69±0.83 and 0.98±0.069 a.u; P=0.011 respectively. However GATA-3 expression was similar in both groups. Intragraft RORc/FoxP3 ratio in CABMR 1.83±1.10 was higher than that of SGF patients 1.04±0.11; P=0.032.
Discussion: Th17 is inflammatory cell secrets IL-17, IL-21,which is associated with B cell maturation and antibody class switching. Recently,study has shown role of IL-17 in acute antibody mediated rejection[1]. Increased Th17/ Treg cell in Intragraft tissue suggest their role in CABMR. Anti Th17 cell therapy may be future of CABMR.

Conclusion: Greater mRNA tissue transcript of Th17, circulating Th17 frequency, and IL-17in serum and culture supernatant; and lower Tregs in CABMR as compared to SGF suggests that Th17 is associated with CABMR.

DEPTOR modulates alloimmunity by increasing regulatory T cell function and stabilizing Foxp3 expression

Johannes Wedel[1,2], Sarah Bruneau[1,2], Kaifeng Liu[1,2], Mathieu Laplante[3], David M.Briscoe[1,2].
[1]Division of Nephrology, Boston Children's Hospital, Boston, MA, United States; [2]Transplant Research Program, Harvard Medical School, Boston, MA, United States; [3]Centre de Recherche de l'Institut Universitaire de Cardiologie et Pneumologie de Québec (CRIUCPQ), Université Laval, Québec, QC, Canada.

DEPTOR is a recently described first-in-kind cell intrinsic mTOR-binding partner that modulates Akt signaling. While its expression and function in T cells is unknown, negative regulation of PI-3K/Akt signaling is described to be critical for $CD4^+$ Treg homeostasis and stability. By qPCR and Western blot analysis, we find high levels of DEPTOR expression in pooled populations of $CD4^+$ cells. We also observed reduced levels of expression following mitogen-dependent activation, suggesting that DEPTOR degradation may function to augment T cell activation. To investigate this possibility, we used a rtTA-inducible DEPTOR transgenic mouse (iDEP) in which DEPTOR overexpression is forced by doxycycline (dox) treatment. We initially transplanted fully MHC mismatched BALB/c ($H\text{-}2^d$) hearts into C57BL/6 wildtype (WT) or iDEP recipients (both $H\text{-}2^b$) ± dox (via chow). We found that forced overexpression of DEPTOR in iDEP recipients was associated with a significant ($p<0.001$) prolongation of graft survival (MST 35 days, n=5) *vs*. WT recipients (MST 7 days, n=14). By FACS analysis on day 6 post-transplant, iDEP recipients had a lower frequency of $CD4^+CD44^{high}CD62L^{low}$ T_{EM} cells, and a higher frequency of $CD4^+CD44^{low}CD62L^{high}$ naive T cells and $CD4^+Foxp3^+$ Treg cells *vs.* WT recipients. Administration of anti-CD25 (PC61, 250 µg on days -5, -2 and +2 peri-transplant to deplete Tregs) reversed the graft survival advantage following DEPTOR overexpression (MST 9 days, n=5). Thus, persistent expression of DEPTOR in $CD25^+$ Tregs functions to prolong graft survival. To further confirm the immunoregulatory effect of DEPTOR in $CD4^+$ T cells, we adoptively transferred $CD4^+$ iDEP T cells (± dox) into $Rag2^{-/-}\gamma c^{-/-}$ mice bearing fully MHC mismatched BALB/c allografts. Notably, dox-treated and DEPTOR overexpressing $CD4^+$ T cells were potent to prolong allograft survival (MST 37 days, n=5) *vs.* untreated cells (MST 16 days, n=6; $p<0.01$). We also cultured naive $CD4^+CD25^-$ iDEP T cells in standard iTreg-inducing media (anti-CD3/anti-CD28, TGF-β, IL-2 and retinoic acid) ± dox (3 µg/ml) and evaluated iTreg differentiation. While the addition of dox had no effect on Foxp3 expression (± dox ~80%), we found that dox-treated iTregs are more potent to inhibit T_{eff} proliferation in *in vitro* suppression assays (no dox: 58.5% suppression *vs*. dox: 91.2% suppression; $p<0.01$). In addition, DEPTOR-overexpressing iTregs were more stable upon mitogen reactivation for 7 days (no dox: ~10% $Foxp3^+$ *vs.* dox: 46% $Foxp3^+$; $p<0.001$). Collectively, these findings identify DEPTOR as a novel cell intrinsic protein in $CD4^+$ T cells that enhances Foxp3 stability and Treg function following transplantation. Our findings provide for the intriguing possibility that pharmacological agents that target DEPTOR degradation will be immunoregulatory and have promise as future therapeutics in transplant medicine.

Role of bone marrow maturity, insulin-like growth factor 1 receptor (IGF1R) and forkhead box protein N1 (FOXN1) in thymic involution and rejuvenation in a preclinical large animal model

Masayuki Tasaki[1,2,3], Vincenzo Villani[2], Mitsuhiro Sekijima[2,3], Akihiro Kawai[2,3], Akira Shimizu Shimizu[2,3], David Sachs[1,2], Kazuhiko Yamada[1,2].
[1]Columbia Center for Translational Research, Columbia University Medical Center, New York, United States; [2]Transplantation Biology Research Center, Massachusetts General Hospital, Boston, United States; [3]Center for Advanced Biomedical Science and Swine Research, Kagoshima University , Kagoshima, Japan.

Background and Aim of the Study: Thymic involution is associated with age-related changes of the immune system as well as the ability to induce tolerance. We have previously demonstrated that aged thymi were rejuvenated after transplantation into juvenile swine. Here we have studied the roles of the age of bone marrow (BM) elements and of the soluble factors forkhead-box protein N1 (FOXN1) and insulin-like growth factor (IGF)-1 in the mechanism of thymic rejuvenation and involution.
Materials and Methods: Study 1: We first examined serum testosterone and IGF1 levels in 60 naïve MHC-inbred miniature swine (age range: 1-32 months).
Study 2: We next examined the roles of the age of BM elements and of the soluble factors, FOXN1 and IGF1 in the mechanism of thymic rejuvenation and involution. 10 MHC inbred miniature swine recipients of MHC-matched, age-mismatched, vascularized thymic lobes were divided into four groups: aged donors and juvenile recipients in Group 1, juvenile donors and aged recipients in Group 2, aged donors and aged recipients in Group 3. Group 4 consisted of aged recipients who were transplanted with juvenile BM in addition to juvenile thymi. We examined thymic rejuvenation and involution by means of histology and flow cytometry. Thymic function was assessed by ability of induction of tolerance.
Results: Study 1: Serum testosterone levels in male pigs increased with age while conversely serum IGF-1 levels decreased. Consistent with this observation, IGF1 receptor (IGF1R) expression was elevated in young naïve thymic medulla but decreased in aged thymus.
Study 2: Aged thymi that were rejuvenated in a juvenile environment restored functional tolerance (Group 1), while juvenile thymi in aged recipients involuted and had a limited ability to induce tolerance (Group 2). However, juvenile BM inhibited the involution process of juvenile thymi in aged recipients, and promoted induction of kidney allograft tolerance even in an aged recipient (Group 4). Group 3 animals showed no changes in the involuted status after transplantation, showing that transplantation *per se* does not enhance rejuvenation of the thymic gland. An increase in the expression of both FOXN1 and IGF-1R was observed in juvenile thymi and rejuvenated thymi in all groups.
Conclusion: The expression of FOXN1 and IGF1R was noted to increase under conditions that stimulated rejuvenation, suggesting that these factors are involved in recover of thymic function. Juvenile BM plays a role in promoting the local thymic milieu as indicated by its ability to inhibit thymic involution in an aged animal. These data provide valuable information for the development of a novel strategy to rejuvenate aged thymi in order to induce transplant tolerance.

Rapamycin promotes allograft survival in elderly transplant recipients linked to an accumulation of IL-10+ CD4+ T cells and CD4+CD25+Foxp3+ T-regs

Jeroen Schuitenmaker, Karoline Edtinger , Midas Seyda , Hirofumi Uehara , Marcus Quante, Abdallah ElKhal , Stefan G. Tullius .
Transplant Surgery Research Laboratory, Brigham and Women's Hospital, Boston, MA, United States.

Immunosenescence is broadly affecting alloimmunity with major implications on immunosuppression. Older recipients have thus far been mostly excluded from clinical trials. Here, we dissected the effect of immunosenescence on the efficacy of Rapamycin in a fully MHC-mismatched skin transplantation model.
Skin grafts of young DBA/2 mice were transplanted onto young (2 months) and old (18 months) C57BL/6 mice that were treated with Rapamycin (1 mg per kg per day, i.p.) or PBS. Old, untreated recipients contained their grafts significantly longer (9 vs. 7 days in young-untreated recipients; p=0,006), suggesting that immunosenescence promotes allograft survival. Of particular relevance, Rapamycin prolonged graft survival in an age-specific fashion: while the median graft survival was only modestly extended in young recipients (12 days), graft survival was significantly prolonged in old recipients (19 days; p=0,008). Next, we dissected age-specific effects of Rapamycin on alloimmunity. $CD4^+$ T cells significantly declined in both young and old recipients when treated with Rapamycin (p=0.0009 and p= 0.0408 resp.) Interestingly, we observed an increase of IL-10^+ producing $CD4^+$ T cells, that are known for their immunosuppressive properties, only in old Rapamycin treated recipients (p= 0.0480). Moreover, we observed a significant decline of $CD11c^+$MHC class II^+ T cells and an increase of $CD4^+CD25^+Foxp3^+$ T-regs in old Rapamycin treated recipients (p=0.01 and p=0.0481 resp.).
Rapamycin prolonged graft survival in old recipients linked to an accumulation of IL-10^+ producing $CD4^+$ T cells and $CD4^+CD25^+Foxp3^+$ T-regs. Those age-specific capacities are of clinical relevance with increasing numbers of elderly transplant recipients.

NAD+ alters CD4+ T cell differentiation and promotes allograft survival independently of CD4+CD25+Foxp3+ regulatory T cells

A. Elkhal[1], H. Rodriguez Cetina Biefer[1,2], H. Uehara[1], T. Heinbokel[1,3], M. Quante[1], F. Krenzien[1], V. Camacho[4], M. Seyda[1], J. Schuitenmaker[1], M. A.de la Fuente[5], I. Ghiran[6], S.G. Tullius[1].
[1]Division of Transplant Surgery and Transplantation Surgery Research Laboratory, Brigham and Women's Hospital/Harvard Medical School, Boston, MA, United States; [2]Clinic for Cardiovascular Surgery, University Hospital Zurich, Zurich, Switzerland; [3]Institute of Medical Immunology, Charité, Universitätsmedizin Berlin, Berlin, Germany; [4]Flow Cytometry Core Facility, Beth Israel Deaconess Medical Center, Harvard Stem Cell Institute, Boston, United States; [5]Instituto de Biología y Genética Molecular, University of Valladolid, Valladolid, Spain; [6]Department of Medicine, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, United States.

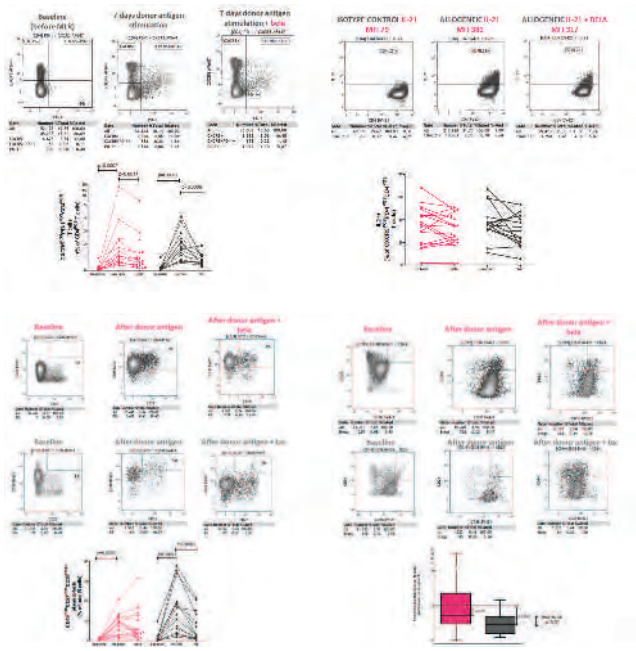
CD4+CD25+Foxp3+ Tregs have been shown to play a central role in homeostasis and to prevent from fatal inflammatory response while Th17cells have been found implicated in a myriad of diseases. We have recently shown that NAD+ protects against autoimmune diseases by regulating CD4+ T cell differentiation via a novel-signaling pathway that promotes CD4+IL-17A+TGF-b+ differentiation and induces CD4+CD25+Foxp3+ Treg-depletion. In addition, we have reported that NAD+ was able to convert naïve CD4+ T cells into IL-17A producing cells under regulatory T cell polarizing conditions. Here, we investigated in-depth the impact of NAD+ on thymus derived CD4+CD25+Foxp3+ regulatory T cells. Using a fully mismatched skin transplant mouse model, we confirmed the unique NAD+ homeostatic properties that are CD4+CD25+Foxp3+ T cell independent. More importantly, in presence of NAD+, CD4+CD25LowFoxp3+ were able to differentiate into Th17 cells. NAD+ induced a decreased expression of CD25 and IL-10 production by CD4+CD25+Foxp3+ Tregs and in parallel increased IL-17A and RORγt expression levels and promoted Th17 cell proliferation in absence of IL-23 through purinergic signaling machinery and the transcription factor STAT3. Collectively, our study unravels a novel immunosuppressive mechanism that regulates regulatory T cell development and unravels a new homeostatic pathway that is independent of CD4+CD25+Foxp3+ Tregs.

427.6

Belatacept fails to inhibit donor-reactive Tfh-B cell interaction, but favors a regulatory transitional B cell profile over tacrolimus

Gretchen de Graav, Dennis A.Hesselink, Marjolein Dieterich, Rens Kraaijeveld, Willem Weimar, Carla C.Baan.
Internal Medicine, Section Transplantation & Nephrology, Erasmus University Medical Center, Rotterdam, Netherlands.

The specialized follicular T-helper (Tfh) cells play a pivotal role in the differentiation of activated B-cells into alloreactive plasmablasts through help via co-stimulation and IL-21[1]. The co-stimulatory inhibitor belatacept effectively blocks this interaction in animal transplant models[2], while conserving regulatory transitional B-cells in stable patients ≥1 year after renal transplantation[3],[4]. This study aims to investigate whether belatacept has the same effect in patients within the first three months after renal transplantation.
Peripheral blood mononuclear cells (PBMCs) were obtained from belatacept-treated patients (n=20) or tacrolimus-treated patients (n=20). All patients had received basiliximab induction therapy, and mycophenolate mofetil and prednisone maintenance therapy. The induction and function of IL-21+ Tfh cells (CXCR5+PD-1+CD4+) and TNFα+ plasmablasts (CD19+CD27+CD38++), and the presence of transitional B-cells (CD19+CD24++CD38++) was assessed after 7-day culture of PBMCs with donor antigen. Some PBMC cultures were spiked with therapeutic concentrations of belatacept (10 µg/mL) or tacrolimus (10 ng/ml). The binding to CD80/86 and the blockade of the CD28-CD80/86 interaction by belatacept in vitro was confirmed by staining for accessible CD86 on donor-antigen activated B-cells.
Following stimulation with donor antigen, an 11-fold and 18-fold increase of Tfh cells was measured for belatacept- and tacrolimus-treated patients, respectively. In vitro addition of belatacept or tacrolimus partially inhibited this increase by a median of 30% and 43%, respectively (p=0.001). However, intracellular IL-21 production by these Tfh cells was not suppressed by belatacept or tacrolimus.



The differentiation of antigen-activated B-cells into TNFα-producing plasmablasts was also induced by donor antigen. Even though belatacept reduced free CD86-expression on donor-antigen activated B-cells more effectively than tacrolimus, median 51% vs 34%, respectively, p=0.03, the formation of plasmablasts was 63% inhibited by tacrolimus, but not by belatacept, p<0.0006. Finally, we observed

that co-culture with tacrolimus reduced the proportion of transitional B-cells by 60%, whereas belatacept preserved this population, p=0.02. In vitro belatacept favors a regulatory profile of renal transplant patients' B-cells but does not inhibit the donor-reactive B cell differentiation into plasmablasts.

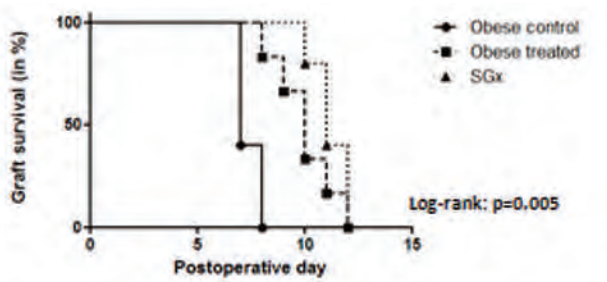
Metabolites associated with bariatric surgery reverse accelerated rejection and augmented alloimmunity in obese allograft recipients

Markus Quante, Abdallah ElKhal, Midas Seyda, Jeroen Schuitenmaker, Hirofumi Uehara, Stefan G.Tullius.
Division of Transplant Surgery & Transplant Surgery Research Laboratory, Brigham and Women's Hospital/Harvard Medical School, Boston, MA, United States.

Background: The obesity epidemic has far-reaching health implications. In transplantation, obesity has become a common co-morbidity linked to impaired transplant outcomes. Here, we delineated mechanisms and consequences of obesity and surgically induced weight loss on alloimmunity and graft survival.
Materials and Methods: Allogenic skin transplantations were performed in diet-induced obese (DIO) C57/Bl6 mice and lean littermates. Additional groups underwent sleeve gastrectomies (SGx) prior to transplantation. The impact of surgery and dietary weight loss was asessed in control animals. Quantitative metabolomic profiling was performed to reveal changes in endogenous metabolites in obesity and during weight loss that might impact the immune response.
Results: Obesity resulted in accelerated allograft rejection. Bariatric surgery prolonged allograft survival beyond that observed in both, obese and lean animals (median graft survival: 7 d obese vs. 9 d lean vs. 11 d SGx; Log-rank test: p=0.005; n=5/group). On a molecular level, obese animals exhibited increased IFN-γ expression in splenic CD4+ T cells; bariatric surgery, in contrast, promoted protective, IL-10-dominated conditions (n=4-6/group by POD 6; p<0.001). Of note, a sham procedure group and a dietary intervention group that was switched to a normal chow diet showed both inferior results in allograft survival and weight loss when compared to animals that underwent SGx. Moreover, bariatric surgery resulted in a significantly compromised alloreactivity confirmed by ELISPOT (n=6/group by POD 6; p<0.05). Metabolomic profiling in obese, lean and bariatric animals identified a secondary bile acid and proteinogenic amino acid as central mediators of alloimmunity. Strikingly, combined application of both compounds reduced obesity and resulted in significant prolongation of graft survival (median allograft survival: 7 d obese controls vs. 10 d obese treated vs. 11 d SGx; n=5-6/group; Log-rank test: p=0.005, Fig.1).



Prolonged graft survival was linked to a less pro-inflammatory alloimmune response in splenic CD4+ T cells obtained from obese animals that underwent metabolic treatment. On a mechanistic level, metabolic treatment resulted in significant reduction of splenic M1-like antigen-presenting cells known to mount and promote pro-inflammatory conditions linked to obesity (n=5-6/group by POD 7; p<0.001,Fig.2).
Conclusions: Obesity augments IFNγ-driven alloimmune responses while bariatric surgery is linked to metabolic changes that induce a switch towards protective, IL-10-dominated conditions. Two metabolic compounds were identified as key mediators skewing the integrated network of metabolism and inflammation towards protective anti-inflammatory conditions. Thus, our results provide a unique

mechanistic link between obesity, metabolism and immunity with high relevance for the steadily growing number of obese transplant recipients and candidates.

Is TH17 associated with chronic calcineurin inhibitor toxicity in renal allograft recipients?

Narayan Prasad[1], Brijesh Yadav[1], Vikas Agarwal [2], Vinita Agarwal [3], R. K. Sharma[1].
[1]Nephrology and Renal Transplantation, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [2]Clinical Immunology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [3]Pathology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India.

Introduction: Th17 a proinflamatory helper T cell, secrets IL-17A cytokines leading to activation and recruitment of other alloreactive immune cells while T regulatory cells(Tregs) suppress alloreactive immune cell and promote stable graft function (SGF). The association of IL-17 with pulmonary and myocardium fibrosis has been reported recently.Calcineurin inhibitors inhibit IL-2 synthesis which is required for T effectors,and Tregs cell differentiation, proliferation and survival as well. Both Th17 and Tregs are plastic and converts into each other also.The immune dysregulation in Chronic calcineurin inhibitor toxicity (CNIT) which is associated with striped fibrosis, arteriolar hyalinosis, and microvascular injury in allograft, is not studied in depth
Aim: To analyze the Th17 and Treg cell frequency; their soluble and biointact cytokines in serum and PBMCs culture supernatant; and their mRNA transcript (RORC and FoxP3) in allograft tissue of patient with CNIT and SGF.
Methods: We recruited total 40 patients; 10 patient with SGF who have no proteinuria and <10% cortical surface area with tubular atrophy and Interstial fibrosis on biopsy; and 30 CNIT following histopathology report of allograft biopsy (hyaline arteriolopathy, nonspecific glomerular sclerosis, striped interstitial fibrosis and tubular atrophy). To further substantiate the diagnosis of CNIT, pateints with BKV, CMV, chronic pyelonephritic changes,donor specific antibody on luminex and C4d + on IF were excluded. we have also collected peripheral blood for flow cytometry cell quantification,and serum and biointact cytokines analysis and allograft tissue specimen for mRNA transcript expression study of RORC and FoxP3 by Taq man Real time PCR.
Results: The mean age of patients in SGF versus CNIT was (40.90±12.67 Vs 38.43±8.87 years; P=0.5) month; post-transplant biopsy interval (49.70±22.71 Vs 56.13±28.37; P=0.52) months; serum creatinine (1.23±0.18 Vs 2.34±0.78; P<0.001) mg/dl and daily urine protein (0.13±0.10 Vs 0.80±0.60 g; P<0.001), respectively.
The frequency of Th17 cell in patient with SGF and CNIT was 4.73±1.22 and 10.11±2.24,P<0.001; Tregs 3.70±1.55 and 2.34±1.22,P=0.007); Th17/Treg cell ration 1.80±1.65 and 5.60±3.18; P=0.001, respectively.
Soluble serum cytokines level (pg/ml) of IL-17A and IL-6 was signicantly high in patient with CNIT and IL-10, TGF-β was signiifcantly low as compared to SGF(Fig.1) Biointact cytokines level (pg/ml) of IL-17A and IL-6 in was significantly high and IL-10, TGF-β level was low in patient of CNIT as compared to SGF (Fig 2). However,TGF-β level remain insignificant. Intragraft mRNA transcript expression of Th17 (RORC) in CNIT(2.08±0.79) was high as compared to SGF(1.02±0.076, P<0.001);and intragraft FoxP3 was also high in CNIT 2.73±1.07; P<0.001) as compared to SGF(0.98±0.069).
Discussion: We oberved increased Th17 cell frequency and IL-17 cytokines level and decreased Treg and IL-10 level in blood of CNI-T patients. However, both Intragraft Th17 and Treg expression were high in CNI-T, suggesting increased Treg cell sequestration to countercheck Th17 inflammatory activity producing CNIT. IL-17 may contribute to interstitial, stripped fibrosis of CNI-T in renal transplant as suggested by role of IL-17 in myocardial and lung graft fibrosis [1],[2].
Conclusion: CNIT is associated with Th17 cell dysregulation contributing to injury and fibrosis in CNIT.It is possible that Intragraft T-regs is not functionally active to suppress pro-inflammatory Th17 activity.

Lymphotoxin on human and mouse Treg promotes migration across lymphatic endothelium

C. Colin Brinkman[1], Keli L.Hippen[2], Bruce R.Blazar[2], Jonathan Bromberg[1].
[1]Surgery, Microbiology and Immunology, University of Maryland School of Medicine, Baltimore, MD, United States; [2]Division of Blood and Marrow Transplantation, Department of Pediatrics, University of Minnesota Cancer Center, Minneapolis, MN, United States.

Introduction: Lymphotoxin (LT) is involved in lymphangiogenesis, helps maintain the structure of secondary lymphoid organs, and LTβ receptor (LTβR) signaling helps promote leukocyte migration into lymph nodes (LN) via high endothelial venules (HEV) and thymocyte migration. We previously showed a requirement for LT for murine Treg to prolong islet allograft survival, and for Treg migration from tissues into afferent lymphatics in the ear and footpad via interactions with LTβR on lymphatic endothelial cells (LEC). We hypothesized that human Treg would also use LT to regulate their interactions with and migration through human LEC.
Methods: Murine Treg were generated from Foxp3GFP mice, and flow-sorted for CD25 and Foxp3GFP. Naïve human T cells were flow-sorted from peripheral blood, and effectors and induced Treg (iTreg) stimulated with anti-CD3 mAb, IL-2 and antigen presenting cells (APCs). iTreg also received TGFβ1 and rapamycin. Human thymus-derived tTreg were isolated from umbilical cord blood and expanded with anti-CD3, IL-2 and APCs. T cells were used in transmigration assays across primary mouse and human skin LEC and the murine LEC line SVEC4-10. For footpad assays murine tTreg were labeled with CFSE, injected into footpads, and analyzed in the downstream popliteal LN after 12 hours. LTβR fusion protein (LTβRIg) was used to block LTαβ interactions with LTβR.
Results: Consistent with our previous results using mouse T cells and endothelial cells, human Treg but not non-Treg CD4 T cell migration to a CCL19 gradient across human skin LEC layers was inhibited by blocking LTαβ interactions with LTβR using LTβRIg. We extended our mechanistic understanding of the expression and action of LT. Both human and murine Treg expressed more LT than did non Treg CD4+ T cells. Murine Treg and non Treg subsets also displayed different knietcis of up- and down-regulation of LT. Murine Treg migration across SVEC4-10 and primary mouse LEC layers was inhibited by blocking LTαβ-LTβR interactions, blocking VCAM-1, or inhibiting non-canonical NFκB signaling, a known downstream mediator of LTβR signaling. Migration of non-Treg T cells in vitro was not inhibited by blocking LT. Inhibitory effects of these treatments were not additive, suggesting they were part of the same pathway. Inhibitory effects were typically enhanced by simulating lymphatic fluid flow across the LEC to better model in vivo conditions. Finally, LT and VCAM-1 blockade also inhibited Treg but not non-Treg CD4+ T cell migration in vivo from footpad to draining LN. .
Conclusions: Engagement of LTβR on lymphatic endothelium by both human and murine Treg but not non-Treg promotes lymphatic migration. This mechanism involves VCAM-1 and the non-canonical NFκB pathway and operates under static conditions and is enhanced by fluid flow. As lymphatic flow is modulated during inflammation this may also result in different sensitivity to this pathway depending upon the phase of the inflammatory response.

T-bet regulates nTreg homing into draining lymph nodes to suppress alloimmune responses

Yanbao Xiong, Sarwat B.Ahmad, Daiki Iwami, C. Colin Brinkman, Jonathan Bromberg.
Surgery, Microbiology and Immunology, University of Maryland School of Medicine, Baltimore, MD, United States.

Introduction: The transcription factor T-bet is required by Treg to suppress Th1 inflammation. However, the mechanisms by which T-bet controls alloimmune responses are not fully understood. We hypothesized that T-bet regulates Treg distribution and suppressive functions, and uncovered a novel molecular mechanism for Treg migration and stability.
Methods: BALB/c (H-2d) donor islets were isolated and transplanted to the renal capsule of streptozotocin-induced diabetic C57BL/6(H-2b) wild type (WT) recipients. Blood glucose was monitored. CD4+CD25+Foxp3-GFP natural Treg (nTreg) from WT or T-bet KO C57BL/6 were isolated and adoptively transferred to allograft recipients, or used for in vitro assays. Flow cytometry and qRT-PCR were performed to analyze expression of effector, adhesion and migration molecules.
Results: T-bet deficient nTreg failed to prolong islet allograft survival as well as WT nTreg. There was no difference in suppression of effector T cell proliferation in vitro between T-bet KO vs WT Treg. However, T-bet KO nTreg failed to prevent antigen-specific CD4 T cell proliferation as well as WT nTreg in vivo. Furthermore, T-bet KO nTreg did not prevent antigen-specific CD4 T cell infiltration into grafts and draining lymph nodes (dLN). Wild type nTreg recovered from the islet grafts expressed higher amounts of T-bet than naïve nTreg, suggesting that T-bet expressed by nTreg played an important role in suppression in the graft. Compared with WT, T-bet KO nTreg remained within the graft and failed to traffic to the dLN from the graft afferent lymphatics. In the graft, T-bet KO nTreg expressed more CCR4 and CD103 than WT nTreg, and their cognate ligands CCL22, CCL17 and E-cadherin were also highly expressed. With a footpad migration assay, E-cadherin blockade restored T-bet nTreg homing to the dLN. Fluorescence imaging analysis showed that T-bet KO nTreg remained associated with interstitial ligands and failed to access afferent lymph vessels. WT nTreg recovered from the graft expressed much more Foxp3 and the suppressor effector molecules IL-10, CTLA4, CD73 and CD39 than T-bet KO nTreg. More T-bet nTreg lost Foxp3 expression and became ex-Treg than WT nTreg.
Conclusion: T-bet regulates nTreg distribution through adhesion and migration molecules, resulting in graft retention that ultimately affects Treg stability, which is essential for in vivo suppression to protect islet allografts. These results demonstrate a novel and unique regulation of Treg migration, genetic stability and suppression. These functional and molecular interactions are foci for therapeutic interventions in immunity and tolerance.

Monocyte-derived dendritic cells promote Th polarization, whereas conventional dendritic cells promote Th proliferation

Kevin V. Chow[1,2,3], Andrew M. Lew[1,2], Robyn M. Sutherland[1,2], Yifan Zhan[1,2].
[1]Immunology, Walter and Eliza Hall Institute of Medical Research, Parkville, Australia; [2]Medical Biology, University of Melbourne, Parkville, Australia; [3]Nephrology, Royal Melbourne Hospital, Parkville, Australia.

Monocyte derived dendritic cells (moDCs) dramatically increase in numbers upon infection and inflammation. We found that this also occurs in response to allogeneic encounters, such as those that occur in the setting of organ transplantation. Despite their prominence in these settings, how emergent moDCs and resident conventional DCs (cDCs) divide their labor as APCs remain undefined. Since, unlike nominal antigens, transplant antigens can be recognised by direct and indirect presentation, we compared both direct and indirect antigen presentation by murine moDCs versus cDCs. We found that, despite having equivalent MHC-II expression and in vitro survival, moDCs were 20-fold less efficient than cDCs at inducing CD4+ T cell proliferation through both direct and indirect Ag presentation. Despite this, moDCs were more potent at inducing Th1 and Th17 differentiation (e.g. 8-fold higher IFN-γ, 2-fold higher IL-17A in T cell co-cultures) whereas cDCs induced 10-fold higher IL-2 production. Intriguingly, moDCs potently reduced the ability of cDCs to stimulate T cell proliferation in vitro and in vivo, partially through nitric oxide production. We surmise that such division of labor between moDCs and cDCs has implications for their respective roles in the immune response.

Urinary levels of chemokines and growth factors in renal transplant patients

Ali Raza[1], Sadaf Firasat[1], Shagufta Khaliq[1], Tahir Aziz[2], Mohammad Mubarak[3], Anwar Naqvi[4], Adib Rizvi[4], Syed Qasim Mehdi[1], Aiysha Abid[1].
[1]CHGMM, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [2]Nephrology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [3]Pathology, Sindh Institute of Urology and Transplantation, Karachi, Pakistan; [4]Urology and Transplantation, Sindh Institute of Urology and Transplantation, Karachi, Pakistan.

Background: Immuno-regulatory molecules such as chemokines and growth factors have a major role in renal allograft rejection. Determination of these chemokines and growth factors in urine could be used as early indicators for renal dysfunction [1]. In this study, urinary expression of chemokines (CXCL10, CXCL9, CCL2 and CCL5) and growth factors (VEGF-α and TGF-β1) was assessed for significant changes in their levels among renal transplant patients at different time intervals and histological conditions.
Methodology: This study is comprised of 511 live-related renal transplant patients. Urine samples were collected at(a) 10th, 30th, 90th & 365 days post-transplantation;
(b) Prior to graft biopsy (n=654), categorized as Rejection (REJ; n=267), non-rejection (NonREJ; n=262) and normal histology (NAD; n=125).(c) Non-biopsy stable functioning graft (SG; n=45)The samples were quantified for biomarkers using the ELISA and analyzed through SPSS software.
Results: (a) Urinary levels of biomarkers at 10th, 30th, 90th and 365 days:We have found raised levels of the CCL2 during the initial post-transplantation phase (i.e. at 10th vs. 90th day). CCL5 also showed significant raised in levels between 10th day and other time intervals (30th, 90th and 365th; P<0.005). Levels of other chemokines CXCL9 and CXCL10 and growth factors (VEGF and TGF-β1) did not differ significantly at different time intervals among renal transplant patients.
(b) Urinary levels among REJ, NonREJ, SG and NAD group:All chemokines (CXCL10, CXCL9, CCL2 and CCL5) and growth factor (TGF-β1) levels were raised significantly in the rejection group compared to the non-rejection except VEGF-A. Raised levels of these biomarkers were also found between rejection and NAD group except TGF-β1 and CXCL9. CCL5 and CXCL10 also showed raised levels in the rejection group compared to SG group.
Conclusion: Raised urinary levels of CCL2 and CCL5 indicate the involvement of these chemokines during the initial post-transplant period and rejection and CXCL9 in later phases of post-transplant duration. These chemokines might reflect the initial renal injury associated either with rejection or surgical complication after post-transplantation.

Positive association of Tcell hyporesponsiveness and age of kidney transplant in patients attending Inkosi Albert Luthuli Central Hospital (Durban, South Africa)

Alain Assounga, Saleha Omarjee, Zama Ngema.
Dept de Nephrology, University of KwaZulu-Natal, Durban, South Africa.

Background: We and others have previously reported a significant reduction in the proliferation of peripheral blood mononuclear cells (PBMC) from transplant patients treated by cyclosporin, tacrolimus or sirolimus based immunosuppressive regimens. Despite the reduction in immunosuppressive dose transplant patients are still subject to infections and malignancies.
Objective: To assess T cell response of kidney transplant recipients according to transplant age.
Method: PBMC were obtained from 38 transplant patients (aged from 0-20 years) by means of density gradient centrifugation of blood samples. Fifty thousand PBMC per well, were incubated overnight (15-18 hours) in triplicate with 5µg/ml of a mitogen, Phytohemagglutinin (PHA). The Promega CellTitre-Glo Luminescent Cell Viability assay which signals the presence of intracellular ATP by means of the luciferin/luciferase. Turner Biosystem luminometer were used to measure ATP in relative lights units (RLU). Results were analysed according to the age of the transplant.
Results: The Chi square test was employed to assess group differences. T cells from transplant patients were less responsive to PHA stimulation as transplant time increased, p=0.0107. (Table 1 below). Furthermore, linear regression analysis indicated that the T cell hyporesponsiveness is not associated with a change in immmunosupressive blood levels (p=0.939).
Conclusion: T cell response of our patients decreased with the age of kidney transplant despite stable blood of levels of immunosuppressive drugs. This may correspond to a progression toward an immune tolerance state. This observation warrant further studies to evaluate factors involved in T cell suppression such as T regulatory cells.

Table 1.

428.1

Development of novel ferroptosis inhibitors for the treatment of ischemia/reperfusion injuries

Bettina Proneth[1], Elke Eggenhofer[2], Edward K.Geissler[2], Marc Weidenbusch[3], Hans-Joachim Anders[3], Marcus Conrad[1].
[1]Institute of Developmental Genetics, Helmholtz Zentrum München, Neuherberg, Germany; [2]Department of Surgery, University Medical Center of Regensburg, Regensburg, Germany; [3]Medizinische Klinik und Poliklinik IV, Klinikum der Universität München, München, Germany.

Introduction: Ischemia/reperfusion injuries (IRI) frequently occur upon organ transplantation and surgical interventions. However, despite the enormous impact on patient outcome, only limited therapeutic options exist. Ferroptosis is a newly discovered regulated cell death routine[1] clearly distinct from apoptosis and necroptosis and when impeded preserves cellular function and organ integrity during tissue IRI[2]. Recent evidence has been provided that ferroptosis plays a pivotal role in the pathological context of liver[3], kidney[4] and cardiac[5] IRI. Therefore, the development of novel ferroptosis inhibitors holds high promise for the management of IRI upon solid organ transplantation.
Materials and Methods: In attempts to develop new and highly efficacious ferroptosis inhibitors, we screened a diverse set of small molecule libraries using an in-house phenotypic cell based high-throughput platform. Subsequently, hit-to-lead, lead optimization and DMPK (drug metabolism and pharmacokinetics) profiling was performed to select compounds with a high therapeutic window, favorable physicochemical properties and promising pharmacokinetic profiles. In vivo proof-of concept was generated in mouse models of hepatic and renal (bilateral) IRI with ischemia times of 90 and 30 min, respectively. Hereby, compounds were administered after (liver) or both, prior and after (kidney) the ischemic period. Tissue protective effects were analyzed by clinical chemistry and histopathology 24 hours after reperfusion.
Results and Discussion: Phenotypic screening for drug-like small molecule compounds identified Liproxstatin-1 as a highly efficacious and specific inhibitor against ferroptotic cell death[3]. Medicinal chemistry and DMPK studies of approximately 200 Liproxstatin analogues not only increased efficacy of Liproxstatin-1 but also yielded substantially improved compounds with increased stability in vitro and in vivo. In addition, Liproxstatins were found to be tissue protective in preclinical mouse models of liver and kidney IRI as measured by significant decreases in markers of liver (ALT/AST) and kidney (creatinine/BUN/KIM-1/NGAL) injury, compared to vehicle treated animals. In addition, histopathologic evaluation of treated tissue samples showed a marked reduction of IRI induced tissue damage.
Conclusion: Inhibition of ferroptotic cell death is a viable approach to protect tissues from undergoing degeneration after IRI upon solid organ transplantation, amenable to pharmacological intervention. Further development of improved next-generation Liproxstatins offers new opportunities to ameliorate or prevent IRI by treating organ recipients, with the potential to significantly improve patient outcome after transplantation.

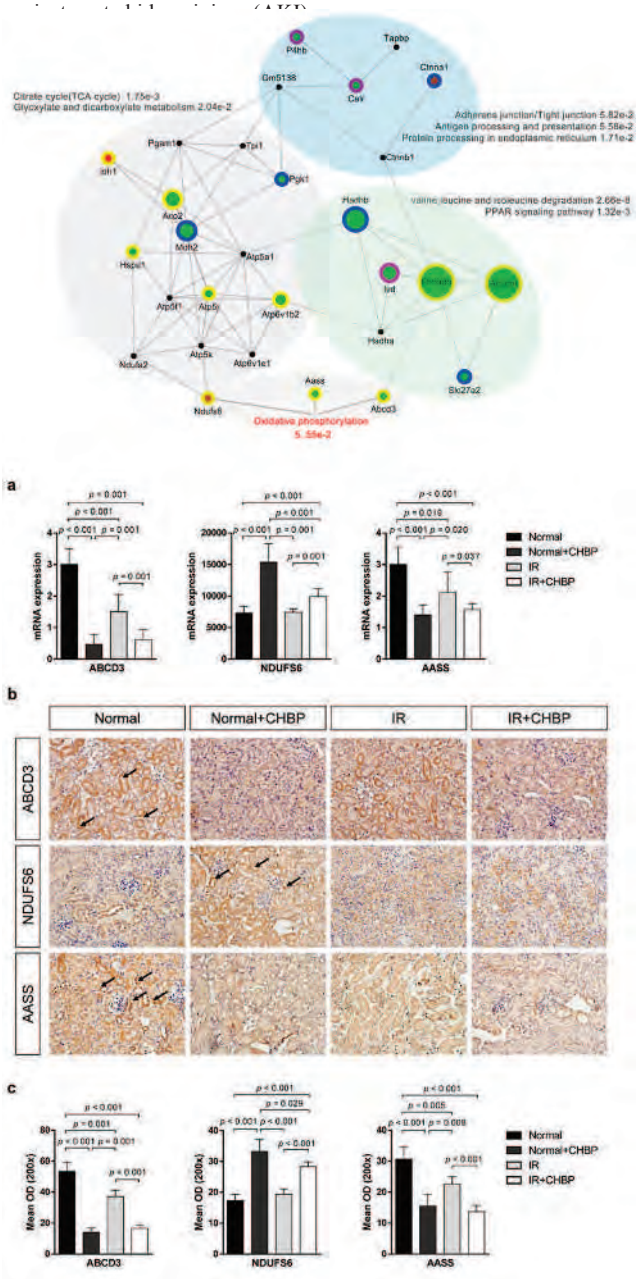
Proteome analysis of renoprotection mediated by a novel cyclic helix B peptide in kidney ischemia reperfusion injury

Cheng Yang[1,3], Junjun Liu[2], Long Li[1,3], Shangfeng Liu[2], Ruiming Rong[1,3].
[1]Urology, Zhongshan Hospital, Fudan University, Shanghai, People's Republic of China; [2]Stomatology, Huashan Hospital, Fudan University, Shanghai, People's Republic of China; [3]Shanghai Key Laboratory of Organ Transplantation, Shanghai, People's Republic of China.

We developed a novel, erythropoietin-derived, non-erythropoiesis, cyclic helix B peptide (CHBP) that displays potent renoprotection



To determine the mechanism of CHBP-mediated protection, we investigated the proteomic profile of mice treated with CHBP in a kidney ischemia-reperfusion (IR) injury model.

The isobaric tags for relative and absolute quantitation (iTRAQ)-labeled samples were analyzed using a QSTAR XL LC/MS system. In total, 38 differentially expressed proteins (DEPs) were shared by all experimental groups, while 3 DEPs were detected specifically in the IR + CHBP group. Eight significant pathways were identified, and oxidative phosphorylation was shown to be the most important pathway in CHBP-mediated renoprotection. The significant DEPs in the oxidative phosphorylation pathway elicited by CHBP are NADH-ubiquinone oxidoreductase Fe-S protein 6 (NDUFS6), alpha-aminoadipic semialdehyde synthase (AASS) and ATP-binding cassette sub-family D member 3 (ABCD3). The DEPs mentioned above were verified by RT-qPCR and immunostaining in mouse kidneys. We tested 6 DEPs in human biopsy samples from kidney transplant recipients. The trend of differential expression was consistent with that in the murine model. In conclusion, this study helps to elucidate the pharmacological mechanisms of CHBP before clinical translation.

428.3

Cyclic helix B peptide inhibits ischemia reperfusion-induced renal fibrosis via the PI3K/Akt/FoxO3a pathway

Cheng Yang, Tongyu Zhu.
Zhongshan Hospital, Fudan University, Shanghai, People's Republic of China.

Renal fibrosis is a main cause of end-stage renal disease. Clinically, there is no beneficial treatment that can effectively reverse the progressive loss of renal function. We recently synthesized a novel proteolysis-resistant cyclic helix B peptide (CHBP) that exhibits promising renoprotective effects. In this study, we evaluated the effect of CHBP on renal fibrosis in an in vivo ischemia reperfusion injury (IRI) model and in vitro TGF-β-stimulated tubular epithelial cells (TCMK-1 and HK-2) model. In the IRI in vivo model, mice were randomly divided into sham (sham operation), IR and IR+CHBP groups (n = 6). CHBP (8 nmol/kg) was administered intraperitoneally at the onset of reperfusion, and renal fibrosis was evaluated at 12 weeks post-reperfusion. Our results showed that CHBP markedly attenuated the IRI-induced deposition of collagen I and vimentin. In the in vitro model, CHBP reversed the TGF-β-induced down-regulation of E-cadherin and up-regulation of α-SMA and vimentin. Furthermore, CHBP inhibited the phosphorylation of Akt and Forkhead box O 3a (FoxO3a), whose anti-fibrotic effect could be reversed by the 3-phosphoinositide-dependent kinase-1 (PI3K) inhibitor wortmannin as well as FoxO3a siRNA. These findings demonstrate that CHBP attenuates renal fibrosis and the epithelial-mesenchymal transition of tubular cells, possibly through suppression of the PI3K/Akt pathway and thereby the inhibition FoxO3a activity.

Outcomes after DCD heart normothermic machine perfusion using banked blood in a porcine model

Hong Chee Chew[1], Jeanette Villaneuva[1], Ling Gao[1], Mark Hicks[1], Andrew Jabbour[1,2], Kumud Dhital[1,2], Peter MacDonald[1,2].
[1]Transplant Laboratory, Victor Chang Cardiac Research Institute, Sydney, Australia; [2]Heart Lung Clinic, St Vincent's Hospital, Sydney, Australia.

Aim: To investigate the functional outcomes of porcine heart recovery during normothermic machine perfusion (NMP) when comparing banked blood to donor blood reperfusion and the metabolic disturbances in the early stages of NMP.
Method: Landrace pigs (n=11) were subjected to circulatory arrest to mimic clinical donation after circulatory death (DCD) conditions. Group 1 (n=6), 1-1.2 litres of blood was collected after cessation of circulation for reperfusion of heart on ex-vivo device; Group 2 (n=5), 1-1.2 litres of banked blood was used to reperfuse the heart on the same device. Baseline metabolic features of the blood were established in each group using handheld i-Stat system, and corrected prior to installation of heart for reperfusion. Functional outcomes measured include aortic flow (AF), coronary flow (CF) and mean aortic pressure (MAP). In both groups, reperfusion of organ was sustained for at least 4 hours unless unfavourable lactate changes.
Results: Metabolic profile of donor blood compared to banked blood reveals significant acidosis (pH 7.53 ± 0.04 vs 6.53 ± 0.04) and electrolyte derangement (K+ 4 ± 0.5 vs 8.9 ± 0.3; Ca2+ 1.32 ± 0.03 vs <0.25; HCO3- 33.8 ± 1.3 vs 0) which requires vigorous correction prior to installation of heart for NMP. Functional outcomes show a significantly higher MAP and AF in banked blood group to achieve a similar coronary flow (MAP 62.3 ± 7.6 vs 98.2 ± 30.5mmHg; AF 0.78 vs. 0.86L/min; CF 0.75 vs 0.71L/min). Lactate profile in both groups remain favourable. (Fig 1) However duration of NMP in the banked blood group is shorter (t= 224 ± 65mins vs 305 ± 46mins).

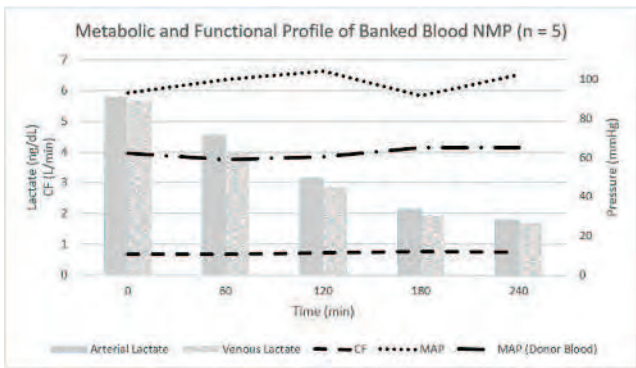

Figure 1. Metabolic and Functional profile of banked blood NMP. MAP in donor blood group is added as comparison.
Conclusion: Donor blood remains superior for the reperfusion of hearts in NMP, however, recovery is achievable using banked blood with vigorous correction of metabolic disturbances. It appears however, components within banked blood induce coronary vasoconstriction during NMP.

428.5

Treatment with tetrahydrobiopterin protects from transplant vasculopathy via prevention of eNOS uncoupling

Rupert Oberhuber[1], Gregor Riede [1], Benno Cardini[1], David Bernhard[4], Barbara Messner[4], Katrin Watschinger[3], Christina Steger[1], Johann Pratschke[1], Gerald Brandacher[1], Ernst Werner[3], Manuel Maglione[1].
[1]Visceral, Transplant and Thoracic Surgery, Innsbruck Medical University, Innsbruck, Austria; [2]Plastic and Reconstructive Surgery, Johns Hopkins University School of Medicine, Baltimore, United States; [3]Biological Chemistry, Biocenter, Innsbruck Medical University, Innsbruck, Austria; [4]Surgery, Vienna Medical University, Vienna, Austria.

Transplant vasculopathy represents a major obstacle to long-term graft survival. Treatment strategies aiming at preventing it are still lacking. Herein we present that the occurrence of transplant vasculopathy crucially depends on oxidative stress formation during organ retrieval. A fully MHC mismatched (BALB/c to C57BL/6) mouse aortic transplantation model was used. Before organ recovery donor animals received either saline (group I - IV) or 50mg/kg b.w. tetrahydrobiopterin i.m. (group V - VIII). Aortic grafts were analysed at 4 different time points: (a) immediately following recovery (group I + V), (b) following 24 hours cold ischemia time (CIT; group II + VI), (c) following 24 hours CIT and 45 min anastomosis time (group III + VII), (d) following 4 weeks graft reperfusion (group IV + VIII). Aortic tetrahydrobiopterin tissue levels were analysed by HPLC, oxidised proteins were measured by the Oxyblot procedure. Monomere/Dimere eNOS ratios were determined using western blot. Transplant vasculopathy was diagnosed by histopathology and immunohistochemistry.
24 hours CIT and 45 min anastomosis time resulted in strong neointima formation and α-smooth muscle actin expression, which could be prevented by donor pre-treatment with tetrahydrobiopterin ($p = 0.008$ and $p = 0.01$, respectively). Similarly, endothelial expression of P-selectin was significantly decreased in the pre-treatment group ($p=0.01$). Interestingly, grafts from pre-treated donor mice showed significantly less oxidised proteins than non-treated grafts already at the time of organ retrieval and following 24 hours CIT, but not at later time points ($p = 0.003$, $p = 0.02$ and p = ns, respectively). Importantly eNOS monomerisation was prevented at the time of organ retrieval by donor BH4 pretreatment.
These data indicate an important role of oxidative stress already during organ recovery, initiating chronic inflammation, which then leads to chronic rejection. Tetrahydrobiopterin protects from early oxidative stress via prevention of eNOS uncoupling.

Atg5/Atg7-independent macroautophagy mediates hepatic sinusoidal endothelial cells' response to ischemia-reperfusion injury

Xiaobing Liu, Xin LI, Alice Yuenyuen MA, Changxian LI, Hui Liu, Jiang Liu, Kevin Tak-Pan Ng, Chung-Mau Lo, Kwan Man.
Surgery, Hong Kong University, Hong Kong, Hong Kong.

Introduction: Macroautophagy is a basic biological process that degrades and recycles intracellular organelles and proteins to maintain energy homeostasis under physiological or pathological conditions. In the past few years, the role of macroautophagy has been implicated in a variety of liver disorders yet contradictory results were reported. Since liver is a multicelluar organ of great complexity, this discordance in data highlights the necessity of dissecting the roles of individual cell type rather than only focusing on parenchymal cells such as hepatocytes. In this study, we examined whether macroautophagy was involved in the response of one non-parenchymal cell—hepatic sinusoidal endothelial cells (HSECs) to ischemia-reperfusion injury (IRI) and explored the underlying mechanisms.
Materials and Methods: Simulated cellular model of IRI was established with HSECs. The cells were exposed to ischemic condition for 3 hr and collected at 0hr, 2hr, 6hr, 24 hr respectively after replenishing with normal medium. Cellular morphological changes were analyzed with transmitting electron microscopy (TEM) or immunofluorescent staining. Kinetic expression of autophagic markers and cell damage were assessed by either qRT-PCR, western blot or flow cytometry. Validation study was further conducted in mouse IRI model and human post-transplantation liver biopsy specimens.
Results: During simulated IRI in HSECs in vitro, TNFa and ROS production increased within the first 6 hours after reperfusion with concurrent reorganization of actin stress fibers in cytoplasmic compartments. Examination with TEM revealed these changes were accompanied with enhanced autophagosome formation peaked at 2 hrs.Meanwhile, involvement of endosomes in autophagosome membrane construction and mitochondria clearance was also identified. Interference assay with macroautophagy inducer rapamycin further showed that heightened macroautophagy suppressed ROS production during IRI. Additionally, gene expression assessment demonstrated that the levels of several autophagic molecules such as ULK1, Fip200, Rab9 were elevated in response to IRI, yet the levels of essential conventional autophagic markers including LC3II, Atg5, Atg7 remained largely unchanged.Emergence of autophagosomes in the HESCs of mouse liver after ischemia-reperfusion was consistent with that of the cellular IRI model. In human living donor liver grafts 2 hr post-transplantation, interestingly, increased autophagosome formation together with augmented apoptosis was observed in HESCs. This may indicate that autophagic machinery was activated yet not being able to resolve the imbalance incurred by injury in living donor liver transplantation.

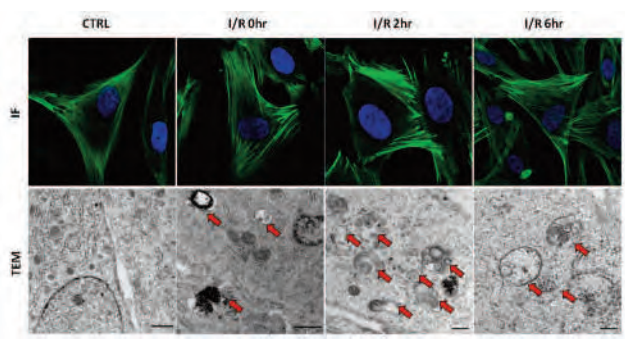

Figure 1. HSECs' response induced by IRI in vitro. Disassembly of stress fibers (upper, phalloidin staining) and increased autophagosome formation (lower) in HSECs after IRI.

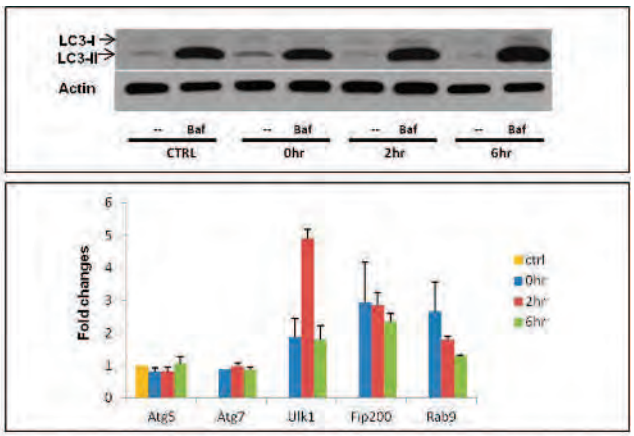

Figure 2. Expression of autophagic markers in HSECs during IRI. The expression levels of conventional autophagic markers including LC3II (upper, without or with bafilomycin interference) , Atg 5 and Atg7 (lower, mRNA) remained unchanged, while levels of ULK1, Fip200, Rab9 increased (lower, mRNA).

Conclusion: Our study showed that activation of macroautophagy in HSECs during IRI shared features of Atg5/Atg7-independent pathway and exerted a protective role. Further investigation on the detailed mechanism may help establish novel therapeutic strategies to improve graft survival.

Donor liver transplant rejuvenation: From bench-to-bedside

Ali Zarrinpar[1], Bibo Ke[1], Haofeng Ji[1], Elaine Reed[2], Ronald Busuttil[1], Jerzy Kupiec-Weglinski[1].
[1]Surgery, UCLA, Los Angeles, CA, United States; [2]Pathology and Lab Medicine, UCLA, Los Angeles, CA, United States.

The organ shortage has prompted the use of marginal livers, which are particularly susceptible to ischemia-reperfusion injury (IRI). In the experimental arm of this study, we discovered that Nrf2 deficiency in the donor liver, a master regulator of intracellular redox homeostasis, exacerbated IRI in mouse orthotopic liver transplantation (OLT; BL6 BL6; 20h of cold storage). However, IRI was mitigated if donor livers were pre-conditioned with bone marrow cells overexpressing anti-oxidant HO-1. The success of donor liver rejuvenation was lost after abrogation of SIRT1 activity, a NAD+-dependent type III protein deacetylase with key roles in stress resistance. Thus, SIRT1 signaling dictates rejuvenation outcomes in the mouse liver, in which Nrf2 expression represents a denominator of donor tissue quality. In the clinical arm of the study, we enrolled 30 liver transplant patients in which portal blood and liver perfusate are collected pre-op; during; and at reperfusion. The severity of liver damage is assessed by a new biopsy pathology scoring system, i.e., minimal/mild IRI (score 1-2) vs. moderate/severe IRI (score 3-4), based on incidence of cholestasis, inflammation, steatosis, ballooning/necrosis.

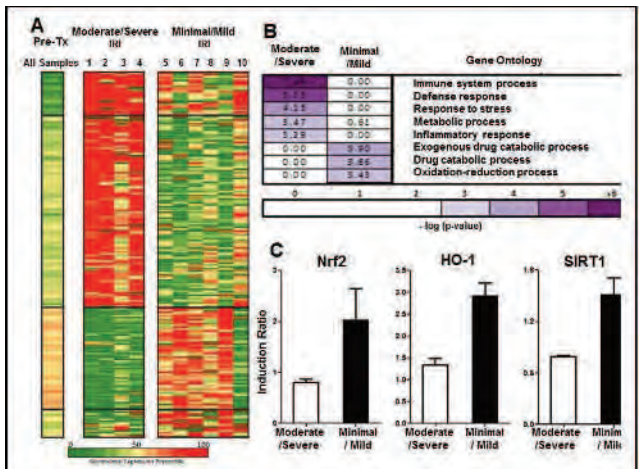

Fig. 1: (A) Human liver transplant transcriptome vs. biopsy-based severity of hepatic IRI; **(B)** Gene Ontology analysis; **(C)** Nrf2, HO-1 and SIRT1 gene induction ratios in human liver transplants (pre-transplant / at reperfusion; mean±SD; n=3-5/gr).

Fig. 1A shows a human liver transplant transcriptome (mRNA pool), as indicated by the heat-map at the bottom. The first column is of the average gene expression in pre-transplant biopsies (n=10). The first sample grouped column (#1-4) represents moderate/severe IRI; the next column (#5-10) identifies minimal/mild IRI. The Gene Ontology analysis (Fig. 1B) revealed the severe IRI cases associate with higher expression of genes with function in the immune system, defense/stress responses, and metabolic processes. Strikingly, and in agreement with our murine OLT functional data, human livers suffering from severe IRI showed ca. 2.5-fold lower induction of Nrf2, HO-1 and SIRT1 genes, compared to IRI-resistant grafts. Conclusion: These findings provide rationale for innovative donor interventions to improve quality and size of the current liver organ supply.

Dendritic cell phenotype and function modification with targeted porous silicon nanoparticles

Sebastian Stead[1], Steven McInnes[2], Svjetlana Kireta[3], Shilpanjali Jesudason[3,4], Shane Grey[5], Darling Rojas-Canales[3,4], Robert Carroll[3,4], Nico Voelcker[2], Patrick T.Coates[1,3,4].
[1]Medicine, University of Adealide, Adealide, Australia; [2]Biomaterials Engineering & Nanomedicine, University of South Australia, Adelaide, Australia; [3]Transplantation, The Centre for Clinical and Experimental Transplantation , Adelaide, Australia; [4]Renal, Royal Adelaide Hospital, Adelaide, Australia; [5]Immunology, Garvan Institute of Medical Research, Sydney, Australia.

Aims: Dendritic cells (DC) are the most potent antigen-presenting cell and are fundamental in the establishment of transplant tolerance. Targeting DC via the DC-SIGN receptor is a potential target for cell specific therapy. Porous silicon nanoparticles (pSiNP) loaded with immunosuppressant rapamycin (RAPA-pSiNP) provides a unique platform to target and modify DC *in vivo*. The aim of this study was to conjugate monoclonal antibody anti-DC-SIGN on to the surface of RAPA-pSiNP and determine the effects on targeted DC phenotype and stimulatory capacity *in vitro*.
Methods: Fluorescein isothiocyanate (FITC)-labelled pSiNP conjugated to either anti-DC-SIGN or isotype control were cultured with whole blood samples *in vitro* to assess specific targeting to DC. Uptake was determined via flow cytometry and transmission electron microscopy (figure 1). Rapamycin loading of pSiNP was confirmed with ultraviolet visualisation and inferred spectrometry. DC were co-cultured with rapamycin loaded pSiNP (RAPA-pSiNP) for 2 days (± LPS), irradiated and co-cultured with CFSE stained allogeneic T-cells.
Results: Anti-DC-SIGN pSiNP favourably targeted and were phagocytised by myeloid DC in whole blood samples in a time and dose dependent manner. Anti-DC-SIGN conjugation increased DC targeting. Myoloid DC were 42% positive for Anti-DC-SIGN functionalised NP compared to only 10% for Isotype control and 5% for unfunctionalised Np. Compared to mature DC, dendritic cells preconditioning with RAPA-pSiNP resulted in a maturation resistant phenotype and significantly suppress allogeneic $CD3^+$ T-cell proliferation by 28.6 ± 1.9% ($p<0.0001$).
Conclusions: RAPA-pSiNP conjugated to anti-DC-SIGN actively targets and modifies DC function and may serve as a novel therapy to target DC *in vivo*.

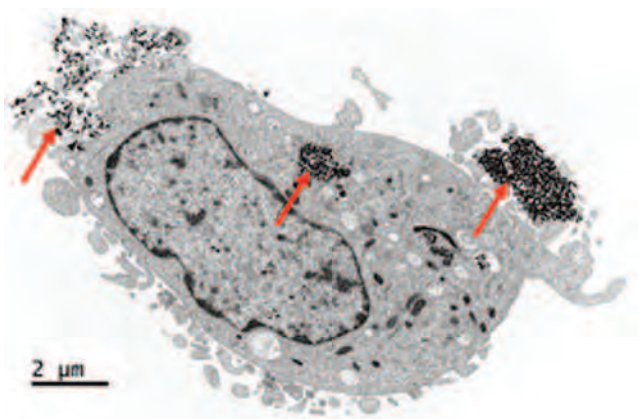

Figure 1: Transmission electron micrograph of human monocyte-derived DC treated with anti-DC-SIGN monoclonal antibody labelled pSiNPs for 2 hours. Arrows show pSiNPs inside the lysosome and on the surface of the DC.

Follistatin modulates ischemia-reperfusion-induced renal fibrosis in mice

Doreen Fang[1,2], Bo Lu[1], Susan Hayward[4], David de Kretser[3,4], Peter Cowan[1,2], Karen Dwyer[2].
[1]Immunology Research Centre, St. Vincent's Hospital, Melbourne, Australia; [2]Department of Medicine, The University of Melbourne, Melbourne, Australia; [3]Faculty of Medicine, Monash University, Melbourne, Australia; [4]Centre for Reproductive Health, Hudson Institute of Medical Research, Melbourne, Australia.

Introduction: Activins, members of the TGF-β superfamily, are key drivers of fibrosis and hence thought to play a significant role in chronic allograft dysfunction which is the predominant cause of renal graft loss. Ischemia-reperfusion injury (IRI), an inherent process in renal transplantation, is a known trigger for development of chronic allograft dysfunction. Follistatin (FS) is a protein that binds activins and inhibits their activity. Intramuscular injection of a recombinant adeno-associated viral vector carrying a FS gene (rAAV-FS) results in a sustained elevation of circulating FS in mice. This study examined the impact of increased FS levels on renal fibrosis in a mouse model of renal IRI.
Materials and Methods: Mice were injected with rAAV-FS (1.2×10^{10} vector genomes) or empty vector (rAAV-empty) 4 weeks before renal IRI surgery (left renal pedicle was clamped for 20 min) to allow for transduction. Sham mice underwent a midline laparotomy only without IRI surgery. A right nephrectomy was performed 48 h before mice were sacrificed at 4 weeks post IRI. Serum activin A, activin B and FS levels, serum creatinine, and pro-fibrotic markers were assessed.
Results and Discussion: At 4 weeks post IRI, rAAV-empty/IRI mice demonstrated increased mRNA expression of the pro-fibrotic markers TGFβ-1 ($p<0.05$), connective tissue growth factor (CTGF) ($p<0.05$), type I collagen ($p<0.05$), and type IV collagen ($p<0.01$). These were accompanied by impaired kidney function (increased serum creatinine 39.25 ± 2.92 µmol/L, sham = 22.0 ± 1.82 µmol/L, $p<0.01$), and reduced kidney weight (141.40 ± 3.42 mg, sham = 183.30 ± 10.06 mg, $p<0.001$). However, there were no significant differences in serum activin A or B levels between the rAAV-empty/IRI and sham mice. This may be due to fibrosis development being a local process in the kidney hence further analysis to assess activin A and B levels in the kidney is required. Serum FS was significantly increased in rAAV-FS/IRI mice ($p<0.0001$), confirming successful transduction. This increase was associated with significantly lower serum activin A and B ($p<0.001$), suggesting binding of activins to FS and subsequent clearance. Expression of pro-fibrotic markers in rAAV-FS/IRI mice was reduced (TGFβ-1, $p<0.05$; CTGF, $p<0.05$; type I collagen, $p=0.05$; type IV collagen, $p=0.05$), accompanied by improved renal function (reduced serum creatinine 29.29 ± 2.20 µmol/L, $p<0.05$), and preserved kidney weight (176.10 ± 8.11 mg, $p<0.01$). Further analysis to assess the extent of fibrosis on histology is required.
Conclusion: We propose that activin A and B contribute to the development of renal fibrosis induced by IRI. Sustained elevation of FS confers protection against renal fibrosis development, suggesting a potential therapeutic application in renal transplantation to prevent chronic allograft dysfunction and improve graft survival.

Liver specific activating transcription factor 5 (ATF5) regulates liver ischemia/reperfusion injury

Gong-Qing Shen[2], Miwa Morita[1], John J. Fung[2], Lina Lu[1,2], Shiguang Qian[1,2].
[1]Immunology, Lerner Reaerch Institute, Cleveland Clinic, Cleveland, OH, United States; [2]General Surgery, Transplant Center, Digestive Disease Institute, Cleveland Clinic, Cleveland, OH, United States.

Activating transcription factor 5 (ATF5), a member of the ATF/cAMP response element-binding proteins, caught our attention because it extremely highly expresses in the liver in both mice and humans, but its functions are largely unknown, although several recent studies suggested that ATF5 participates in hepatic stress process. The aim of this study was to investigate the effect of ATF5 on regulating liver ischemia/reperfusion (I/R) injury, for which the ATF5 knockout mice were developed. However, homozygous ($ATF5^{-/-}$) pups had ~85% perinatal mortality (died in 24 hours). It turned out to be difficult to obtain sufficient $ATF5^{-/-}$ mice for studies. We then alternatively generated the conditional ATF5 knockout ($cATF5^{-/-}$) mice using an albumin-Cre-LoxP approach. The $cATF5^{-/-}$ mice were identified via genotyping ($Neo^{+}Cre^{+}Loxp^{+}$), and confirmed by null expression of ATF5 in hepatocytes (qPCR and western). A nonlethal model of segmental (30%) hepatic warm ischemia (60 min) followed by 6h reperfusion (an optimal condition based on blood ALT test) was used for I/R study. Deficiency in ATF5 resulted in marked increases in blood ALT levels (U/L) in a dose dependent manner: 3320±124 (WT), 5875±884 ($ATF5^{+/-}$) and 9096±133 ($ATF5^{-/-}$) ($n=3$, $p<0.05$). Histological I/R scores were well correlated with ALT changes, indicating that ATF5 is a crucial transcription factor in regulating liver I/R injury. Surprisingly, blood ALT levels in $cATF5^{-/-}$ group (3370±116, $n=3$) were comparable to WT ($p>0.05$), markedly lower than $ATF5^{+/-}$ and $ATF5^{-/-}$ groups ($p<0.05$). Conditional knockout status of those $cATF5^{-/-}$ mice were reexamined and confirmed by qPCR and western blotting. The possible explanation is that liver I/R injury is not directly regulated by ATF5 in hepatocytes, rather regulated by non-parenchymal cells (NPC). To determine what type of liver NPC mediate the transcription regulation of liver I/R injury, the expression of ATF5 in hepatocytes, $CD45^{+}$ and $CD45^{-}$ NPC from WT mice was examined by qPCR, showing that NPC expressed minimum amount of ATF5 (only ~1/50 of hepatocytes). Whereas, when ATF5 was knocked out in hepatocytes ($cATF5^{-/-}$), expression of ATF5 in NPC was dramatically increased, implicating an important role of ATF5 in the liver. Our lab is now intensively investigating the functions of ATF5 in NPC in regulating I/R injury and the underling molecular pathways.

Low expression in preimplantation biopsies of FABP3, a gene that codes for fatty acid binding protein, is a marker for delayed kidney graft function

Tuíla B.Mourão[1], Karina L.Mine[1], Érika F.Campos[1], José O.Medina-Pestana[2,3], Hélio Tedesco-Silva[2], Maria Gerbase-DeLima[1].
[1]Immunogenetics Institute, AFIP - Associação Fundo de Incentivo à Pesquisa, São Paulo , Brazil; [2]Hospital de Rim e Hipertensão , Fundação Oswaldo Ramos, São Paulo, Brazil; [3]Nephrology, Universidade Federal de São Paulo , São Paulo, Brazil.

Introduction: The purpose of this study was to investigate markers for prediction of delayed graft function (DGF) in kidney transplantation (Tx).
Material and Methods: We evaluated, in pre-implantation biopsies (PIB), the expression of five genes selected from a previous large scale gene expression study in PIB performed at our laboratory: ACSL4 (acyl-CoA synthetase long-chain family member 4), CUBN (cubilin), DEFB1 (defensin, beta 1), FABP3 (fatty acid binding protein), and GK (glycerol kinase). Gene expression (real-time TaqMan PCR) was measured in 43 PIBs, corresponding to 22 Tx with DGF and 21 Tx without DGF. Three reference genes (POLR2K, HPRT1, GUSB) were used for gene expression normalization. Lower expression levels of DEFB1 ($p=0.004$), FABP3 ($p=0.001$), and GK ($p=0.016$) were observed in cases with DGF, whereas there were no significant differences concerning ACSL4 or CUBN. In a multivariate analysis, including also clinical variables, only FABP3 expression remained independently associated with DGF. FABP3 expression lower than -1.32 log2 transformed units of relative expression conferred an odds ratio for DGF of 41.1.
Discussion and Conclusions: The lower expression of DEFB1 in Tx with DGF could be reflecting the decrease in the number of tubular cells due to ischemia-induced cell death, since this gene encodes an antimicrobial peptide of urogenital tissues constitutively produced by renal tubular cells (Zhao C et al, 1996; Valore EV et al, 1998); the lower FABP3 expression could be associated with a decreased protection against ischemic damage, as fatty acid-binding proteins have been shown to minimize the tissue damage caused by ischemia by reducing the effects of oxidative stress through the binding of fatty acids and products of lipid peroxidation (Kamijo-Ikemori A et al, 2006; Yamamoto T et al, 2007); an explanation for the association of low GK expression with DGF could be that low levels of glycerol kinase compromise the phosphorylation of glycerol, resulting in increased glycerol levels which were shown to induce acute kidney injury in mice (Homsi E et al, 2006; Rahib L et al, 2007).
Conclusion: This study revealed FABP3 expression in PIB as a very promising marker for DGF, and disclosed new genes possibly involved in the pathogenesis of DGF.

Using intravoxel incoherent motion MR imaging and blood oxygen level-dependent MR imaging to evaluate rat acute allograft rejection model

Song Zeng[1], Lu Liang[2], Qiang Zhang[1], Yue Xu[1], Wenrui Xue[3], Zijian Zhang[1], Wei Wang[1], Xiaodong Zhang[1], Tao Jiang[2], Xiaopeng Hu[1].
[1]Urology, Chao-Yang Hospital, Beijing, People's Republic of China; [2]Radiology, Chao-Yang Hospital, Beijing, People's Republic of China; [3]Urology, You-An Hospital, Beijing, People's Republic of China.

Objectives: To combine the intravoxel incoherent motion (IVIM) imaging and blood oxygen level-dependent MR imaging (BOLD) for assessment of the renal allograft pathological process and differentia between acute rejection (AR) and acute tubular necrosis (ATN) at the early stage after renal transplantation in rat model.
Materials and Methods: AR was induced by transplantation of Dark Agouti (DA) donor kidneys into Lewis recipients (allogenic ktx) (n=12). Lewis rat that received Lewis kidneys (isogenic ktx) (n=12) served as controls. ATN rat model was caused by ischemia/reperfusion injury (IRI) in Lewis rats (n=12). Six rats of each group were imaged longitudinally at postoperative day (POD) 1, 4 and 7, respectively; two rats were randomly chosen from the rest for histological studies. The apparent diffusion coefficient (ADC), the diffusion coefficient of microcirculation or perfusion (D*), the diffusion coefficient of pure molecular diffusion (D), and perfusion fraction (f) were calculated from IVIM, and R2* was obtained from BOLD. R2* is a measure of the rate of signal loss in a specific region and is related to the amount of deoxyhemoglobin present. Histological changes in the kidney were evaluated according to Banff criteria. Immunofluorescence was used to quantify cell infiltrates and fibrosis in kidney.
Results: After allogenic transplantation, animals developed acute allograft rejection which was confirmed by histological analysis and the severity of AR increased progressively over time. D, f value of the acute rejection group was significantly lower ($p<0.05$) than that in the native kidney and other groups at POD 1, 4, 7 while a progressive reduction in D* was observed at POD 4, 7 in renal cortex. Mean medullary R2* values in AR group were lower than in the isogenic ktx group and ATN group ($p<0.05$) at POD 7. In addition, f and D* were strongly correlated with R2*. **Conclusions:** IVIM imaging coupled with BOLD MR imaging is an effective tool for monitoring progress of AR and differentiating AR from ATN in rat models. Otherwise,it may help elucidate the underlying mechanisms of acute rejection and ATN.

Immune-modifying nanoparticle therapy reduces kidney ischemia reperfusion injury

Huiling Wu[1], Daniel Getts[2], Jin Ma[1], Xiaochen Chen[1], Caryn Van Vreden[2], Nicholas King[2], Steven J.Chadban[1].
[1]Renal Medicine and Kidney Node Laboratory, The Charles Perkins Centre, Royal Prince Alfred Hospital and The University of Sydney, Sydney, Australia; [2]The Discipline of Pathology, Sydney Medical School, The University of Sydney, Sydney, Australia.

Inflammatory monocyte-derived effector cells play a significant role in the pathogenesis of numerous inflammatory diseases including kidney ischemia-reperfusion injury. However, specific therapeutic agents to target these cells are not available. Recently, we reported the capacity of immune modifying nanoparticles (IMPs) to bind to circulating inflammatory monocytes/macrophages (MΦ) via the specific scavenger receptor MARCO, thereby causing inflammatory MΦ removal in spleen with subsequent protection in models of infection, autoimmunity and ischemia injury. Here we investigated the therapeutic potential of IMPs to target MΦ in kidney ischemia-reperfusion injury.
Methods: Kidney ischemia was induced for 22 minutes followed by reperfusion. C57BL/6 mice were randomized to receive 300ul (1.46x1010 particles/ml, 500nm in diameter) of negatively charged IMPs or neutral nanoparticles as a control by tail vein injection 2 hours after ischemia and continued daily for 3 days. Samples were collected at days 1 and 5 after reperfusion.
Results: Mice treated with IMPs were protected against kidney ischemia-reperfusion injury, with lower serum creatinine and less tubular damage versus control mice at days 1 and 5 ($p<0.05$-0.01). Tubulo-interstitial accumulation of neutrophils (day1, $p<0.05$) and CD68+ macrophages (day 5, $p<0.05$) was markedly less in mice treated with negatively charged IMPs versus controls. IFNg expression in ischemia-reperfusion injury kidney at day 1 was significantly reduced while TGFb expression in ischemia-reperfusion injury kidney was increased at day 5 by negatively charged IMPs treatment ($p<0.05$).
Conclusion: IMP infusion affords significant protection from kidney ischemia-reperfusion injury in mice, which may be associated with inhibition of inflammatory MΦ migration and function.

Knock-in of anti-CD2 and human thrombomodulin transgenes into pig GGTA1 using CRISPR/Cas9

Evelyn Salvaris[1], Nella Fisicaro[1], Ivan Vasiliev[2], Stephen McIlfatrick[2], Mark Nottle[2], Jamie Brady[3], Andrew Lew[3], Peter Cowan[1,4].
[1]Immunology Research Centre, St Vincent's Hospital, Melbourne, Australia; [2]Obstetrics and Gynaecology, University of Adelaide, Adelaide, Australia; [3]Immunology Unit, Walter and Eliza Hall Institute, Melbourne, Australia; [4]Department of Medicine, University of Melbourne, Melbourne, Australia.

Introduction: Successful pig-to-human organ xenotransplantation will require genetic modification of the donor pig to attenuate antibody, coagulation and T cell-mediated immune responses. The CRISPR/Cas9 genome editing system offers a unique opportunity to streamline this process by allowing efficient integration of protective transgenes into detrimental porcine genes such as *GGTA1*, which specifies expression of the major xenoantigen alphaGal. Although a CRISPR-mediated 4.2-kb transgene knock-in pig was reported recently[1], it was generated using the original Cas9, which has a relatively high rate of off-target events, and targeted a 'neutral' locus with minimal relevance for xenotransplantation. In this study, we investigated whether a high fidelity CRISPR system employing the modified nuclease *Fok*I-dCas9 could be used to knock larger transgenes into the pig *GGTA1* locus.
Aim: To separately integrate two 10-kb transgenes, expressing either a chimeric anti-CD2 monoclonal antibody (CD2hb11) or human thrombomodulin (hTBM), into *GGTA1* in the pig genome.
Materials and Methods: Wild type pig fetal fibroblasts (PFF) were transfected with (i) expression constructs for *Fok*I-dCas9 and two guide RNAs targeting exon 9 of *GGTA1*, plus (ii) a neomycin-resistant (Neo^R) H2Kb promoter-driven CD2hb11 or hTBM knock-in construct. Stable Neo^R clones were screened by FACS either directly to detect Gal or hTBM expression, or indirectly (culture supernatant incubated with human T cells) to detect CD2hb11 expression. Suitable clones were used for somatic cell nuclear transfer (SCNT).
Results and Discussion: In an initial small-scale experiment using the CD2hb11 construct, 12 Neo^R clones were isolated, of which one was Gal-negative and secreted the antibody. Using the hTBM construct, 240 Neo^R clones were isolated, of which 11 were Gal-negative and hTBM-positive. PCR and sequencing confirmed correct transgene integration in both CD2hb11 and hTBM clones. Interestingly, molecular analysis of several clones indicated knock-in of the transgene by homology-directed recombination (HDR) at one allele of *GGTA1* and knockout of the second allele by non-homologous end joining (NHEJ). This is consistent with previous studies indicating that NHEJ out-competes HDR at Cas9-mediated double-stranded DNA breaks[1]. Five rounds of SCNT using the CD2hb11 knock-in clone have resulted in 2 pregnancies, with one currently at 11 weeks.
Conclusion: We have used the high fidelity CRISPR/*Fok*I-dCas9 system to efficiently knock two separate transgenes into *GGTA1* in pig cells. The modified cells are being/will be used for SCNT to generate donors for our preclinical pig-to-baboon kidney and islet xenograft models. This is the first report of CRISPR-mediated transgene knock-in in pig cells for xenotransplantation purposes.

CD39 plays an important role in the suppressive capacity of xenoantigen stimulated and expanded non-human primate regulatory T cells

Dandan Huang, Ya Wang, Wayne J. Hawthorne, Joanne Hawkes, Heather Burns, Yi Vee Chew, Sussan Davies, Yuanfei Zhao, Min Hu, Shounan Yi, Philip O'Connell.
Centre for Transplant & Renal Research, The Westmead Institute for Medical Research, University of Sydney, Sydney, Australia.

Introduction: We have previously shown that porcine xenoantigen stimulated and expanded baboon $CD4^+CD25^+$ regulatory T cells (Treg) acquired effector Treg phenotype with enhanced suppressive capacity in the xenogeneic response in vivo. However the mechanisms involved are yet to be identified. Since CD39 has been shown to be important for effector Treg to induce allograft tolerance by regulating the metabolism of extracellular ATP, we investigated in this study whether CD39 played a role in the enhanced suppressive function of xenoantigen expanded Treg.
Materials and Methods: Baboon Treg were ex vivo expanded with irradiated porcine peripheral blood mononuclear cells (PBMC) for four weeks. Freshly isolated and expanded Treg were assessed by phenotyping and xenogeneic mixed lymphocyte reaction (MLR) plus and minus CD39 activity inhibitor polyoxometalate-1 (POM-1). In vivo suppressive function of ex vivo expanded Treg was evaluated in NOD-SCID IL-$2Rr^{-/-}$ recipient mice of neonatal porcine islet clusters (NICC) transferred with baboon PBMC alone or plus autologous Treg. NICC xenograft survival, the existence of splenic $CD39^+$ baboon Treg and intragraft gene expression of Treg function markers Foxp3 and CD39 were analysed at predetermined time points after baboon cell transfer.
Results: In addition to upregulated levels of activated markers HLA-DR and ICOS, ex vivo expanded baboon Treg exhibited a $Foxp3^+CD39^+$ phenotype (87.5% of $Foxp3^+CD39^+$ cells) and were more potent in xeno MLR, when compared to freshly isolated Treg (6.5% of $Foxp3^+CD39^+$ cells). The suppressive capacity of expanded Treg in the xenogeneic response was substantially impaired by including POM-1 into the MLR. While baboon PBMC alone reconstituted recipient mice rejected their xenografts completely within 35 days after baboon cell transfer, NICC xenografts remained intact with insulin secretion function in recipients over 100 days after cotransfer with baboon PBMC and expanded Treg. Furthermore, a significant proportion of splenic baboon $CD39^+$ Treg and upregulated levels of intragraft gene expression of baboon Treg function markers Foxp3 and CD39 were detected in the cotransferred recipients.
Discussion: Ex vivo expanded baboon Treg with porcine xenoantigen stimulation acquire effector Treg phenotype with high levels of Foxp3 and CD39 expression, which leads to their enhanced capacity to inhibit the xenogeneic response in vitro. The suppressive capacity of $Foxp3^+CD39^+$ baboon Treg in vitro could be inhibited by CD39 activity inhibitor POM-1. Adoptive transfer of ex vivo expanded baboon Treg protected against porcine islet xenograft rejection in a primatized mouse model and the prolonged xenograft survival was associated with the existence of $CD39^+$ baboon Treg in baboon PBMC and expanded Treg cotransferred recipients.
Conclusion: Ex vivo expanded baboon Treg are capable of suppressing the xenogeneic responses both in vitro and in vivo via at least in part, CD39 involved mechanism(s).

Long-term islet xenograft survival requires effective early control of xenogeneic IL-17 response but late control of xenogeneic IFN-γ response

Hee Kap Kang[1], Shusen Wang[2], Xiaomin Zhang[3], Amar Singh[5], Lei Zhang[1], Wilma Suarez-Pinzon[5], Stephen D.Miller[4], Bernhard J.Hering[5], Xunrong Luo[1,3,4].
[1]Division of Nephrology and Hypertension, Northwestern University Feinberg School of Medicine, Chicago, IL, United States; [2]Tianjin Union Medical Center, Nancy University Affiliated Hospital, Tianjin, People's Republic of China; [3]Comprehensive Transplant Center, Northwestern University Feinberg School of Medicine, Chicago, IL, United States; [4]Department of Microbiology and Immunology, Northwestern University Feinberg School of Medicine, Chicago, IL, United States; [5]Schulze Diabetes Institute, University of Minnesota, Minneapolis, MN, United States.

Introduction: Tolerance induction for xenogeneic islet transplant remains a challenge. We have previously shown that peri-transplant infusion of donor cells treated with 1-ethyl-3-(3'-dimethylaminopropyl)-carbodiimide (ECDI) is an effective treatment for inducing long-term donor-specific allograft protection. The current study tested the efficacy of this therapy in islet xenogneic transplantation and examined mechanisms of protection against early rejection and causes of late rejection.
Method: ECDI-treated porcine splenocytes (SP) were infused to B6 mice at day -7, +1. Anti-CD20 (250 ug) was given on day -10, +1. Rapamycin (1mg/kg daily) was given from day -1 to +9. 3,000 IEQ of porcine islets were transplanted in B6 mice on day 0.
Results: In this model, we found that donor-stimulated IL-17 production played a prominent role in the early rejection of porcine islet xenograft. The anti-donor IL-17 response was induced by both direct and indirect donor stimulation, and was seen in both CD4 and CD8 compartments. Recipient treatment with donor porcine ECDI-SP significantly reduced the anti-donor IL-17 and anti-donor DTH response, however by itself did not provide significant protection to the transplanted porcine islets (MST = 12 days). Interestingly, rejecting porcine islet xenografts were heavily infiltrated with recipient B220+ B cells, and depletion of B cells with anti-CD20 mAb at the time of donor ECDI-SP infusion further extended islet xenograft survival (MST = 45 days). When we further added a short course of peri-transplant rapamycin (rapa, 1mg/kg from day -8 to day +10) to the dual therapy, the resulting triple therapy (pig ECDI-SP + anti-CD20 + rapa) led to further porcine islet xenograft protection and long-term (> 100 days) graft survival in ~65% recipients. The protection provided by the triple therapy correlated with sustained inhibition of anti-donor IL-17 response. However, recipients with islet xenograft survival >100 days experienced late rejection between 100 – 200 days post transplant. The late rejection coincided with the emergence of robust anti-donor IFN-g response and extensive B cell infiltration in the graft, although a complete absence of anti-xenogeneic antibodies.
Conclusions: Early rejection of discordant islet xenografts is predominantly driven by anti-donor IL-17 response, whereas late rejection in triple therapy treated recipients is driven predominantly by anti-donor IFN-g response and possibly graft-infiltrating B cells exerting a direct graft effect beyond that of their capacity in xenogeneic antibody production.

Human regulatory macrophages are more potent in suppression of the xeno- than the allo-response

Fei Guo[1], Dandan Huang[1], Wayne J. Hawthorne[1], Min Hu[1], Yuangfei Zhao[1], Joanne Hawkes[1], Heather Burns[1], Benjamin Heng[2], Gilles Guillemin[2], Chia K.Lim[2], Shounan Yi[1], Philip O'Connell[1].
[1]Centre for Transplant and Renal Research, The Westmead Institute for Medical Research, Westmead, Australia; [2]The Australian School of Advanced Medicine, Macquarie University, Sydney, Australia.

Introduction: Regulatory macrophages (Mreg) have been shown to suppress polyclonal T cell proliferation in vitro and prolong allograft survival in a mouse model, and are being currently under evaluation in a clinical trial for living donor renal transplantation (The One Study). However whether they are capable of suppressing the xenogeneic response remain to be investigated. In this study the suppressive capacity of human Mreg in the xenogeneic response was evaluated in a parallel comparison with their suppressive potency in the allogeneic response in vitro.
Materials and Methods: CD14+ monocytes selected from human peripheral blood mononuclear cells (PBMC) were cultured with macrophage colony-stimulating factor (M-CSF) for 7 day with IFN-γ added at day 6 for Mreg induction. Mreg suppressive function was assessed by mixed-lymphocyte reaction (MLR) using irradiated pig and human PBMC as xenogeneic and allogeneic stimulator cells respectively, human PBMC as responder cells and autologous Mreg as suppressor cells. mRNA expression of IDO, IL-10, IFN-γ, iNOS and TGF-β by Mreg after MLR was measured by real-time PCR. Supernatants collected from MLR cultures were used for IDO activity assay by HPLC.
Results: Both proliferating allo and xeno reactive human responder cells were inhibited significantly by Mreg with stronger suppressive potency in the xenogeneic response even at a 1:32 ratio of Mreg: responder cells. While they expressed similar levels of IL-10 and TGF-b, and extremely low level of IFN-γ and iNOS gene expression, Mreg harvested from xeno but not allo MLR cultures demonstrated remarkably high levels of IDO mRNA detected by real-time PCR. Consistently, a stronger IDO activity measured by kynurenine/tryptophan ratio was revealed in the supernatants collected from xeno MLR cultures when compared to that from allo MLR cultures.
Discussion: Human Mreg showed a more potent suppression in the xeno-response compared to that they did in the allo-response. This stronger suppressive characteristic in the xeno-response may be attributedat least in part, to the higher levels of their IDO expression and activity, one of reported main mechanisms used by Mreg to regulate immune responses.
Conclusion: Human Mreg are more suppressive in vitro with IDO-involved mechanisms in the xeno- than in the allo-response, suggesting their potential in immunomodulation of the xenogeneic response.

SCR-4 is required for CD55-induced suppression on macrophage-mediated cytotoxicity

Akira Maeda[1], Thuy-vy Choi[2], Pei-Chi Lo[1], Rieko Sakai[1], Mayumi Asada[1], Kazuaki Yamanaka[1], Kengo Nakahata[1], Rei Matsuura[1], Hiroshi Eguchi[1], Hiroomi Okuyama[1], Shuji Miyagawa[1].
[1]Department of Surgery, Osaka University Graduate School of Medicine, Suita, Japan; [2]School of Biological Sciences, University of Calfornia, Irvine, CA, United States.

Human CD55 is well-known to bind and inactivate complement C3b. Thus, transgenic expression of human CD55 on porcine cells may be a very attractive strategy to reduce xenogeneic complementary rejection. Transgenic expression of human complement regulatory proteins has been found to reduce the frequency of hyper acute rejection (HAR) in xenotransplantation. After a strategy to handle HAR was developed, the delayed-type rejection, which is mediated by monocytes, macrophages, and NK cells, became a critical problem. We previously reported that human CD55 suppresses not only complement-mediated rejection but also macrophage-mediated xenogeneic cytotoxicity. In the present study, we investigated the mechanisms of human CD55-induced suppression in macrophage-mediated xenogeneic cytotoxicity. The amelioration of macrophage-mediated cytotoxicity by various deletion mutants was studied using WST-8 assay. Naïve swine endothelial cells (SEC) and SEC/hCD55 were co-cultured with human monocyte-like cells, THP-1, which were differentiated to macrophages with 200nM PMA. 24hours after co-culture, cytotoxicity by THP-1 cells was measured by WST-8 assay. While differentiated THP-1 cells induced significant cytotoxicity against SEC (%cytotoxicity: 29.3±17.7%), human CD55 significantly reduced the THP-1 mediated cytotoxicity (%cytotoxicity: 15.2±27.8%, $p<0.05$ vs SEC). Furthermore, delta-short consensus repeats (SCR) 4-CD55 did not show any suppression of macrophage-mediated cytotoxicity (%cytotoxicity: 26.1±18.2%, $p<0.05$ vs SEC/hCD55), indicating that SCR4 is responsible for the inhibitory function of human DAF in macrophage-mediated cytotoxicity. Next, we studied the function of hCD55 in phagocytosis by macrophages. CFSE-labeled SEC or SEC transfectants were co-cultured with LPS-stimulated monocytes for 24hours. Subsequently, cells were harvested and stained with APC conjugated anti-CD14. The percentage of phagocytosis was calculated as [(number of CFSE+CD14+ cells)/ (number of CD14+ cells)] x100. While the phagocytosis of SEC/hCD55 and SEC/hCD55 delta-SCR1 was significantly suppressed compared to that of naïve SEC, hCD55 delta-SCR4 failed to suppress the phagocytosis by macrophages. These findings indicate that CD55 might suppress macrophage-mediated rejection via binding of SCR4 to an inhibitory receptor on macrophages.

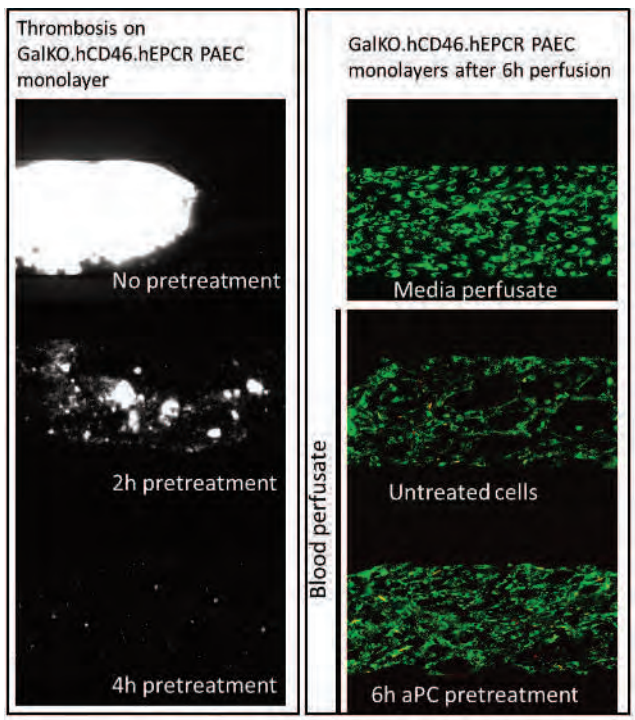
Pretreatment of transgenic porcine endothelium expressing human endothelial protein C receptor with activated protein C attenuates endothelial damage and thrombosis during human blood perfusion

Christopher Laird[1], Beth M.French[1], Donald Harris[1], Xiangfei Chang[1], David Ayares[2], Richard NPierson[1], Agnes M.Azimzadeh[1].
[1]Surgery, University of Maryland School of Medicine, Baltimore, United States; [2]Revivicor, Inc., Blacksburg, United States.

Introduction: In spite of extensive genetic modification, porcine lung xenografts still exhibit acute dysfunction following transplant into non-human primates. This dysfunction is associated with endothelial damage, inflammation, platelet activation, and thrombosis. Activated Protein C (aPC), acting primarily through the human endothelial protein C receptor (hEPCR), mediates anti-thrombotic and anti-inflammatory cytoprotective effects in humans. We hypothesized that treatment of hEPCR expressing porcine endothelial cells (ECs) with recombinant aPC would attenuate endothelial cell injury in a xenotransplant model. **Materials and Methods:** Confluent GalKO.hCD46 and GalKO.hCD46.hEPCR porcine aortic EC (PAEC) monolayers in microfluidic channels were pretreated with 0.02μg/mL recombinant human aPC (raPC) several hours prior to perfusion with heparinized human blood. Blocking anti-EPCR antibody and nonblocking IgG1 antibodies were used to confirm that effects were caused by addition of raPC. Thrombosis, viability, and endothelial surface area coverage were calculated by fluorescent analysis using image processing software.



Results and Discussion: raPC pretreatment of ECs reduced platelet adhesion (45.6±16.2 % surface area (SA) coverage in untreated hEPCR+ cells) to 27.3±10.2% after 2 h exposure to aPC ($p=.085$ vs. untreated), 6.6±1.6% after 4h ($p=.003$), and 5.3±1.8% after 6h ($p=0.0025$). Relative to untreated monolayers (63.45±30 au), platelet aggregation also decreased with increasing duration of aPC Rx from 2h (34.6±16.1 au, $p=0.13$) to 6h (26±8.2 au, $p=0.05$). When perfused with human blood, untreated GalKO.hCD46.hEPCR PAEC monolayers showed cellular damage (7.4±1.8 propidium iodide (PI) positive

cells/hpf, vs. none with cell culture medium) and reduced surface area coverage (75±3.5%, vs. 100% with cell culture medium). Six hour pretreatment with raPC was associated with significantly fewer PI+ cells (3±1.23 cells/hpf, p=0.0003 vs. untreated EC), and significantly higher EC surface coverage (87.3±2.9 %, p<0.0001). Prevention of increased permeability of hEPCR+ PAEC after human thrombin exposure, measured by electrical impedance (xCELLigence), correlated directly with increasing duration of EC pretreatment with aPC. Effects of aPC pretreatment were only seen with pAECs that express hEPCR, and these protective effects disappeared with addition of blocking anti-EPCR antibodies.
Conclusions: aPC pretreatment of hEPCR-expressing PAEC monolayers significantly reduced thrombotic potential and pEC damage after simulated perfusion with human blood. This strategy may be useful to mitigate dysfunction of hEPCR-expressing pig lung xenografts following transplantation by inhibiting clot initiation, thrombus propagation, and endothelial cell injury.

Reducing the inflammatory response by expressing human thrombomodulin in pigs

Hidetaka Hara[1], Hayato Iwase[1], Yuko Miyagawa[1], Whayoung Lee[1], Cassandra Long[1], Carol Phelps[2], David Ayares[2], David K.C.Cooper[1]. [1]Surgery, Thomas E. Starzl Transplantation Institute, University of Pittsburgh, Pittsburgh, PA, United States; [2]Revivicor, Inc., Blacksburg, VA, United States.

Introduction: Regulation of inflammation is an important target in xenotransplantation. The expression of thrombomodulin (TBM), which reduces coagulation, has been shown to be down-regulated by inflammatory cytokines, such as TNF-α. Although pigs transgenic for human (h)TBM have been developed to reduce coagulation dysfunction, the role of the anti-inflammatory effect of hTBM pigs is unknown. The aim of this study was to investigate in vitro (i) whether hTNF-α stimulated cells increase human platelet aggregation, (ii) whether cells from hTBM pigs could regulate the inflammatory reaction through a coagulation-independent assay.
Materials and Methods: Human aortic endothelial cells (hAECs) and AECs from α1,3-galactosyltransferase gene-knockout pigs transgenic for hCD46 (GTKO/CD46) and from GTKO/CD46/hTBM pigs (p) were used for this study. To investigate the inflammatory response in AECs after hTNF-α stimulation, the expression of NFk-B, TBM, E/P-selection, VCAM-1, and MCP-1 on hAECs and pAECs was measured by either flow cytometry or real-time PCR. Using platelet-aggregometry, human whole blood platelet aggregation was evaluated after co-incubation with hTNF-α stimulated AEC.
Results: After hTNF-α stimulation, there were significant reductions (60% hAECs, 90% GTKO/CD46 pAECs, p<0.05) in the expression of TBM on hAECs and GTKO/CD46 pAECs, and significant increases (50%, p<0.05) of NFk-B signal, E/P-selectin and VCAM-1 expression. In contrast, hTBM expression on the GTKO/CD46/hTBM pAECs was not affected by hTNF-α stimulation whereas the expression of pTBM mRNA was significantly reduced (by 90%, p<0.05). After stimulation, there was significant suppression of the expression of E-selection (30% reduction, p<0.05), VCAM-1(70% reduction, p<0.05), and MCP-1 (50% reduction, p<0.05) on GTKO/CD46/hTBM pAECs compared to GTKO/CD46 pAECs. There was a significant increase in platelet aggregation following incubation with hTNF-α stimulated hAECs or pAECs, which was suppressed by hTNF-α or NFk-B inhibitors.
Conclusions: (i)It is important to suppress the inflammatory reaction to prevent the down-regulation of TBM expression in both the recipient and the pig graft because TBM can have an anti-inflammatory effect (possibly independent of its effect on coagulation). (ii) Stable expression of hTBM in hTBM transgenic pigs may locally regulate the inflammatory reaction, in addition to its anticoagulant effect.

Growth hormone receptor knockout on porcine endothelial cells: effect on complement and coagulation

Riccardo Sfriso[1], Nikolai Klymiuk[2], Joerg D.Seebach[3], Eckhard Wolf[2], Robert Rieben[1].
[1]Departement Klinische Forschung, Universität Bern, Bern, Switzerland; [2]Institute of Molecular Animal Breeding and Biotechnology, Ludwig-Maximilian University, Munich, Germany; [3]Division of Immunology and Allergology, University Hospital and Medical Faculty, Geneva, Switzerland.

Background: Growth hormone insensitivity (GHI) is a group of inherited disorders characterized by a reduction or absence of signaling triggered by growth hormone (GH). Laron syndrome - a classical example of GHI - is caused by mutations in the growth hormone receptor (GHR) gene and it is characterized by dwarfism. GHR knockout (GHRKO) pigs have already been produced and due to the smaller size of their organs they might be suitable candidates for xenotransplantation. Furthermore, Laron syndrome affected people are protected from vascular diseases such as atherosclerosis and type II diabetes. For that reason this study aims to screen whether the GHRKO phenotype may help to prevent vascular disorders in the context of delayed xenograft rejection.
Methods: An immortalized porcine aortic endothelial cell line lacking αGal expression (PED GalTKO) was further modified by knocking out the GHR gene. The resulting cell line, PED GalTKO/GHRKO, was used in vitro to assess the effect of GHR deletion in a xenotransplantation setting. After transformation, cells were characterized by immunofluorescence (IF) for expression of endothelial cell markers such as CD31, VE-cadherin and von Willebrand Factor (vWF). Cell ELISA was carried out to screen the effect of the GHR deletion on deposition of complement (C3b/c and C4b/c) and immunoglobulins after incubation with pooled normal human serum. In order to evaluate whether GHRKO affects coagulation, a whole blood clotting assay was performed using endothelial cell-coated microcarriers.
Results: PED GalTKO/GHRKO present a clear endothelial phenotype, undistinguishable from the original PED GalTKO. A strong expression of CD31, vWF, VE-cadherin, and heparan sulfate proteoglycans was observed by immunofluorescence. Cell ELISA after incubation with pooled normal human serum showed significantly lower IgM, IgG and C3b/c deposition compared to wild type porcine endothelial cells. Binding of immunoglobulins and complement were similar to the PED GalTKO cell line. Furthermore, PED GalTKO/GHRKO cells grown on microbeads significantly delayed the clotting time of freshly drawn, whole, non anticoagulated human blood as compared to wild type porcine endothelial cells (53 ± 21 min vs. 19.8 ± 7 min). These data are similar to the what was observed for the original PED GalTKO cell line (50 ± 31.8 min).
Conclusions: Our data show that GHR deficiency on porcine endothelial cells with GalTKO background preserved the endothelial phenotype. No differences in immunoglobulin binding, complement deposition or anticoagulant properties were observed as compared with the original PED GalTKO cell line. The used in vitro tests did not reveal a significant benefit of the growth hormone receptor knockout with respect to the anticoagulant properties of the endothelial cells and in vivo experiments may be needed to provide a better understanding of the long term effects of this phenotype on coagulation.

Surface modification of porcine aortic endothelial cells with Corline Heparin Conjugate (CHC) protects against xenogeneic thrombosis and inflammation

Anjan Bongoni[1], Evelyn Salvaris[1], Bo Lu[1], Bo Nilsson[2], Sofia Nordling[2], Peetra U.Magnusson[2], Peter J.Cowan[1,3].
[1]Immunology Research Centre, St. Vincent's Hospital Melbourne, Melbourne, Australia; [2]Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; [3]Department of Medicine, University of Melbourne, Melbourne, Australia.

Background: Genetic modification of the donor pig to remove xenoantigens and to correct molecular incompatibilities has demonstrably improved the survival of porcine xenografts in preclinical models. However, it does not fully address the problem of transplant-associated endothelial activation and shedding of the glycocalyx, a layer of heparan sulfate proteoglycans on the luminal surface of the endothelium. This process contributes to the development of a pro-inflammatory and pro-coagulant environment at the vascular surface of xenograft endothelium. Corline Heparin Conjugate (CHC), a macromolecular branched conjugate comprising multiple heparin molecules, can be used to coat living cells with a glycocalyx-like layer without compromising their biological function. In this project, we investigated in an in vitro model whether CHC coating of pig endothelial cells protects them from activation and injury mediated by human blood.
Aim: To demonstrate the feasibility of using CHC to protect vascular endothelial cells in an in vitro pig-to-human xenotransplantation setting.
Methods: Binding of CHC to wild-type porcine aortic endothelial cells (PAEC) was measured using FITC-labeled CHC. To test the effect of CHC on complement activation, C3b/c deposition on PAEC was measured after incubation with normal human serum (NHS) in the presence of CHC. To test the effect of CHC on hemocompatibility, PAEC were grown on microcarrier beads, coated with CHC under starvation conditions, and incubated with freshly drawn non-anticoagulated whole human blood in a model that closely mimics the in vivo small vessel endothelial surface-to-blood volume ratio. Uncoated PAEC were used as controls.
Results: Confocal microscopy demonstrated a uniform coating of CHC on the surface of PAEC. Treatment of PAEC with NHS (1:10) in the presence of CHC (50-200µg/ml) resulted in a significant reduction of C3b/c deposition, in a dose-dependent manner ($p=0.05$ to 0.001). In the whole blood coagulation assay, surface coating of CHC significantly improved the human blood compatibility of PAEC, as shown by increased clotting time (CHC 50.8±8.1 min vs. untreated 29.9±6.4 min, $p<0.001$) and reduced CD41-positive platelet deposition (CHC 58.5±4.0% vs. untreated 100%, $p<0.01$). EDTA-plasma was collected from the coagulation assays at 20 min (i.e. before the onset of clotting) and analyzed by ELISA. Soluble markers of complement activation (sC5b-9) ($p<0.0001$), coagulation activation (thrombin-antithrombin complex and D-dimer) (both $p<0.0001$) and inhibition of fibrinolysis (tPA/PAI-1) ($p<0.0001$) were all significantly lower with CHC-PAEC than with untreated PAEC.
Conclusion: Our results indicate that surface immobilization of the multi-arm heparin conjugate CHC protects PAEC from the pro-coagulant and pro-inflammatory environment induced by xenotransplantation. This strategy provides a possible therapeutic option to attenuate thromboinflammation in xenotransplantation.

429.10

Inhibition of xenogeneic platelet activation and aggregation by surface conjugation of apyrase to porcine aortic endothelial cells

Anjan Bongoni[1], Evelyn Salvaris[1], Yuji Teramura[2], Sana Asif[3], Bo Nilsson[3], Peter J.Cowan[1,4].
[1]Immunology Research Centre, St. Vincent's Hospital Melbourne, Melbourne, Australia; [2]Department of Bioengineering, University of Tokyo, Tokyo, Japan; [3]Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; [4]Department of Medicine, University of Melbourne, Melbourne, Australia.

Background: Activation and aggregation of recipient platelets is a key feature of the dysregulated coagulation that is frequently observed in pig-to-primate xenotransplantation. Platelet activation is associated with complement and contact system activation, which in turn leads to inflammation. The platelet agonist ADP is an obvious target for platelet inhibition. Apyrase is a soluble enzyme that, like CD39, hydrolyzes extracellular ATP and ADP. In this study, we hypothesized that coating porcine aortic endothelial cells (PAEC) with apyrase will inhibit xenogeneic platelet activation.
Aim: To investigate the impact of surface-conjugated apyrase on PAEC in an in vitro model of xenograft-induced thrombosis and inflammation.
Methods: PAEC from wild-type pigs were cultured to confluence on Biosilon microcarrier beads. Maleimide-PEG-lipid was used to immobilize thiolated apyrase (25µg/ml) on the PAEC surface. Apyrase activity was measured using an ATPDase assay. Apyrase-PAEC on beads were tested in an in vitro coagulation assay by incubation with non-anticoagulated whole human blood in a ratio that mimics that in small vessels in vivo. Uncoated and maleimide-PEG-lipid coated PAEC were used as controls. EDTA-plasma samples collected from the assay were used to measure complement, coagulation and fibrinolytic cascade activation markers by ELISA. Platelet-white blood cell aggregation was analyzed by FACS.
Results: Immobilization of apyrase on PAEC was confirmed by confocal microscopy. Beads coated with apyrase-PAEC degraded exogenous ATP in a dose-dependent manner (ATPDase activity: 9.9±1.1 nmol/20min at 10µg/ml apyrase; 17.7±0.6 at 25µg/ml). Immobilized apyrase retained approximately 81% of the activity of the native form. Apyrase-PAEC significantly prolonged clotting of human blood (65.2±14.4 min vs. untreated PAEC 29.9±6.4 min, $p<0.001$, n=5). Deposition of CD41-positive platelets was significantly lower on apyrase-PAEC (27.0±3.6% vs. untreated 100%, $p<0.0001$). Aggregation of CD42a-positive platelets with CD14-positive monocytes was significantly reduced by apyrase-PAEC (36.4±2.7% vs. untreated 58.1±5.9%, $p<0.05$). In addition, the concentration of markers of complement activation (sC5b-9) ($p=0.015$), coagulation activation (thrombin-antithrombin complex and D-dimer) (both $p<0.0001$) and inhibition of fibrinolysis (tPA/PAI-1) ($p<0.0001$) was lower with apyrase-PAEC than untreated PAEC.
Conclusion: Apyrase immobilization on PAEC inhibits xenogeneic platelet activation and aggregation and suppresses coagulation in a whole blood assay. Therefore, this approach, like transgenic expression of CD39, is a potential therapy to inhibit xenotransplantation-associated thrombotic inflammation. Furthermore, this assay can be used to evaluate the potential of novel therapeutic substances not only in xenotransplantation but also in allotransplantation and ischemia/reperfusion injury.

429.11

Foxp3+ regulatory T cells are essential for the induction and maintenance of tolerance to neonatal porcine islet cell cluster xenografts induced by co-stimulatory blockade

Yi Wen Qian[1], Wayne Hawthorne[1], Jingjing Wu[1], David Liuwantara[1], Heather Burns[1], Yi Vee Chew[1], Stephen Alexander[2], Philip O'Connell[1], Min Hu[1].
[1]Centre for Transplant and Renal Research (CTRR), Westmead Millennium Institute, Sydney, Australia; [2]Centre for Kidney Research, Children's Hospital at Westmead, Sydney, Australia.

Introduction: CTLA-4 Fc and MR-1 (anti-CD154) antibodies inhibit B7-CD28 pathway and CD40-CD154 pathway respectively, and are able to induce tolerance towards porcine islet cell cluster (NICC) xenografts in mice. We previously reported that depletion of Foxp3+ Tregs break tolerance in a mouse kidney allotransplantation tolerant model, however the role of Foxp3+ regulatory T cells (Tregs) in NICC xenografts tolerance is not clear.
Aim: To investigate the role of Tregs in a NICC xenotransplantation mouse model, and whether Foxp3+ Treg are essential for the induction and maintenance of tolerance to NICC xenografts.
Methods: C57BL/6-DEREG mice were transplanted with 2000 to 4000 NICC under the renal capsule. DEREG mice have diphtheria toxin receptor-eGFP attached to their Foxp3 gene, therefore Foxp3+ Tregs can be selectively depleted with diphtheria toxin (DT). Recipient mice were treated IP with CTLA-4 Fc (500µg) at day 0, and MR-1 (500µg) at day 0, 2, 4, and 6. Tregs were depleted by DT (12ng/gram/mouse) during the induction phase (3 days pre-transplantation), or maintenance phase (80 days post-transplantation) for 21 days. Treg population in the lymphoid tissues were quantified with FACS (CD3+CD4+CD25+FoxP3+) at day 8-12, 20, 60-80 and 100. Rejection was determined by histology and insulin/glucagon staining, and function was determined by porcine c-peptide concentration. The expression of FoxP3, IFNγ, TGFβ, CTLA-4, granzyme A, Blimp-1, IL-10 and CD39 was assessed for graft and lymphoid tissues on day 8 and day 100 using RT-PCR.
Results: Without DT, tolerance to NICC xenografts was achieved in DEREG mice with histology at 100 days, showing xenografts with positive insulin staining and elevated porcine C-peptide (mean=480 pmol/L, n=6). Large numbers of Foxp3+ Treg were observed in NICC xenografts in tolerant mice on day 8, fewer on day 20, then at a greater number on day 100. DT treated mice during both the induction and maintenance phases have massive cell infiltration, no insulin or glucagon staining were present in their NICC grafts, and no porcine C-peptide in their serum. Treg proportion of CD4+ T cells were higher in the draining lymph nodes (DLN) in the tolerant mice when compared to their peripheral lymph nodes on day 60-80. FoxP3 was expressed significantly higher in the DLN of tolerant mice on both day 8 ($P=0.0010$) and 100 ($P=0.0128$) when compared to the control group. Tolerant grafts also expressed higher CTLA-4 ($P=0.0022$) on day 8, and IL-10 ($P=0.0042$) and CD39 ($P=0.0047$) on day 100. These data suggest Foxp3 Tregs are expanded within the xenografts and DLN, and xenografts tolerance induced by co-stimulation is dependent upon Foxp3+ Tregs.
Conclusion: Foxp3+ Tregs are essential for both the induction and maintenance of tolerance to islet xenografts after co-stimulation blockade by CTLA-4 Fc and anti-CD154 antibodies.

429.12

Comparison of post transplant inflammatory response from 6-gene vs. 3-gene donor pigs in heterotopic cardiac xenotransplantation

Avneesh Singh[1], Joshua Chan[1], Philip Corcoran[1], Marvin Thomas[2], Billeta Lewis[2], David Ayares[3], Keith Horvath[1], Muhammad Mohiuddin[1].
[1]Cardiothoracic Surgery Research Program, NHLBI /NIH, Bethesda, MD, United States; [2]Division of Veterinary Resources, NIH, Bethesda, MD, United States; [3]Revivicor, Inc., Blacksburg, VA, United States.

Introduction: We have recently reported xenograft survival of more than 2.5 years in a pig to baboon heterotopic cardiac xenograft model. Some of the animals exhibited a local and systemic inflammatory response to the xenograft, which aided in graft rejection. We report the benefits of using donor organs expressing 5 human transgenes along with one gene knock out and the ability of multi-transgenics to improve graft survival and suppress the inflammatory response.
Methods: Six young (8-12Kg) specific pathogen free baboons received heterotopic cardiac xenografts from either Group 1 (GTKO.CD46.EPCR.DAF.TFPI.CD47) (n=2) or (GTKO.CD46.EPCR.DAF.CD39.TBM) (n=1) and Group 2 (GTKO.CD46.TBM) (n=3) pigs. Recipient baboons were treated with a modified immunosuppression protocol developed at the NHLBI. Graft survival was monitored with continuous telemetry, periodic echocardiography and manual palpation. Cytokines (e.g. IFNg, IL-6, TNFa, IL-4, IL-10 and IL-13) in baboon recipient serum was measured weekly or biweekly during three months after cardiac xenotransplantation by Affymetrix Luminex assay. Statistical t test and F test were used for determining the differences between the groups.
Results: Heterotopic cardiac xenografts from both 6-gene and 3-gene donor pigs on average survived more than 6 months (ranging from 46 to 945 days) in baboons. One of the grafts in Group 1 (6-gene pigs) ceased contracting on day 46 and was explanted. The remaining grafts are still surviving for 142 and 207 days. No signs of any inflammation or adhesions were observed during laparotomy for graft evaluation and biopsy procedures. However, while the Group 2 xenografts (3-gene pigs) survived longer (ranging from 156 to 945 days), some adhesions and inflammation were observed after transplantation. Florescent intensity (FI) measured by Luminex for inflammatory cytokines (e.g. IFNg (5.2±0.2 vs. 6.6±0.3; $p<0.01$), TNFa (14.4±0.3 vs. 15.4±0.3; $p<0.05$)) and IL-6 (22.8±8.8 vs. 55.9±25.5; $p=0.09$) were significantly inhibited in recipient serum receiving xenografts from 6-gene vs. 3-gene donor pigs. Anti-inflammatory (IL-4, IL-10 and IL-13) cytokines were also slightly inhibited but the difference was not significant.
Conclusion: The expression of multiple human genes prevented xenograft rejection for an extended period of time and also helped in avoiding inflammatory reactions. While further evaluation is required, the presence of additional human transgenes on the xenografts might have reduced immunogenicity that may have contributed to avoiding inflammation.

429.13

Human CD200 suppresses the M0 macrophage-mediated cytotoxicity in xenotransplantation

Akira Maeda[1], Pei-Chi Lo[1], Thuy-vy Choi[2], Rieko Sakai[1], Mayumi Asada[1], Kazuaki Yamanaka[1], Kengo Nakahata[1], Rei Matsuura[1], Hiroshi Eguchi[1], Hiroomi Okuyama[1], Shuji Miyagawa[1].

A number of approaches, such as generation of alpha-1,3-Galactosyltransferase knocked-out pigs and CD55 transgenic pigs, have been investigated to inhibit pig to human xenogeneic rejection. Our mission in the future is to develop the strategies to hurdle not only hyper acute rejection (HAR) but also delayed type rejection (DXR). Although macrophages have been well known to play a critical role in DXR, monocyte/macrophage-mediated xenogeneic rejection has not been well studied. In this study, we evaluated the effect of CD200 in xenogeneic rejection by macrophages. CD200 is a member of the Ig supergene family (IgSF) and relatively ubiquitously expressed. The suppressive function of CD200 was suggested to depend upon engagement with a receptor (CD200R). CD200 is also an IgSF protein, with an inhibitory intracellular NPXY signaling motif. CD200R is mainly detected on cells of the myeloid lineage. Therefore, we checked the expression of CD200R on monocyte-like cells, THP-1, and peripheral blood monocyte-derived macrophages, which were generated by M-CSF (M0 macrophage), by flow cytometry. While the expression level of CD200R on THP-1 was faint, M0 macrophages expressed a significant amount of CD200R. The effect of human CD200 in macrophage-mediated cytotoxicity was studied using WST-8 assay. Naïve swine endothelial cells (SEC) and SEC/CD200 were co-cultured with THP-1 or M0 macrophages. 24hours after co-culture, cytotoxicity was measured by WST-8 assay. While CD200 failed to suppress a significant amount of cytotoxicity against SEC by THP-1 (%cytotoxicity: SEC 46.3%±7.1%, SEC/CD200 43.8±7.1%, n=3), M0 macrophage mediated cytotoxicity was significantly suppressed by human CD200 (%cytotoxicity: SEC 24.9±11.2%, SEC/CD200 18.4±13.9%, $p<0.05$, n=9). Furthermore, to test the phagocytosis of SEC by M0 macrophages, CFSE-labeled SEC and SEC/CD200 were co-cultured with M0 macrophages for 24hours. Subsequently, cells were stained with APC-conjugated anti-CD14 and analysis by flow cytometry revealed that human CD200 suppresses M0 macrophage-mediated cytotoxicity (%phagocytosis; SEC 70.7%, SEC/CD200 60.8%, n=1). Our findings indicate that human CD200 suppresses the xenogeneic rejection by CD200R+ macrophages and the generation of hCD200 transgenic pigs are very attractive for use in xenografts to prevent delayed type rejection.

Background and Aim: Induction of tolerance is an ultimate goal in organ transplantation. We conducted a clinical study aiming to induce operational tolerance in living donor liver transplantation (LDLT) patients by applying the cell-therapy using donor antigen-pulsed regulatory T cells (Tregs). Herein, we report long-term follow-up results of the ongoing clinical trial.
Patients and Methods: Ten adult liver transplant recipients (HBV; 1, HCV; 1, Alcoholic: 2, NASH; 3, PBC; 2, PSC; 1) received a left-lobe liver allograft from living donors. After LDLT, immunosuppression (IS) was initiated with steroid, MMF and calcineurin inhibitor (CNI). Cyclophosphamide was given on day 4. Donor antigen-pulsed Tregs were generated *ex-vivo* by co-culturing recipient-PBMCs (+splenocytes) and irradiated donor-PBMCs under αCD80+αCD86 mAbs for 2-weeks, and were infused on day 13. Steroid and MMF was stopped within a month. CNI was space-weaned every 3 months starting from 6 months post-LT, and was finally stopped.
Results: After ex vivo cell culture, the $CD4^+CD25^+Foxp3^+$ T cells increased from 6.7±3.8% to 28.1±17.7%. The mean infused $CD4^+CD25^+Foxp3^+$ T cell number was $2.3x10^8$ cells/body. No adverse event was noted related to the cell infusion. The mean follow-up time after LDLT was 53 (42-61) months. IS was successfully withdrawn in 7 (70%) LT recipients, whereas a mild ACR occurred in the other 3, who are maintained with a minimally required IS. All IS-free patients are maintaining a good liver graft function without an episode of rejection for 34.6 (24-41) months. Four cases are IS-free for over 3 years. Among seven IS-free patients, 3 developed DSA, while latest graft histology did not show any sign of rejection, fibrosis progression or C4d deposition. Immunological assays revealed a hyporesponsiveness state against the donor-antigens.
Conclusion: The cell therapy using the *ex-vivo* generated donor antigen-pulsed Tregs allows early IS withdrawal, and promotes operational tolerance in LDLT.

Donor-specific anti-HLA antibody mediated rejection in liver transplant recipients

Tomasz Dziodzio[1], Nils Lachmann[2], Sinem Ünlü[1,2], Sascha Weiss[1], Sascha Chopra[1], Safak Gül[1], Undine Gerlach[1], Christian Denecke[1], Matthias Biebl[1], Constanze Schönemann[2], Johann Pratschke[1], Robert Öllinger[1].
[1]Department of General, Visceral and Transplantation Surgery, Charité-Universitätsmedizin Berlin, Berlin, Germany; [2]Center of Tumor Medicine, HLA-Laboratory Campus Virchow-Klinikum, Charité-Universitätsmedizin Berlin, Berlin, Germany.

Introduction: The clinical role of donor-specific anti-HLA antibodies (DSAs) in liver transplantation (LT) is not clearly established. We investigated the impact of antibody-mediated rejection (AMR) on the clinical course, morbidity and mortality of LT recipients.
Materials and Methods: Between 2008 and 2015 649 LTs were performed at our institute. DSAs were determined by the Luminex® assay for all patients. Patients with more than two positive DSA results were included in the study. The mean fluorescence intensity (MFI) was used to quantify DSAs and was correlated with the patient courses and the success of AMR therapy.
Results: Thirty-three patients with class-I and/or class-II DSAs were identified. Of those, 19 patients (57.6%) showed clinical signs of AMR. In 17 patients (51.5%) an additional cellular rejection was observed. Sixteen patients (48.5%) were treated with steroids, 11 (33.3%) with plasmapheresis and immunoglobulins and 6 patients (18.2%) received anti-thymocyte globuline. Six patients (18.2%) showed a decay of rejection (MFI value reduction of >84%) and improvement of clinical parameters. Six patients needed a re-transplantation. Overall mortality was 21.2% with sepsis being the leading cause of death (5 patients). Fourteen patients (12.1%) with persistent elevated MFI values showed no clinical signs of AMR .
Conclusion: AMR after LT is relatively rare, however DSAs can cause fulminant rejections with fatal courses. Current therapy concepts were only successful in a quarter of patients. Interestingly, sepsis was the leading cause of death. Further, nearly half of the patients with positive DSAs showed no signs of AMR. Thus, future investigations need to focus on the balancing of AMR treatment and its side-effects, as well as the causes of heterogeneous susceptibility of LT recipients to AMR.

Seven year follow-up of a phase 2 clinical trial to induce tolerance in living donor renal transplant recipients

Joseph R. Leventhal[1], John Galvin[1], Dianne Stare[1], Lorenzo Gallon[1], Joshua Miller [1], James M. Mathew[1], Michael M. Abecassis[1], Suzanne T. Ildstad[2].
[1]Northwestern University, Chicago, IL, United States; [2]Institute for Cellular Therapeutics, University of Louisville, Louisville, KY, United States.

Introduction: 31 subjects have been transplanted in a phase 2 protocol (IDE 13947) to induce tolerance in recipients of living donor renal allografts (KTx).
Materials, Methods, Results and Discussion: The protocol is based upon tolerogenic CD8+/TCR-facilitating cells (FCRx) and 200 cGy TBI-based nonmyeloablative conditioning, with fludarabine (30mg/kg/dose, days -5,-4,-3), cyclophosphamide (50mg/kg/dose, day-3 and+3), 200 cGy TBI (day-1) followed by KTx (day0). A G-CSF mobilized peripheral blood mononuclear cell product was apheresed from the donor >2 weeks pre-KTx, processed to remove graft-versus-host disease (GVHD)-producing cells yet retain CD34 + cells and FC, and cryopreserved until administration day+1 post-KTx. Subjects ranged in age from 18-65 years and were from 6/6 HLA matched related to 0/6 matched unrelated. 12 subjects had unrelated and 19 had related donors. 30 of 31 subjects exhibited donor chimerism at one month post KTx. The one subject without chimerism (NW9) was highly sensitized (PRA>50%). MMF and tacrolimus based immunosuppression (IS) was weaned and discontinued at 1 year if chimerism, normal renal function and normal KTx biopsy were noted. There was a learning curve in the early phases of this study. Subjects NW1 and NW4 received a suboptimal cell dose and were only transiently chimeric (< 6 months). Another subject (NW11) with a high PRA (33%, maximum historic 64%) developed transient chimerism. Transiently chimeric subjects resumed endogenous hematopoiesis and are on low-dose IS with stable renal fcn. 1 subject (NW27) exhibited grade 1-2 GVHD that was successfully treated with corticosteroids. A second subject (NW33) developed concomitant Grade 2-3 GVHD and CMV disease and is undergoing treatment. There have been 2 KTx losses related to infections post-Tx. 1 and 5yr Pt survival is 100%. High levels of chimerism allowing for full IS withdrawal developed in 19 subjects (time off IS ranging from 3 – 65 months). 16 subjects had "full" (> 98% donor) chimerism, and three subjects mixed chimerism. All stable chimeric subjects retained chimerism after removal of IS and remain rejection-free, as demonstrated by protocol biopsy, while 3 of 5 who were transiently chimeric had subclinical rejection. None of the durably chimeric subjects has developed recurrence of autoimmune disease while two of the transiently chimeric subjects have.
Conclusion: In summary, high levels of chimerism and tolerance with low incidence of GVHD have been achieved in mismatched related/unrelated recipients of combined FCRx and living donor KTx.

450.2

Relationship between mixed chimerism and clinical tolerance after combined kidney and hematopoietic cell transplantation using total lymphoid irradiation and antithymocyte globulin conditioning

Stephan Busque, John D. Scandling, Judith Shizuru, Robert Lowsky, Asha Shori, Kent Jensen, Edgar Engleman, Samuel Strober.
Stanford University School of Medicine, Stanford, CA, United States.

Combined living donor kidney and hematopoietic cell transplants were given to 22 fully HLA matched recipients who received posttransplant conditioning with 10 doses of total lymphoid irradiation (each dose 120 cGy) and 5 doses of rabbit antithymocyte globulin, and an infusion of $1x10^6$ T cells/kg and $4\text{-}17x10^6$ CD34+ cells/kg from G-CSF "mobilized" donor apheresis products. Eighteen of 22 recipients developed mixed chimerism that persisted for least 12 months, and these patients were withdrawn from all maintenance immunosuppressive drug therapy. Mycophenolate mofetil was discontinued after 1 month and cyclosporine was discontinued by 6 to 14 months. Nine of the 18 patients continued with mixed chimerism after drug withdrawal and were without evidence of rejection at the last observation point during followup of up to 7 years off drugs. The remaining 9 patients withdrawn from immunosuppressive drugs had a loss of mixed chimerism during the second year posttransplant. Eight of these 9 had no subsequent evidence of kidney graft rejection, up to 7 years off drugs. One of these 9 lost tolerance and developed a Banff1A rejection episode about 4 years after the withdrawal of cyclosporine. Rejection rapidly resolved with treatment. Thus, after immunosuppressive drug withdrawal, tolerance has been maintained in all (9 of 9) HLA matched patients with persistent donor mixed chimerism and in the majority of recipients (8 of 9) who had a late (after 1 year) loss of donor hematopoietic cells. In further study, 13 HLA haplotype-matched patients were given combined transplants. Mixed chimerism persisted for at least 10 to 21 months in 5 patients given the highest doses (up to $50x10^6$/kg) of T cells and CD34+cells/kg (up to $22x10^6$cells/kg). Mixed chimerism was lost rapidly in the first 2 of these mismatched patients when mycophenolate mofetil and tacrolimus withdrawal was completed at one year posttransplant. In contrast to the fully matched patients, the latter HLA mismatched patients developed rejection episodes shortly after losing chimerism. Rejection rapidly resolved with treatment. In conclusion, the loss of chimerism after immunosuppressive drug withdrawal may be a biomarker of rejection in the HLA mismatched patients and a biomarker of increased risk of losing tolerance after several years in fully matched patients.

450.3

A randomized-controlled trial comparing the efficacy of CYP3A5 genotype-based with bodyweight-based tacrolimus dosing after living donor kidney transplantation

Nauras Shuker[1,2], Rachida Bouamar[2], Ron H. Nvan Schaik [3], Marian C. Clahsen -van Groningen [4], Jeffrey Damman[5], Carla C. Baan[1], Jacqueline van de Wetering[1], Ajda T. Rowshani[1], Willem Weimar[1], Teun van Gelder[1,2], Dennis A. Hesselink[1].
[1]Internal Medicine , Erasmus MC, Rotterdam, Netherlands; [2]Hospital Pharmacy , Erasmus MC, Rotterdam, Netherlands; [3]Clinical Chemistry, Erasmus MC, Rotterdam, Netherlands; [4]Pathology , Erasmus MC, Rotterdam , Netherlands; [5]Pathology , Academic Medical Centre, Amsterdam, Amsterdam , Netherlands.

Background: The expression of the metabolizing enzyme cytochrome P450 (CYP) 3A5 is determined by polymorphisms in the CYP3A5 gene[1]. Renal transplant recipients (RTRs) carrying the CYP3A5*1 allele require a higher dose of the immunosuppressant tacrolimus to achieve therapeutic exposure[2].
Methods: We did a randomized-controlled, parallel-group, single-center trial with the primary aim to study whether a tacrolimus starting dose based on a patient's CYP3A5 genotype leads to a higher proportion of patients achieving the target tacrolimus predose concentration (C_0) on day 3 after kidney transplantation compared with a standard tacrolimus dose based on bodyweight. Between November 10, 2010 and September 30, 2013, 240 recipients of a living donor kidney were randomly assigned to either arm. Randomization was performed by use of sealed, opaque, sequentially-numbered envelopes containing treatment allocation. Secondary, outcome measures included the incidence of acute rejection.
Results: Of the 237 RTRs who were available for the intention-to-treat analysis, 119 and 118 were assigned to the standard-dose and genotype-based groups, respectively. On day 3, 37.4% (95% CI: 28.5 – 47.0%) and 35.6% (95% CI: 27.0 – 45.0%) of the patients in the standard-dose and genotype-based groups, respectively, were within the target tacrolimus C_0 range ($p = 0.79$). The proportion of patients with a sub-therapeutic (i.e. <10 ng/mL) or a supra-therapeutic (i.e. >15 ng/mL) Tac C0 in the two groups was also not significantly different (Figure 1).The incidence of acute rejection was comparable between both groups ($p = 0.82$).

Figure 1.

	Standard-dose group	Genotype-based group	p
	n = 99	n = 104	
Supra-therapeutic concentration	39 (39.4%)	31 (29.8%)	0.20
Therapeutic concentration	37 (37.4%)	37 (35.6%)	0.79
Sub-therapeutic concentration	23 (23.2%)	36 (34.6%)	0.10

Conclusion: Pharmacogenetic adaptation of the tacrolimus starting dose does not lead to a higher proportion of patients reaching the target tacrolimus C_0 early after transplantation and does not lead to improved clinical outcome. Therefore, routinely genotyping RTRs for CYP3A5 cannot be recommended.

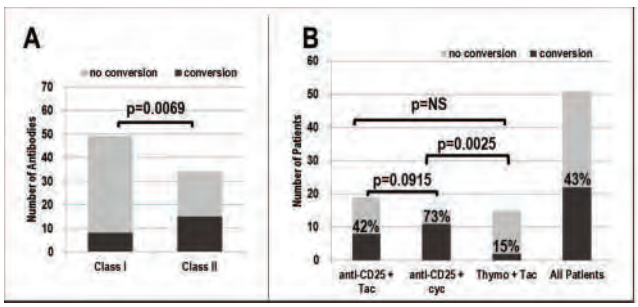
Impact of induction and maintenance immunosuppression on pre-transplant IgM DSA to post-transplant IgG DSA conversion

Anh Nguyen[1], Lorita M.Rebellato[2], Carl E.Haisch[2], Kimberly P.Briley[2], Paul Bolin[2], Scott A.Kendrick[3], Angela Q.Maldonado[4], Claire Morgan[2], Matthew Everly[1].
[1]Terasaki Foundation Laboratory, Los Angeles, CA, United States; [2]East Carolina University, Greenville, NC, United States; [3]Eastern Nephrology Associates, Greenville, NC, United States; [4]Vidant Medical Center, Greenville, NC, United States.

Body: Considering the impact that post-tx IgG donor specific anti-HLA antibodies (DSA) has on late graft loss, it may be important to understand why and how many pre-tx IgM convert to IgG DSA post-tx. Our aim was to learn more about the IgM-IgG conversion post-tx and determine if immunosuppression affected this conversion.
Methods: We retrospectively analyzed 218 consecutive kidney tx patients at a single center, transplanted between 1/06 and 12/10, with a minimum 3 year follow-up. We excluded 20 patients from the analysis due to HLA-matched tx, insufficient patient information, or lack of patient sera. Sera sampling occurred pre-tx, 1, 3, 6, 9, 12 months post-tx and annually thereafter. Antibody identification was determined by LABScreen single antigen beads.
Results: 26% (51/198) of patients had pre-tx IgM DSA but were negative for IgG DSA. Of the 51 patients, 22 patients (43%) converted pre-tx IgM to IgG DSA post-tx of the same specificity.IgM to IgG DSA conversion was most common (54%) within the 1st post-transplant year. Interestingly, significantly more Class II antibodies (44%) converted as compared to Class I antibodies (16%), Fig. A. Also, IgM DQ DSA was >2 times more likely to convert to IgG DSA (of the same specificity) when compared to other HLA loci. Patients on an induction + main immunosuppression combination of Thymoglobulin (Thymo) + Tacrolimus (Tac) had the least conversion (15%) as compared to patients on anti-CD25 + Tac (42%) and anti-CD25 + cyclosporine (73%), Fig. B. Delayed graft function, acute rejection, nonadherence, and BK virus positivity was not shown to affect pre-tx IgM to post-tx IgG conversion.



Conclusion: Significantly more Class II Abs convert post-tx. Induction with Thymo combined with Tac as the main immunosuppression may be most effective in preventing post-tx IgG DSA conversion from pre-tx IgM. More studies are needed to further understand the conversion and confirm the effect immunosuppression has on the process.

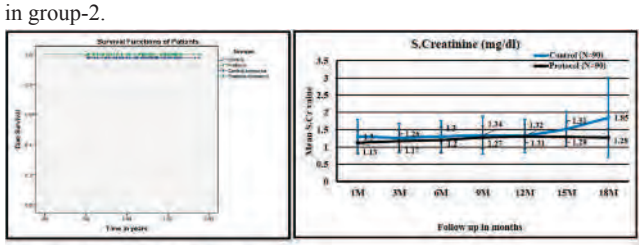
T-regulatory cells support stem cells in safe minimization of immunosuppression in renal transplantation

Hargovind L.Trivedi[1,3], ArunaV. Vanikar[2,3], Himanshu V.Patel[1].
[1]Department of Nephrology and Transplantation Medicine, Institute of Kidney Diseases & Research Centre- Institute of Transplantation Sciences, Ahmedabad, India; [2]Department of Pathology, Laboratory Medicine, Transfusion Services and Immunohematology, Institute of Kidney Diseases & Research Centre- Institute of Transplantation Sciences, Ahmedabad, India; [3]Department of Regenerative Medicine and Stem Cell Therapy, Institute of Kidney Diseases & Research Centre- Institute of Transplantation Sciences, Ahmedabad, India.

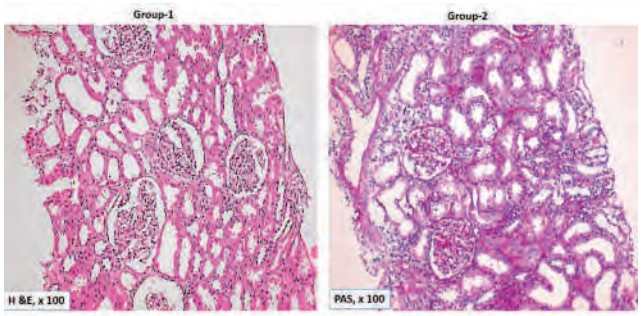
Background: Trials for safe, effective immunosuppression (IS) minimization using deletional agents and stem cell (SC) therapy are ongoing. We report interim results of portal and intrathymic infusion of donor adipose derived mesenchymal SC (AD-MSC), hematopoietic SC (HSC) and T-regulatory cells (Treg)[CD4+CD25highCD127neg/low] in living donor renal transplantation (LDRT).
Material and Methods: This was a prospective study of demographically well-balanced 2 groups, each with 90 patients, predominantly males with mean age, 30.03 years in group-1 and 33.6 years in group-2. Mean donor HLA-match was 2.72 and 2.6 respectively. After baseline tests of anti-human globulin lymphocyte cross-match(XM) (AHG), T/B-cell flow-XM(T/B-FXM) and donor specific antibody (DSA), group-1 underwent non-myeloablative conditioning of subtotal lymphoid irradiation (200 cGYx4), cyclophosphamide, 20 mg/kgBW to create space[1] followed by portal and intrathymic infusion[2],[3] of cytokine-stimulated donor peripheral blood stem cells 169.66x108/kgBW with mean CD34+ 2.05x106/kgBW and AD-MSC 12.5x106/kgBW with mean CD45-/CD90+/CD73+ 2.18/0.59x106/kgBW and peripheral infusion of 2.5x106/kgBW T-regs. RT was performed after favorable cross-match with perioperative rabbit-antithymoglobulin (r-ATG) (1.5 mg/kgBW). Methylprednisone (MP) 500 mg was given on day-1, 0, +1 of RT. Bortezomib 1.3 mg/m2x4 with MP 125mg was administered every 3rd day after 2nd postoperative day. Group-2 received r-ATG and Bortezomib. Group-1 IS included Tacrolimus, 0.03 mg/kgBW/day +Prednisone, 10 mg/day for 3 months subsequently Tacrolimus was replaced by Sirolimus 1 mg/day or mycofenolate 360 mg BD, prednisone was reduced to 5 mg/day. Group-2 received Tacrolimus 0.05 mg/kgBW/day, Mycofenolate 360 mg TID/QID and Prednisone 20 mg/day tapered to 10 mg/day after 1 month.
Tregs and AD-MSC were generated in vitro from donor adipose tissue and recipient blood by indigenous techniques[4]. Monitoring included serum creatinine (SCr-mg/dL), complete blood counts, urinalysis and liver enzymes. DSA were planned 3-monthly. Biopsy was performed in event of graft dysfunction and treated as per standard guidelines. Protocol biopsy was planned after 1 year in willing patients.
Results and Discussion: Over 18 months follow-up there was 100% graft and patient survival in group-1 and 97.8% patient and death-censored graft survival in group-2 with SCr of 1.28 in group-1 and 1.85 in group-2.



Key: Control= Group-2, Protocol= Group-1

Group-1 had more stable graft function. MSC are tolerogenic and recruit T-regs which exert their immunomodulatory effect by infectious tolerance and linked suppression[5]-[8]. There were 9 episodes of acute

rejection (AR) with Banff score ≤ag1at1av1ai2, PTC score-0 in group-1 and 4 episodes in group-2. Group-2 also had 17 episodes of AR score >ag1at1av1ai2, PTC score-0.



DSA were absent in majority of group-1 patients. Protocol biopsy permission was not granted.

Conclusion: T-regs support SC in safe minimization of IS in LDRT.

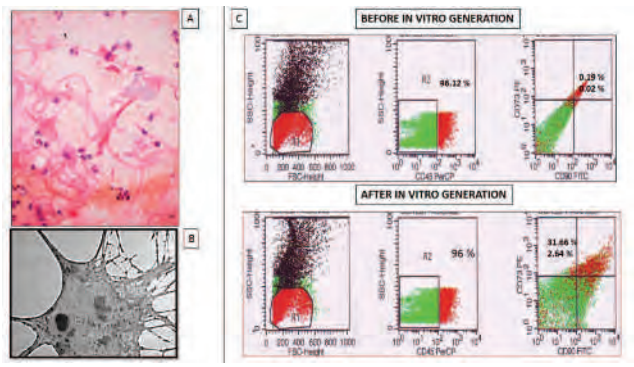
Tolerance induction in renal transplantation using stem cell therapy: Lessons learned

Aruna Vanikar[1,3], Hargovind L.Trivedi[2,3], Himanshu V.Patel[2].
[1]Department of Pathology, Laboratory Medicine, Transfusion Services and Immunohematology and , IKDRC-Dr.H.L.Trivedi Institute of Transplantation Sciences , Ahmedabad, India; [2]Department of Nephrology and Transplantation Medicine, IKDRC-Dr.H.L.Trivedi Institute of Transplantation Sciences , Ahmedabad, India; [3]Department of Regenerative Medicine and Stem Cell Therapy, IKDRC-Dr.H.L.Trivedi Institute of Transplantation Sciences , Ahmedabad, India.

Background: Strategies for tolerance induction (TI) include chimerism and clonal deletion[1]. We present 5 year experience of TI in living-donor renal transplantation (LDRT) using adipose derived mesenchymal stem cell (AD-MSC) and hematopoietic stem cell (HSC) infusion under non-myeloablative conditioning.

Material and Methods: Twenty patients divided in 2 demographically balanced groups underwent LDRT between Dec'09 and April,'11 under TI protocol consisting of conditioning with Bortezomib, 1.3 mg/m2 in 4 divided doses, rabbit-anti-thymocyte globulin, 1.5 mg/kgBW and Rituximab, 375 mg/m2. Group-1 (7 males, 3 females) with mean age of 31.6 years received mean 27.1 hemodialysis and 2.5 third party transfusions. Mean donor age was 43.6 years with mean HLA-match of 2.33. Group-2 (10 males) with mean age, 33.7 years received mean 26 hemodialysis and 1.4 third party transfusions. Mean donor age was 42.5 years with mean HLA-match of 2.4. Group-1 underwent portal infusion of in vitro generated mean AD-MSC, 19.4×104/kgBW and bone marrow-derived HSC, 0.37×108/kgBW with mean CD34+ 21.8×104/kgBW.



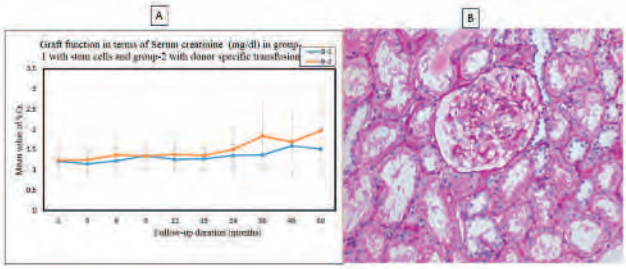
Peripheral blood stem cells, 34.4x108/KgBW were infused in periphery. Group-2 were administered donor specific transfusions (DST) with mean 46.2×103 cells/kgBW. Transplantation was carried out with at least 2 of 3 favorable tests; anti-human globulin lymphocyte cross-match <20%, flow cross-match with T-cells <50 median channel shift (MCS), B-cell <100 MCS and donor specific antibody (DSA) <1000 mean fluorescent intensity. No conventional immunosuppression was to be given. Monitoring included serum creatinine (SCr-mg/dL) and DSA. Protocol biopsies were planned after 100 days and yearly, in willing patients. In event of rejection/rise in DSA, rescue immunosuppression was planned.

Results and Discussion: No adverse effect of conditioning/ SC infusion was reported. Over mean 5.1 year follow-up, there was 70% patient + graft survival in both groups with mean SCr of 1.52 in group-1 and 1.97 in group-2.

There was loss of 2 patients (pneumonia in 1, chronic graft dysfunction in other) and 1 graft to unexplained interstitial fibrosis and tubular atrophy (IF/TA) in group-1. In group-2, 1 patient was lost to de novo focal segmental glomerulosclerosis and 2 grafts were lost to CMV infection and IF/TA respectively. In group-1, 5 patients are on no

conventional immunosuppression, and 2 on mycofenolate + prednisone. In group-2, 4 patients are on no conventional immunosuppression, 2 on mycofenolate+ prednisone, and 1 on Tacrolimus in addition. DSA appeared in 4 patients of group-1 without affecting graft function and 3 of group-2 causing graft dysfunction.

MSC evade immune injury since they do not express HLA-DR[2]. They recruit and generate T-regulatory cells which induce infectious tolerance and linked suppression. HSC help in supporting MSC by engraftment in BM niches. DST are effective in safe minimization of immunosuppression. Portal infusion was selected to exploit the tolerogenicity of liver[3].



Conclusion: To our knowledge this is the first clinical report of 5-year follow-up of tolerance induction in LDRT across HLA barriers where no conventional immunosuppression was used from day zero of transplantation. Immune tolerance induction is possible using stem cells and DST. However stem cells have the added benefit of immunomodulatory properties of AD-MSC.

Malignancies contribute to presensitization with alloreactive T-cells in kidney transplant recipients

Thomas Schachtner[1,2], Maik Stein[2], Petra Reinke[1,2].
[1]Nephrology and Internal Intensive Care, Charité Campus Virchow Clinic, Berlin, Germany; [2]Berlin-Brandenburg Center for Regenerative Therapies, Charité Campus Virchow Clinic, Berlin, Germany.

Introduction: Alloreactive T-cells have been suggested to impact allograft outcome due to a higher incidence of acute rejection in the initial period after kidney transplantation. Knowledge on risk factors for the development of preformed and de-novo activated alloreactive T-cells and their impact on patient and allograft outcomes, however, remains scarce.

Material and Methods: Here, we analyzed clinical characteristics and outcomes of 327 kidney transplant recipients (KTRs) of a first kidney allograft transplanted at our center from 2008 to 2013. KTRs were grouped with respect to the presence of alloreactive T-cells pretransplantation. KTRs without alloreactive T-cells pretransplantation were grouped with respect to the development of alloreactive T-cells posttransplantation. Samples were collected pretransplantation, at +1, +2, and +3 months posttransplantation, and alloreactive T-cells were measured using an interferon-γ Elispot assay.

Results and Discussion: Among 327 KTRs, 107 KTRs (33%) showed detectable alloreactive T-cells pretransplantation, whereas 220 KTR (67%) didn't. Risk factors for the presence of preformed alloreactive T-cells included older age, diabetes, and prior cancer ($p<0.05$). Preformed alloreactive T-cells were associated with a higher incidence of delayed graft function ($p=0.017$). Among 220 KTRs without alloreactive T-cells pretransplantation, 31 KTRs (14%) showed detectable alloreactive T-cells posttransplantation, whereas 189 KTR (86%) didn't. Risk factors for the development of de-novo alloreactive T-cells included younger age, female sex, and prior cancer ($p<0.05$). KTRs with preformed/de-novo alloreactive T-cells showed inferior patient survival, allograft survival, and allograft function ($p<0.05$). In addition, those KTRs showed a higher incidence of acute cellular rejection and a higher rate of allograft loss due to acute cellular rejection ($p<0.05$). KTRs with preformed/de-novo alloreactive T-cells showed a higher incidence of septic complications, posttransplant cancer, and death from cancer ($p<0.05$).

Conclusion: The presence of alloreactive T-cells strongly impacts patient and allograft outcomes. Our data highly suggest that cured or undetected cancer at transplantation may lead to presensitization with preformed alloreactive T-cells. Caution should be taken in KTRs with alloreactive T-cells with regards to minimizing immunosuppression.

The effect of everolimus and tacrolimus exposure levels on renal histology parameters 6 months post-transplantation

F. Vincenti[1], D. Shaffer[2], Y. Qazi[3], F. Shihab[4], K. McCague[5], D. Patel[5], V.R. Peddi[6], S. Yilmaz[7].
[1]University of California San Francisco, San Francisco, CA, United States; [2]Vanderbilt University, Nashville, TN, United States; [3]University of Southern California, Los Angeles, CA, United States; [4]University of Utah, Salt Lake City, UT, United States; [5]Novartis Pharmaceuticals Corporation, East Hanover, NJ, United States; [6]California Pacific Medical Center, San Francisco, CA, United States; [7]University of Calgary, Calgary, AB, Canada.

Introduction: Morphologic changes in renal transplant protocol biopsies provide early evidence of renal damage. Arteriolar hyalinosis (AH) is of particular interest as previous studies have implicated chronic calcineurin inhibitor (CNI) nephrotoxicity in the development of AH following kidney transplantation. We examined renal histology scores, including AH, in renal transplantation patients with different exposure levels of everolimus (EVR) and tacrolimus (TAC) over 6 months.
Methods: Renal transplant patients (N=613) were randomized (1:1) to EVR+low-dose TAC (EVR+LTAC) or mycophenolate mofetil+standard-dose TAC (MMF+STAC). EVR+LTAC received EVR to maintain a trough of 3–8 ng/mL with LTAC (C0h 0–2 Months(M): 4–7 ng/mL, 2–6M: 3–6 ng/mL, 6–12M: 2–5 ng/mL. MMF+STAC received 2 g/day of MMF with STAC (C0h 0–2M: 8–12 ng/mL, 2–6M: 7–10 ng/mL, 6–12M: 5–8 ng/mL). EVR exposure level in the EVR+LTAC group was assessed at 6 months using area-under-curve (AUC) values and patients were ranked and divided into 3 groups (highest to lowest, n=43 in each group). Histological scores, acute and chronic/sclerosing lesion scorings at 6 month protocol biopsies, were compared between the high and low exposure groups using Banff classification. The same analysis was undertaken for TAC exposure level in the EVR+LTAC group.
Results: Histological scores were typically lower for those with higher EVR levels but this effect was not seen with higher TAC levels (Table). AH scores were not correlated with TAC exposure and were similar in patients with upper and lower AUC levels at 6 months (Table).
Discussion: These data show that patients with higher EVR AUC levels had reduced morphological changes associated with renal damage than those with lower EVR AUC levels. While etiological factors in the development of AH in kidney transplant biopsies are not well understood, previous studies have implicated CNI toxicity. Our findings do not support such an association.
Conclusion: Higher EVR levels were more effective at limiting renal damage 6 months post transplantation. TAC treatment was not associated with AH in renal transplant patients 6 months post-transplant. Longer term data are needed to examine these conclusions beyond 6 months.

Table. The effect of everolimus (EVR) and tacrolimus (TAC) exposure levels on renal histology parameters 6 months post-transplantation

	Low vs High EVR area under curve mean (SD)			Low vs High TAC area under curve mean (SD)		
	Low	High	P-value	Low	High	P-value
Area-under-curve	653 (115)	1222 (169)	<0.0001	841 (186)	1041 (259)	<0.0001

Everolimus plus reduced-exposure cyclosporin versus mycophenolic acid plus cyclosporin: long-term follow-up of Australia and New Zealand kidney transplant recipients in the A2309 randomised controlled trial

Steven Chadban[1], Helen Pilmore[2], Graeme Russ[3], Kanellis John[4], Scott Campbell[5], Philip O'Connell[6], Wai H. Lim[7], Mark Lutherborrow[8], Nicols Kurstjens[8], Rowan Walker[9].
[1]Royal Prince Alfred Hospital, Sydney, Australia; [2]Auckland City Hospital, Sydney, Australia; [3]3Central Northern Adelaide Renal and Transplantation Service, Royal Adelaide Hospital, Adelaide, Australia; [4]Monash Medical Centre, Melbourne, Australia; [5]Princess Alexandra Hospital, Brisbane, Australia; [6]Westmead Hospital, Sydney, Australia; [7]Sir Charles Gairdner Hospital, Perth, Australia; [8]Novartis Pharmaceuticals Australia, Sydney, Australia; [9]The Alfred Hospital, Melbourne, Australia.

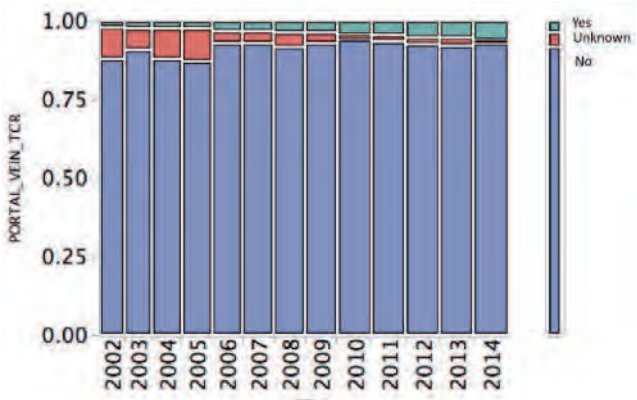
Background: The A2309 was a 2-year, phase III randomized controlled trial evaluating the effect on graft and patient outcomes of three treatment groups:1.5mg everolimus plus reduced exposure cyclosporin (EVR1.5), 3.0mg everolimus plus reduced exposure cyclosporin (EVR3.0) or 1.44g mycophenolic acid plus standard cyclosporin (MPA). The aim of this study was to evaluate the long-term clinical outcomes of 95 Australia and New Zealand (ANZ) participants in the A2309 study.
Methods: Seven-year data for 95 ANZ A2309 participants were extracted from the Australia and New Zealand Dialysis and Transplant (ANZDATA) registry. Associations between treatment and outcomes, including rejection, estimated glomerular filtration rate (eGFR), graft loss, death and cancer incidence were examined using adjusted generalized linear regression or Cox regression analyses using an intention-to-treat analysis. Adverse events and discontinuation of study drugs (up to 2-years) were compared between treatment groups using data from Novartis.
Results: Of the 95 participants, 66 (75.2%) were randomized to EVR1.5 or EVR3.0 and 29 (24.8%) to MPA. Compared to MPA, the combined everolimus treatment groups were associated with adjusted hazard ratios of 0.34 (95%CI 0.13, 0.91), 0.35 (0.09, 1.25) and 0.32 (0.15, 0.71) for non-melanoma skin cancers (NMSC), non-skin cancers and any cancers respectively, independent of age, gender and waiting time. The adjusted mean (95%CI) difference in eGFR at 2 and 5-years were numerically (but not statistically significant) higher in the EVR1.5 group compared to MPA group (2 years: 8.66, 95%CI 1.46, 15.85; and 5 years: 4.68, 95%CI -5.37, 14.7mL/min/1.73m2). There were no associations between treatment groups and other clinical outcomes, including rejection, graft loss or death up to 7-years post-transplant. Adverse events and discontinuation rates were similar between treatment groups after 2-years post-transplant.
Conclusions: Compared to standard-dose cyclosporin, everolimus with reduced-exposure cyclosporin was associated with over a 50% reduction in cancer incidence, particularly NMSC. This data supports a class-effect for mammalian target of rapamycin (mTOR)-inhibitors in reducing the burden of cancer after transplantation.

451.1

Broad assessment of the clinical impact of portal vein thrombosis in the waitlist for liver transplantation

Martin Montenovo, Jorge Reyes, James Perkins.
Surgery, University of Washington, Seattle, United States.

Introduction: Portal vein thrombosis (PVT) is quite common in patients with cirrhosis, but its effect on the waitlist outcomes is not well defined. The objective of this study was to determine the impact of PVT on the waitlist outcomes.
Methods: We conducted a retrospective cohort analysis using the United Network for Organ Sharing database from January 2002 through June 2014, including adults (³18 years old) who were listed for primary OLT. We looked at rate of PVT during the study period, the waiting time from listing until transplant and the rate and cause of drop-off of the waiting list among those patients with PVT at listing vs those without PVT. Logistic regression was used to adjust for recipient characteristics in order to estimate the risk factors associated with being removed from the waitlist.
Results: A total of 134,109 patients listed for primary OLT were identified. The rate of PVT at listing has increased over the course of the years (fig 1).



Patients with PVT at listing have a shorter waiting time (350 ±558 days vs 439±668 days p<.0001); are transplanted at a higher rate (52% vs 49% p<.003); are more likely to be removed from the waitlist for being too sick (11% vs 9% p<.0001) and have a higher lab MELD (23 vs 21 p<.0001). On the multivariate analysis PVT at listing was an independent risk factor of falling off the waitlist (table 1).

Table 1. Logistic Regression Analysis of Factors Predicting Falling off the Waitlist.

Variable	Removal from Waitlist	
	HR	95% CI
PVT at listing	1.12	1.01-1.23
Recipient age	1.03	1.02-1.03
Life support	1.37	1.25-1.51
Previous abdominal surgery	1.06	1.01-1.11
Albumin at time of tx	0.94	0.91-0.96
Ascitis	1.08	1.03-1.13
MELD at time of tx	12.6	10.4-15.3
HD at time of tx	1.31	1.24-1.4
Diabetes	1.11	1.06-1.16
HCC	2.68	2.41-2.97

Conclusions: PVT at listing has significantly increased over the course of the years representing a quite significant burden in the waitlist for liver transplantation. PVT at listing is an independent predictor of being removed from the waitlist. Guidelines for the management of PVT in cirrhosis are needed to improve the access to these patients to liver transplantation.

Clinical and immunological significance of controlling portal vein pressure in living donor liver transplantation

Kazuhiro Taguchi[1,2], Takashi Onoe[1,2], Shinji Hashimoto[2], Yuka Tanaka[2], Hideki Ohdan[2].
[1]Institute for Clinical Research, National Hospital Organization Kure Medical Center and Chugoku Cancer Center, Kure City, Hiroshima, Japan; [2]Department of Gastroenterological and Transplant Surgery, Hiroshima University, Hiroshima, Japan.

Recently, an importance of controlling portal vein pressure (PVP) in living donor liver transplantation (LDLT) has attracted more attention. Nonetheless, clinical significance of portal hypertension in LDLT as risk factor is still controversial. Furthermore, the immunological impact of portal hypertension remains unclear. In this study, we investigated significance of portal hypertension for graft survival and anti-donor immune response.
First, we investigated a significance of portal hypertension as the risk factors for graft survival. In this study, 158 consecutive adult patients undergoing LDLT were included. We categorized the patient into low (<15 mmHg) and high (≥15 mmHg) PVP groups, based on the level of PVP at the end of surgery. The Kaplan-Meier and log-rank test revealed that the 2-year graft survival rate was significantly lower in high PVP group than that in low PVP group (P <0.05). Next, we performed univariate and multivariate analysis of the variables (recipient factors, donor factors and operative factors) including portal hypertension to determine significant risk factor for 2-years graft survival. Multivariate analysis showed that HCV infection and high PVP were independent risk factors (P = 0.005 and 0.018, respectively). In analysis of high PVP subpopulation, multivariate analysis showed that HCV infection, donor older age and longer operation time were significant risk factors for 2-year graft survival (P = 0.001, 0.019 and 0.026, respectively).
Second, we investigated an impact of portal hypertension on immunological reaction in same cohort. For monitoring the cellular alloreacivity of the patients, multiparameter MLR assays were routinely performed at 2 weeks intervals after LDLT. Patients were divided into low or high PVP groups and immunological outcomes were compared. To overcome bias due to the different distribution of covariates in the 2 groups, propensity score matching was performed. The propensity score analysis revealed that 53 matched pairs were selected and those had the same background characteristics (excluding the PVP level). MLR assay revealed that the stimulation index of CD8+ T cells which indicates the anti-donor proliferative response was significantly higher in high PVP group than that in low PVP group within one month after LDLT (P = 0.005). Furthermore, percentage of CD25+ cells among CD8+ T cells which indicates proportion of activated CD8+ T cells in high PVP group was also significantly higher than that in low PVP group (P = 0.005). In addition, the incidence of acute rejection episode within 3 months after LDLT was significantly higher in high PVP group than that in low PVP group (34% vs 11.3%, respectively, P = 0.01). Those data indicates that immunological anti-donor response was promoted in recipients of high PVP group.
In conclusion, those results show that postoperative portal hypertension has significantly adverse impact on graft survival as well as immunological anti-donor response. Our results might propose a novel concept to prevent an acceleration of alloimmune responses and improve survival by controlling PVP or modulating immunosuppressant in high PVP patients after LDLT, especially in patients with HCV infection or with graft from aged donor.

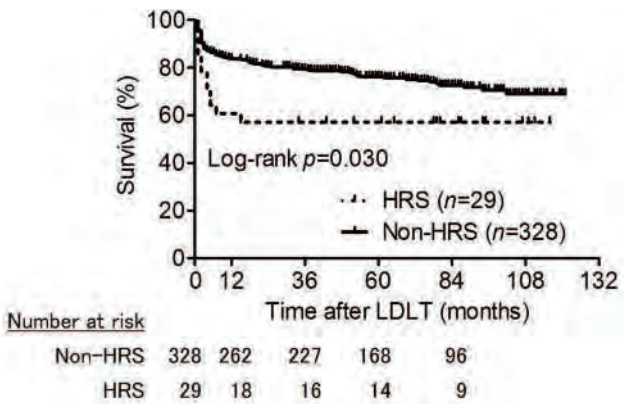
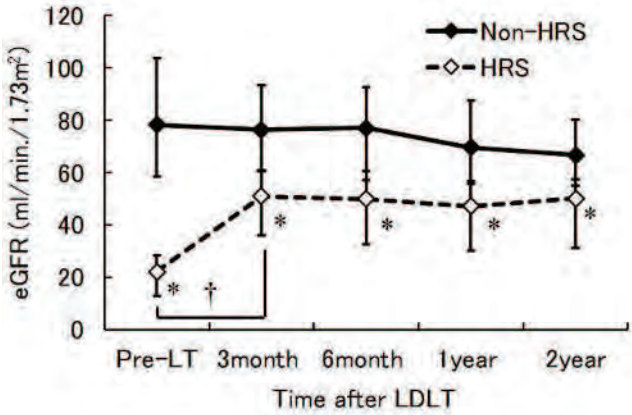
Impact of hepatorenal syndrome on outcome of living donor liver transplantation: A single-center experience in 357 patients

Yusuke Okamura, Koichiro Hata, Ichiro Tamaki, Yermek Nigmet, Osamu Inamoto, Toyonari Kubota, Hirofumi Hirao, Shintaro Yagi, Atsushi Yoshizawa, Hideaki Okajima, Toshimi Kaido, Shinji Uemoto.
Division of Hepato-Biliary-Pancreatic Surgery and Transplantation, Department of Surgery, Kyoto University, Kyoto, Japan.

Introduction: Hepatorenal syndrome (HRS) is one of the most serious complications in end-stage liver diseases, characterized by renal failure and disrupted splanchnic circulation. However, impact of HRS on the patient outcome after living donor liver transplantation (LDLT) is still unclear. The aim of this study was to evaluate the impact of HRS on the outcome of LDLT.
Methods: We retrospectively analyzed consecutive 357 adult patients who underwent primary LDLT between January 2005 and March 2013 in Kyoto University hospital. The median follow-up period of the population was 60 (IQR, 22-88) months. The outcome of the patients with HRS were compared with those without HRS. The definition of HRS was based on the established diagnostic criteria published in 2007 by the International Ascites Club, as follows: cirrhosis with ascites; serum creatinine>133mmol/L (1.5 mg/dL); no improvement of serum creatinine (decrease to a level of<133mmol/L) after at least 2 days with diuretic withdrawal and volume expansion with albumin; absence of shock; no current or recent treatment with nephrotoxic drugs; and absence of parenchymal kidney disease as indicated by proteinuria>500 mg/dL, microhaematuria and/or abnormal renal ultrasonography.
Results: Twenty nine patients (8%) were diagnosed as HRS (Group-HRS) preoperatively, and the other 328 cases (92%) were not (Group-Non-HRS). In Group-HRS, 15 patients (52%) were classified into type-1 HRS, while 14 (48%) were type-2. Group-HRS had significantly higher MELD scores (32 [IQR, 21-40] vs. 18 [IQR, 14-23], p<0.001), requiring significantly more preoperative renal replacement therapy than in Group-Non-HRS (55% vs. 3%, p<0.001). Patient survival in Group-HRS were significantly worse than that in Group-Non-HRS (Log-rank p=0.030) (Figure 1). The 1-, 3- and 5-year survival of the recipients were 60.7%, 57.1% and 57.1% in Group-HRS, and 83.7%, 79.4% and 76.2% in Group-Non-HRS, respectively. Concomitant HRS significantly elongated post-LDLT hospital stays (75 [IQR, 46-142] vs. 50 [IQR, 38-75] days, p=0.003), as well as significantly predisposed to higher in-hospital mortality (41% vs. 18%, p=0.005). The eGFR in Group-HRS was significantly improved after LDLT (22.1 [IQR, 13.1-28.3] preoperatively vs. 50.9 [IQR, 36.1-61.0] ml/min./1.73m2 at 3 months postoperatively, p<0.001) (Figure 2). The values had then plateaued until 2 years after LDLT. Despite such significant recovery of eGFR in Group-HRS, it was still lower than in Group-Non-HRS throughout the observation period of 2 years.





Conclusions: Recipients' as well as renal outcome in HRS patients after LDLT has been seldom elucidated so far. Here we thus report the largest series of analysis in LDLT than ever, demonstrating not only HRS resulted in significantly worse recipients' survival after LDLT, especially in the early posttransplant period, but also prolonged renal dysfunction after transplant even in the long-term.

451.4

Risk factors for primary sclerosing cholangitis recurrence after othotopic liver transplantation

Pavel Drastich[1], Lukas Bajer[1], Monika Drastichova[3], Eva Sticova[2], Pavel Trunecka[4], Julius Spicak[1].
[1]Hepatogastroenterology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [2]Pathology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [3]Radiology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic; [4]Transplancentre, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background: Primary sclerosing cholangitis (PSC) is a chronic liver disorder of unknown etiology. The disease may progress to cirrhosis and eventually to liver failure and death. For those who develop end – stage liver disease, orthotopic liver transplantation (OLT) remains the only effective treatment currently available. However, recurrent form of PSC (rPSC) often appears in patients after OLT and may eventually lead to graft loss and liver re - transplantation (re - OLT). The aim of our retrospective study was to identify risk factors for rPSC.
Patients and Methods: A total number of 115 orthotopic liver transplantations for PSC were performed at Institute for Clinical and Experimental Medicine, Prague, Czech Republic between July 1994 and May 2015. The diagnosis of rPSC was based on histology and cholangiographic findings. We retrospectively analyzed medical records of all PSC patients from our computed database. Only patients with a proper record of pre - OLT (≤ 12 months) colonoscopy and those monitored for a time period of ≥ 60 months post - OLT were included.
Results: We analyzed a cohort of 47 patients. 31 were male, 16 female, with median age of 36 (range 15 - 68) and median follow - up 122 months (range 60 - 249) after OLT. In 21/47 (44.7%) patients, rPSC was diagnosed during the follow - up. Two patients underwent re - OLT (after 103 and 116 months respectively, both for rPSC). According to performed univariate analysis, presence of de - novo colitis ($p = 0.0002$; OR 27.50, 95% CI 3.13 – 241.94) and OLT for overlap with autoimmune hepatitis (PSC/AIH) ($p = 0.0133$) were significantly associated with rPSC. Presence of HLA-DRB1*04 in the recipient was identified as protective factor for rPSC ($p = 0.0287$). In case of de - novo colitis, statistical significance was further confirmed by nominal logistic regression analysis ($p = 0.0094$; OR 22.00, 95% CI 2.04 – 591.60). Neither gender, nor age, CMV infection, acute cellular rejection (ACR), corticoresistant ACR, use of OKT3, presence of HLA-DRB1*08, history of cholangiocarcinoma, cold ischemia time and length of corticosteroids use were significantly associated with rPSC.
Conclusion: Recurrent PSC is an important clinical entity with high prevalence in patients after OLT. De - novo colitis is a novel significant risk factor associated with rPSC, along with PSC/AIH overlap, while presence of HLA-DRB1*04 in the recipient appeared to have a protective effect on rPSC.

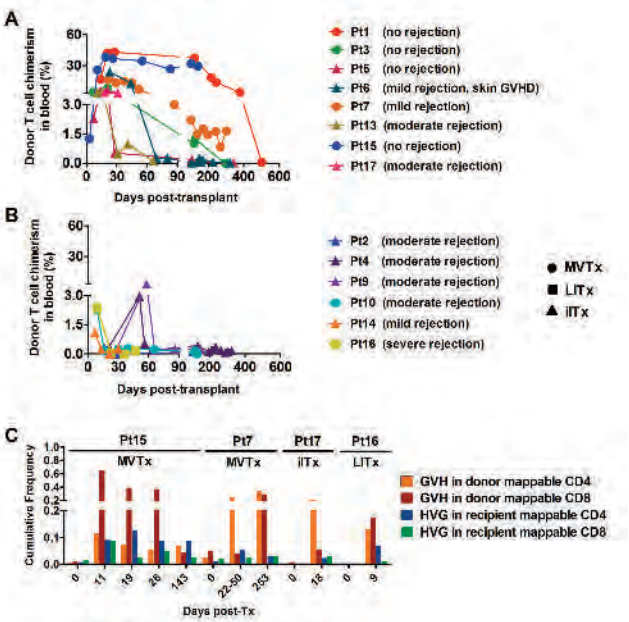
Generation of naïve donor-derived lymphocytes from graft-resident lymphoid progenitors after human intestinal transplantation

Jianing Fu, Julien Zuber, Brittany A.Shonts, Sai Ping Lau, Aleksandar Obradovic, Thomas M.Savage, Michael Simpson, Suxiao Yang, Michelle Miron, Yufeng Shen, Donna Farber, Mercedes Martinez, Adam Griesemer, Tomoaki Kato, Megan Sykes.
Columbia University Medical Center, New York, NY, United States.

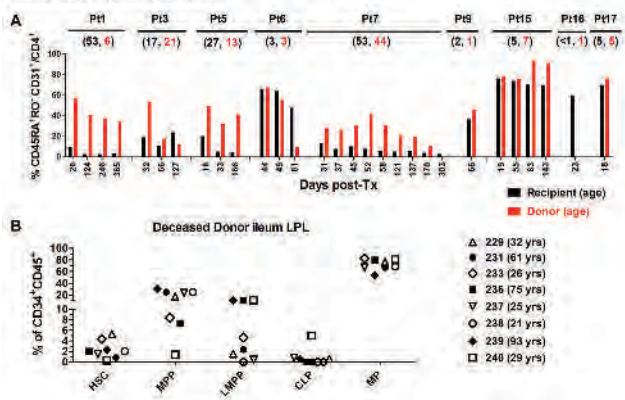
Multivisceral transplantation (MVTx) is associated with a lower rate of severe graft rejection than isolated intestinal transplantation (iITx). We recently demonstrated that mixed T cell macrochimerism (>3% donor cells) often appears in blood (8/14), usually without graft-versus-host disease (GVHD), following ITx, and is greatest in MVTx recipients[1]. However, reasons for the occurrence and persistence of donor T cell macrochimersim in blood are unknown.
We analyzed the phenotype, repertoire, alloreactivity and origin of donor circulating T cells in ITx recipients using flow cytometry, mixed lymphocyte reaction and a high-throughput TCR sequencing to identify and track alloreactive T cells.

Figure 1: (A-B) Donor T cell macrochimerism (>3%) in blood associated with lower rejection rates post-ITx (POD<90). (C) High cumulative frequency (>0.2) of GVH clones in circulation early post-ITx (POD<50) in patients with donor T cell macrochimerism.



The donor T cells among patients with macrochimerism but without GVHD were markedly enriched for the naïve recent thymic emigrant (RTE) phenotype ($CD45RA^{+}CD31^{+}$) and for T-cell receptor excision circles compared with recipient cells and could persist > 1 year. RTE represented 40-95% of donor T cells regardless of donor age (1-44 years old), while the level of recipient-derived RTE usually remained below 25-40%, except in young children less than 6 years old. Surface markers of donor circulating T cells were characteristic of blood ($CD28^{high}CD69^{-}CD103^{-}$), rather than intestinal ($CD28^{-}CD69^{high}CD103^{high}$) T cells. Furthermore, expanded graft-versus-host (GVH) clones were detected early in intestinal biopsies in association with rapid myeloid antigen-presenting cell replacement in the graft by the recipient. GVH-reactive clones were enriched in recipient blood early post-MVTx, even in the absence of GVHD, representing up to 35-65% of donor CD8 cells or 20-25% of donor CD4 cells in early PBMCs (POD<50). GVH clones were later absent in circulating naïve donor-derived T cells (POD>100), consistent with their de novo generation from progenitors. In addition, donor chimerism was identified in circulating T-cell progenitors in 4 MVTx patients. We also detected donor-derived hematopoietic stem cells (HSC) and/or multiple types of progenitors, including multipotent progenitors (MPP), lymphoid-primed multipotent progenitors (LMPP), common lymphoid progenitors (CLP), and mixed myeloid progenitors (MP) in liver and ileum of organ donors, and in perfusates from donor liver, small intestine, and transplanted multivisceral organ blocks.

Figure 2: (A) Circulating donor-derived naive T cells display a recent thymic emigrant (RTE) phenotype. (B) Hematopoietic stem cell and progenitors are detectable in deceased donor ileum lamina propria lymphocytes (LPL).



Together, our findings suggest that GVH-reactive donor T cells expand initially within the graft. These then enter the recipient circulation and may attack host hematopoietic cells, usually without causing GVHD. This lymphohematopoietic GVH response might allow the survival and expansion of donor hematopoietic progenitors from the graft that enter the peripheral blood and then the thymus, resulting in de novo T cell generation, and promoting sustained T cell chimerism. This pathway provides new insights into the underlying mechanism of blood mixed chimerism and may help to reduce graft rejection after ITx.

NIH NIAID Grant P01 AI106697. Research reported in this publication was performed in the Columbia Center for Translational Immunology (CCTI) Flow Cytometry Core, supported in part by the Office of the Director, National Institutes of Health under awards S10RR027050 and S10OD020056

De novo donor-specific HLA antibodies after combined intestinal and vascularized composite allotransplantation

Georgios Vrakas, Annemarie Weissenbacher, Mian Chen, Srikanth Reddy, Philip Allan, Henk Giele, Anil Vaidya, Sue Fuggle, Peter Friend.
Oxford Transplant Centre, Oxford University Hospitals, Oxford, United Kingdom.

Introduction: The numbers of both, intestinal and VCA transplantations, are small compared to other solid organ transplants. In the young field of VCA as well as in bowel and multivisceral transplantations, the occurrence of DSAs has been described. Our aim was to investigate the incidence and clinical effect of de novo DSAs in our cohort of patients receiving an intestinal transplant together with a full-thickness, vascularised abdominal wall graft (a VCA).
Materials and Methods: This is a single-center, retrospective clinical study. The patient cohort includes all recipients of deceased donor intestinal and VCA transplants performed at the Oxford Transplant Centre between October 2008 and December 2015. Pre-transplant HLA antibody status was available for all patients. Clinical and HLA antibody data were obtained monthly for the first year and 3 monthly thereafter, as well as at the time of clinical events.
Results: Thirty-two intestinal transplants were included. One patient underwent a second small bowel and abdominal wall transplant. All organs were retrieved from DBD donors. There were 8 modified multivisceral transplants (8/32, 25%) and 24 isolated small bowel transplants (24/32, 75%). An abdominal wall VCA (from the same donor) was used in 18 cases (18/32, 56%). All patients received alemutzumab induction and tacrolimus maintenance immunosuppression.
DSAs were detectable in 2/31 (6.5%) recipients before the combined transplant. Twelve (38.7%), of the remaining 29, developed de novo DSAs. Five patients developed de novo DSAs against HLA class-I (15.6%), 4 against class-II (12.5%) and 3 patients (9.4%) against both classes. The mean MFI of DSAs was 8250 ± 6580SD. In the VCA group, a lower percentage developed de novo DSAs compared to the group without VCA; 6/14 (42.9%) vs. 6/18 (33%).
Intestinal rejection was proven in 5/14 (35.7%) cases without VCA and 3/18 (16.7%) cases with the VCA. VCA rejection was seen in 7/18 (38.9%) cases. One was grade 1, 1 grade 2 and 5 grade 3. There were no episodes of intestinal rejection without VCA rejection. The occurrence of de novo DSAs in the absence of clinical rejection, has not led to organ or patient deterioration and has not been treated.
Discussion: The combination of intestinal transplantation with a VCA is immunologically complex: although we have found no evidence that the VCA sensitises the patient, predisposing to rejection of both organs, further experience is needed. The development of DSAs in intestinal transplantation, in line with other organ types, is detrimental to the long-term survival of the graft.
Conclusion: Our data suggest that combining an abdominal wall VCA with an intestinal transplant does not increase the incidence of de novo DSAs.

Intestinal retransplantation in children: Single center experience

Neslihan Celik[1], Frederick Vyas[1], Geoffrey J.Bond[1], Kyle A.Soltys[1], Jeffrey Rudolph[2], Rakesh Sindhi[1], George V.Mazariegos[1].
[1]Hillman Center for Pediatric Transplantation, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA, United States; [2]Intestinal Care and Rehabilitation Center, Department of Pediatrics, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA, United States.

Aim: To analyze the patient and graft characteristics and improvement in patient outcomes for intestinal retransplantation (Re-ITx) in the era of induction immunosuppression with the comparison of outcomes between 1990-2000 and 2001-2015.
Methods: The data of all children receiving Re-ITx between 1990 and 2015 at our center were reviewed retrospectively.
Results: 242 children received primary intestinal grafts. 23 children (9.5%) were retransplanted with 24 grafts. Causes of graft failure were acute cellular rejection (n=3), liver failure (n=2), chronic rejection (n=11), post-transplant lymphoproliferative disorder (n=3), graft dysmotility or dysfunction (n=2), volvulus (n=1), arterial graft aneurysm (n=1), and aortic graft thrombosis (n=1). Re-ITx was with isolated small bowel in five, liver-small bowel±pancreas in five, multivisceral in thirteen and modified multivisceral in one. Sixteen (69.6%) patients are alive with functioning grafts at a mean current follow-up time of 8.8 years. 5 year patient and graft survival improved to 89% and 79% respectively since 2001. Seven patients died primarily from infectious complications at a mean time of 35.7 months post-Re-ITx. Two patients had allograft enterectomies due to severe acute rejection and chronic rejection. 93% of surviving patients with their retransplanted intestine weaned-off total parenteral nutrition and intravenous fluids.

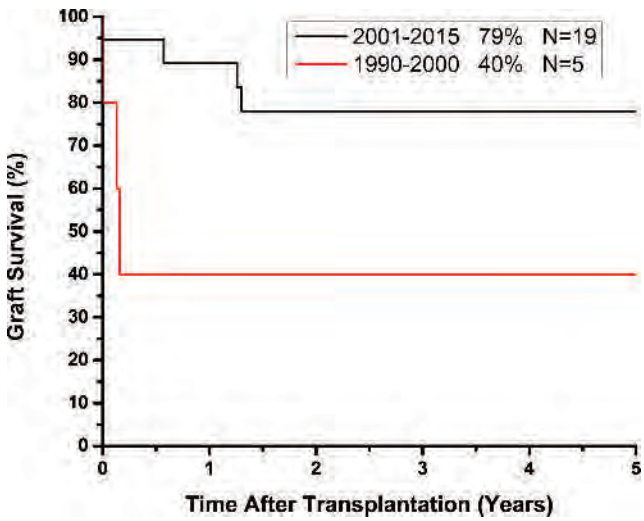

Figure 1. Five year graft survival for Re-ITx by era.
Conclusions: Improved early and intermediate term survival and outcome in pediatric Re-ITx may be attributed to improvements in initial immunosuppression protocols, technical modifications, proper timing, and improved infectious disease monitoring. Careful patient selection and post-transplant management are essential for successful long-term outcome.

Skin GVHD in paediatric intestinal transplant recipients – experience from a National UK Centre

Suzan Warner[1], Sarah Lawson[2], Malobi Ogboli[3], Arun Alfred[4], Peter Taylor[4], Jane Hartley[1], Girish Gupte[1].
[1]Hepatology , Birmingham Children's Hospital, Birmingham, United Kingdom; [2]Haematology , Birmingham Children's Hospital, Birmingham , United Kingdom; [3]Dermatology, Birmingham Children's Hospital, Birmingham , United Kingdom; [4]Haematology, Rotherham Hospital, Rotherham, United Kingdom.

Introduction: Severe skin GVHD in intestinal transplantation is hard to treat. Various regimens have been tried, with more novel approaches such as extracorporeal photophoresis (ECP) and mesenchymal stem cell infusions (MSC) in recent years. We report our experience in the management of skin GVHD in intestinal transplant patients.
Materials and Methods: Retrospective study by review of clinical case-notes and electronic database of intestinal transplant recipients with skin GVHD from 1993 to 2016.
Results: 12 out of 94 patients had skin GVHD from 1993 to 2016; age range 10mths to 9yrs – median age 24mths. Data from 11 of these patients were obtained (1 medical notes cannot be traced); underlying diagnosis were NEC (n=3), Megacystis microcolon-intestinal hypoperistalsis syndrome (MMIH; n=3), Gastroschisis (n=2), Microvillus inclusion disease (n=2) and malrotation with volvulus (n=1).
Five had combined liver and small bowel, 3 isolated small bowel, 2 multivisceral and 1 modified multivisceral transplants. All transplants were from DBD donors (dead after brain-dead). Median cold ischaemic time was 6hrs 57minutes (range 4hrs 43mins to 9hrs 38mins). Median warm ischaemic time was 33minutes (range 20mins to 1hr 5mins).
Mean onset time from transplant to skin GVHD was 3mths; seven had Grade 4, two Grade 3 and two Grade 1 skin GVHD. 5 patients had mucositis (oral ulceration), 4 ocular GVHD, 4 haemolytic anaemia (bone marrow GVHD), 1 liver GVHD and one had neurological involvement (immune mediated Myasthenia gravis).
Chimerism studies at 4mths post-transplant from our cohort showed mostly CD3+ donor cell mixed chimerism (range 6-67%, mode 17%) and a reduced donor B cell lineage.
All except 3patients had intravenous steroids at diagnosis; 4 had Infliximab and Basiliximab, 1 had Infliximab alone, 2 Dacluzimab, 2 Campath, 1 Methotrexate, 5 ECP and 7 MSC. ECP and MSC became available at our centre from 2010; average time of referral for these treatments from GVHD onset was 1month from 2014 onwards compared to 7mths from 2010 to 2013.
Although 4 patients initially had resolution of their skin GVHD and 5 had chronic skin GVHD, four patients (all Grade 4 skin GVHD) eventually died as a result of complications from the skin GVHD.
Discussion: Skin was the primary organ affected with GVHD in our cohort of patients. Mixed chimersm studies showed higher than expected CD3+ activated donor cells at 4mths and thereafter. This may reflect a correlation with GVHD activity.
Our initial experience of steroid refractory skin GVHD with a combination of interleukin 2 receptor antagonists (Basiliximab and Daclulizimab) and TNFα (Infliximab) were ineffective. Second line therapy with ECP and MSC had more success with clinical improvements, particularly if patients were referred earlier as seen from 2014.
Conclusion: Skin GHVD in intestinal transplant populations can progress rapidly, is associated with high mortality and should be treated aggressively. ECP and MSC should form second line treatment in children with steroid refractory GVHD.

Donor-specific antibodies are associated with rejection after intestinal transplant in pediatric patients

C. Andrew Bonham[1], Thomas Pham[1], Jackie Lee[1], Ricardo Castillo[2], Sarah Conlon[1], Waldo Concepcion[1], Carlos Esquivel[1].
[1]Surgery, Stanford University Medical School, Palo Alto, CA, United States; [2]Pediatrics, Stanford University Medical School, Palo Alto, CA, United States.

Isolated small bowel or multi-visceral transplant is the treatment of choice in children with chronic intestinal failure with or without end stage liver disease. Acute and chronic intestinal allograft rejection negatively impacts long term patient and graft survival. The role of donor specific antibodies (DSAs) and their impact on rejection and graft survival is well documented following kidney and heart transplant but remains unclear in pediatric small bowel transplant. We hypothesize that the presence of DSAs combined with positive C4d staining is a marker for humoral rejection and thus may influence treatment decisions. DSAs were reviewed in fifteen children aged 1 to 18 years undergoing small bowel transplant between the years 2002 to 2014. Ten of these children underwent combined multi-visceral transplants. Six patients had documented clinical acute rejection ranging from mild to severe. There were no graft losses documented. DSAs were analyzed at or soon after the time of rejection and were detectable in 5 of 6 (83%) patients with rejection. The one patient that did not have detectable DSAs had a cumulative panel reactive antibody of 8% and negative C4d staining at the time of rejection. C4d staining ranged from focal/weak to strong in the remaining 5 patients but did not correlate to the severity of rejection, the amount of panel reactive antibodies or the quantity/intensity of DSAs detected. Detectable DSAs persisted for years following rejection episodes, even in the absence of further rejection. The remaining nine patients did not have documented rejection but had DSAs analyzed post-transplant. Only one of them had detectable DSAs but no C4d detected on biopsy. The presence of detectable DSAs was significantly higher in those who had documented rejection (n=5) as compared to those who never had rejection (n=1) (p=0.001). There was no significant difference in rejection (p=0.5) and presence of DSAs (p=0.5) between isolated small bowel and multi-visceral transplants. Following small bowel and multi-visceral transplant, DSAs are associated with rejection and C4d deposition into the graft, which is suggestive of antibody-mediated rejection. The addition of a liver allograft did not translate into a decrease in recipient DSAs. Routine DSA monitoring will help treat rejection more efficiently and possibly prevent future episodes thus prolonging graft and patient survival.

MicroRNAs in EBV+ B cell lymphomas and secreted exosomes

Vandana Kaul, Aleishia Harris-Arnold, Carlos Esquivel, Olivia M. Martinez, Sheri M. Krams.
Department of Surgery, Division of Abdominal Transplantation, Stanford University School of Medicine, Stanford, CA, United States.

Introduction: Post-transplant lymphoproliferative disorder (PTLD) is a potentially fatal complication of organ transplantation commonly associated with Epstein Barr virus (EBV) infection. EBV viral loads are typically monitored by qPCR but EBV viremia does not always portend PTLD, and EBV$^+$ PTLD can occur in the absence of increased viral levels. Thus, new biomarkers are critical to improving patient outcomes.
Methods: microRNA-microarray profiling (Taqman-TLDA cards) was used to quantitate expression levels of 639 microRNAs in RNA isolated from spontaneously arising EBV$^+$ B lymphoma cell lines from patients with PTLD (SLCL) (n=6), B lymphoblastoid cell lines (LCL) generated in vitro with the B95.8 strain of EBV (n=4), and normal human B cells (n=4). One-way ANOVA analysis was used to identify the microRNAs differentially modulated within the groups. Further, real-time qPCR analysis was used to validate the specific differentially expressed microRNAs identified from microarray profiling. Exosomes are nanometric (30-150nm) membrane vesicles that are released by most cell types. Studies have shown that exosomes contain and transfer microRNAs between cells thus allowing for local and distant intercellular communication. Exosomes were isolated from the culture supernatant of SLCL using ExoQuick-TC and centrifugation. RNA was isolated from exosomes and microRNAs quantitated
Results: 133 microRNAs were significantly modulated by EBV infection in both B lymphoblastoid cell lines (LCL) and SLCL Sixteen microRNAs, 13 increased and three decreased, were uniquely modulated in EBV+ B lymphoma cell lines from patients with PTLD (SLCLs). Real-time qPCR validated a panel of 5 microRNAs (miR-19a, miR-100, miR-106a, miR-422a miR-449b) that were significantly increased in SLCLs as compared to normal EBV$^+$ B cells. Exosomes, which were confirmed by transmission electron microscopy, were present in very high levels in SLCL supernatants. Interestingly, miR-30c, which was down regulated in SLCLs, was increased in SLCL exosomes. Importantly, microRNAs including miR-19a and high levels of miR-106a were readily detected in exosomes from SLCL suggesting that circulating cell-free microRNAs are associated with PTLD.
Conclusion: EBV$^+$ B lymphoma cell lines from PTLD patients produce microRNA-containing exosomes and this may constitute a mechanism of intercellular communication by microRNA transfer to other cells. Importantly, cellular and cell-free microRNAs have great potential as non-invasive biomarkers of PTLD.

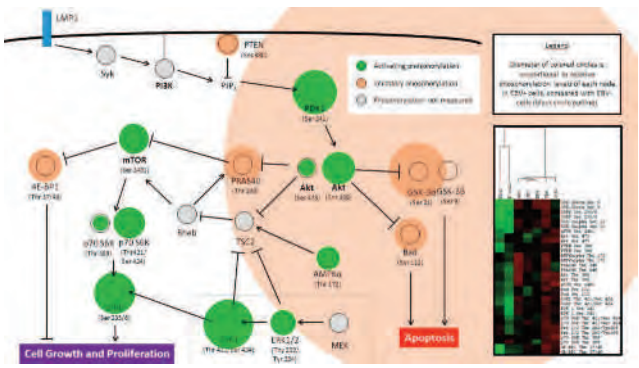
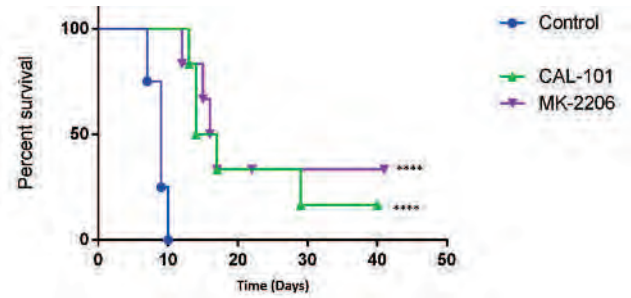
Inhibition of the constitutively active PI3K/Akt/mTOR signaling pathway in epstein-barr virus B cell lymphomas demonstrate both antitumor and antirejection properties

Adam Sang, Geoffrey T.Ivison, Xiumei Qu, Carlos O. Esquivel, Sheri M. Krams, Olivia M. Martinez.
Abdominal Transplantation, Stanford University School of Medicine, Stanford, CA, United States.

Introduction: Epstein-Barr virus (EBV) B cell lymphomas in post-transplant lymphoproliferative disorder (PTLD) is a major problem in organ transplantation. Treatment options for PTLD are limited and may harm the graft. Rationally-targeted antitumor therapies with antirejection properties would be of great importance to PTLD patients. Previous studies have shown that multiple cellular signal transduction pathways, including the PI3K/Akt/mTOR pathway, are dysregulated in EBV+ B cell lymphomas, and that inhibiting mTOR with rapamycin results in partial inhibition of proliferation. We hypothesize that targeting molecules upstream of mTOR would more effectively inhibit EBV+ B cell lymphoma proliferation. Moreover, blockade of this pathway may prolong graft survival, since this pathway is also known to be activated downstream of the T cell receptor.
Materials and Methods: Phosphorylation of the PI3K/Akt/mTOR signaling cascade was determined by pathway protein array on cellular lysates from EBV+ B cell lymphoma lines taken from five patients with PTLD. Cellular lysates from B cells of healthy donors and EBV- Burkitt's lymphoma lines were used as controls. The effect of small-molecule inhibitors (rapamycin (mTOR inhibitor), CAL101 (PI3K inhibitor), and MK2206 (Akt inhibitor)) on cellular proliferation was determined using colorimetric MTS assay.
A mouse heterotopic heart transplant model using Balb/C donors and MHC-mismatched C57Bl/6 recipients was used to assess the effect of these inhibitors (rapamycin, CAL101, MK2206) on transplant graft survival (n=6 in each group). The heart grafts were palpated daily to assess for survival.
Results and Discussion: EBV+ B lymphoma cell lines showed hyperactivation of multiple nodes along the PI3K/Akt/mTOR pathway, including mTOR, 4EBP1, S6K, and GSK3α/β, compared to EBV- cell lines (Fig 1). Hierarchical clustering distinguished the EBV+ B cell lines from EBV- B cells (Fig 1, Inset).



Several signals upstream of mTOR, such as PDK3 and Akt, were also constitutively phosphorylated, offering a possible explanation for the modest effect of rapamycin alone, as well as novel therapeutic targets. Inhibiting upstream PI3K with CAL101 resulted in a dose-dependent decrease in proliferation (x=51.6±6.6%, range 39.8-62.6%) of the EBV+ B cell lymphoma lines (n=3). Likewise, inhibition of Akt with MK2206 also decreased proliferation (x=52.1±3.5%, range 46.5-58.5%).
T cells, which play a central role in graft rejection of MHC-mismatched organs, also use the PI3K/Akt/mTOR pathway for activation. We show that in vivo treatment of cardiac allograft recipients with either CAL101 or MK2206 prolonged allograft survival from 8.75 days (control) to 21.2 (SEM ±4.48) and 20.5 (±4.31) days, respectively (Fig 2).



Conclusion: The inhibition of signaling nodes upstream of mTOR, such as PI3K and Akt, demonstrates antitumor properties and immunosuppressive effects, suggesting this approach may be an attractive therapeutic option for treatment of EBV+ PTLD.

Lymphoproliferative disorders after renal transplantation along two decades: a large longitudinal study of 21.546 recipients

Antonio Franco[6], Dolores Burgos[7], Angel Alonso[4], Naroa Maruri[1], Marta Crespo[2], Domingo Hernandez[7].
[1]Nephrology, Hospital Cruces, Bilbao, Spain; [2]Nephrology, Hospital del Mar , Barcelona, Spain; [3]Nephrology, Hospital carlos Haya, Malaga, Spain; [4]Nephrology, Hospital Juan Canalejo, La Coruña, Spain; [5]Nephrology, hospital Ramon Y Cajal, madrid, Spain; [6]Nephrology, Hospital General, Alicante, Spain; [7]Nephrology, Hospital Carlos Haya, Malaga, Spain.

Post-transplant lymphoproliferative disorders (PTLD) are heterogeneous lymphoid proliferations in recipients of solid organs which seem to be related to Epstein Barr Virus (EBV). The use of antilymphocyte antibodies, EBV seronegativity in the recipient, acute rejection and Citomegalovirus infection have been identified as classical risk factors.
We have evaluated in a longuitudinal study the cumulative incidence of PTLD, its relationship with EBV, presence of classical risk factors and outcome in 21546 simple adult renal transplant recipients from cadaveric and living donors, transplanted in 21 hospitals from 1990 to 2009. The follow up was at least of 5 years.
A total of 272 recipients 193 males (70,9%) and 79 females (29,1%) aged 50,6 (14,7) years, developed PTLD (1,2%), 8.18 cases (8.16;8.19)/10.000 patients/year. Cumulative incidence was 1.72 ‰, 5.72 ‰ and 10.5 ‰ at 1, 5 and 10 years post-transplant. Two hundred forty-two (88,9%) were 1st transplant recipients and 266 (97,7%) from cadaveric donors. At diagnosis the recipients received cyclosporine (58,8%) FK (35,4%), Micophenolate (40,3%), azathiprine (22,6%) and steroids (83,1%) . EBV in the tissue was reported in 94 out of the 155 studied recipients (60.6%) and 86.0 % of the proliferations were due to B lymphocytes . PTLD median appearance after transplant were 42.months (p25,75;12,77,5) , 81,7 in recipients with EBV positive (25;129) and 82,8 in negative (41;109) in tissue (p=0,725).One hundred eighty-eight recipients (69.1 %) had any classical risk factor and the use of antilymphocyte antibodies was the most frequent.
During the follow-up , 172 patients died (63,2%) and 100 (36,7%) had a complete remission, but 20 of them lost their grafts (7,3%). The main cause of death was PTLD progression (n=91, 52,9%),followed by sepsis (n=24, 13,9%).
Patient survival after diagnosis was 53%, 46% and 40% after 1st , 2nd and 5 th years, respectively. Finally, overall graft survival was 48%, 39% and 33% at 1, 2 and 5 years.
In conclusion, most of the proliferations are due to B lymphocytes and seem to have a close relationship with EBV .PTLD can develop in the absence of classical risk factors, the use of antilymphocyte antibodies, the most frequent .There is no relationship between presence of EBV and appeareance after transplant .Although PTLD incidence is low , the prognosis is poor at 1 year, mainly due to PTLD progression, but later the survivors can even mantein their grafts.

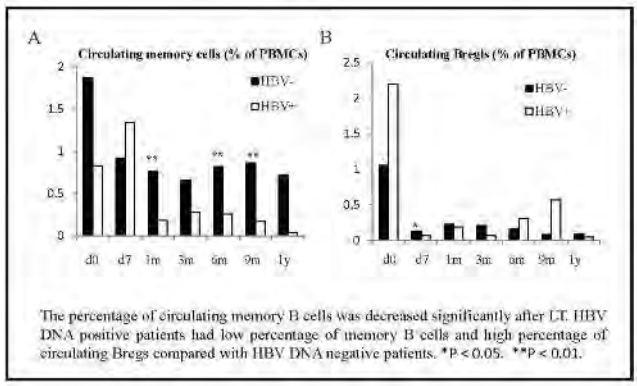
Stem cell like memory B cells attenuate hepatitis B virus relapse in hepatocellular carcinoma patients post liver transplantation

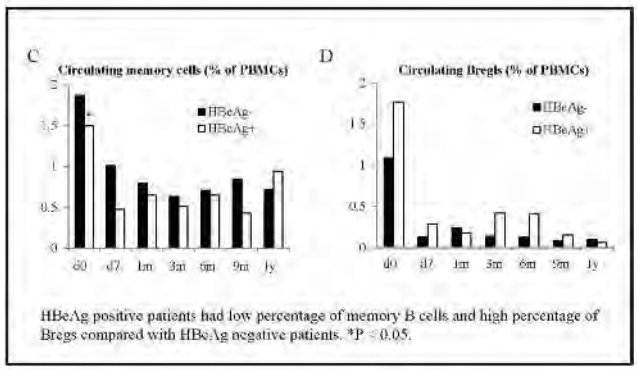
Y Shao, CM Lo, YF Lam, QS Liu, KTP Ng, K Man.
Surgery, The University of Hong Kong, Hong Kong, Hong Kong.

Background and Objective: Memory B cells play an important role in the clearance of hepatitis B virus (HBV). Stem like memory B cells with the ability of self-renewal and multipotency might enhance the clearance of HBV and anti-tumor specifically. We previously reported that the relevance of HBV genotype and HBV-specific CD4 T cell immunity is not responsible for viral clearance after liver transplantation (LT) under antiviral prophylaxis[1]. Here, we aimed to identify stem like memory B cells and investigate their role in HBV relapse in hepatocellular carcinoma (HCC) patients after LT.
Methods: The correlation of circulating B cell subsets and clinical-pathological data were analyzed in 53 HCC recipients before and after LT. The plasma levels of PD1 were detected by ELISA. HBV in liver tissues were detected with Orcein stain. A stem-like memory B cell subset (CD80+PDL2+) was isolated from human bloods and identified by self-renewal and multipotency in vitro.

Fig. 1.



The percentage of circulating memory B cells was decreased significantly after LT. HBV DNA positive patients had low percentage of memory B cells and high percentage of circulating Bregs compared with HBV DNA negative patients. *P < 0.05. **P < 0.01.



HBeAg positive patients had low percentage of memory B cells and high percentage of Bregs compared with HBeAg negative patients. *P < 0.05.

Results: Clinically, there was a close correlation between HBV DNA and the numbers of circulating memory B cells (CD19+CD24+CD38-) (p=0.038). HBV DNA positive patients had less memory B cells (after LT, 1 month: P=0.004, 6 month: P=0.0002 and 9 month: P=0.001) (Fig1. A). Consistently, HBeAg positive patients had less memory B cells compared with HBeAg negative patients before LT (1.5(0.32-4.15) Vs. 1.875 (0.11-16.21) %, P=0.028) (Fig1. C). The percentage of circulating memory B cells was negatively correlated with HBV DNA after LT. The positive association between memory B cells and serum HBV specific IgG level was confirmed by ELISA. In addition, high circulating regulatory B cells (Bregs: CD19+CD24+CD38+) tended to correlate with HBV DNA or HBeAg status (Fig1. B and D). Stem like

memory B enhanced proliferative and survival capacities compared with conventional memory B cells. HBV pulsed memory B cells enhanced CD8+ T cell cytotoxicity, while Bregs suppressed it. Blockade of PD-1/PDL pathways increased memory B-cell activation, proliferation, the production of inflammatory cytokines and IgG production.

Conclusion: Memory B cells may play an important role in attenuation of HBV relapse by switching into HBV-specific plasma cells and regulating CD8+ T cell immunity. Stem memory B cell may prevent HBV recurrence though PD1-PDL interaction.

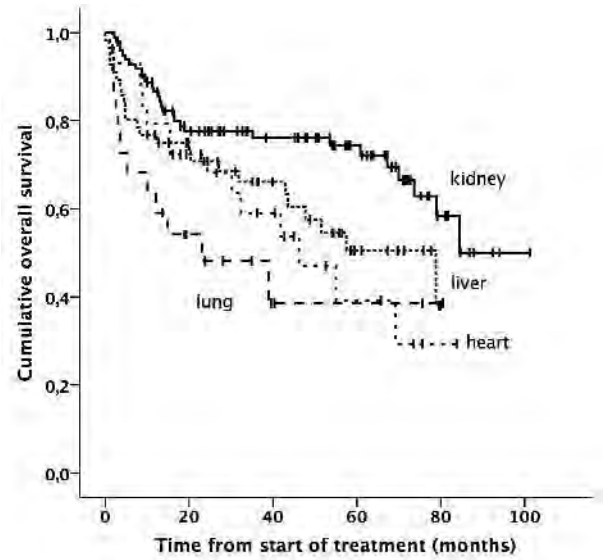
Background: The PTLD-1 trials have tested sequential treatment with rituximab and CHOP-based chemotherapy in CD20-positive post-transplant lymphoproliferative disorder (PTLD). Based on the hypothesis that rituximab consolidation might be sufficient treatment for patients already in a complete response (CR) after rituximab induction, trial treatment was changed in 2007 through a protocol amendment introducing risk-stratified sequential treatment (RSST): rituximab consolidation for patients in CR after rituximab induction and R-CHOP-21 consolidation for all others.

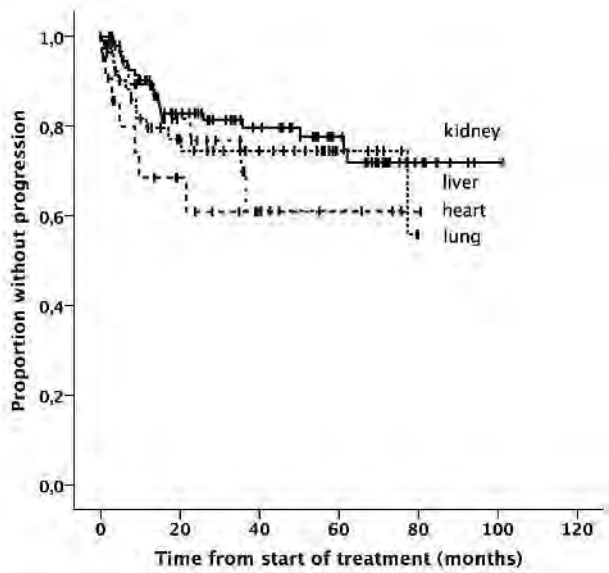
Methods: This is a pooled analysis of the patients treated in both international, multicenter, phase II trial protocols (NCT01458548 and NCT00590447). Treatment-naïve adult SOT recipients diagnosed with CD20-positive PTLD were treated with rituximab (375 mg/m2 IV) on days 1, 8, 15 and 22. In the original PTLD-1 protocol (NCT01458548), all patients continued with four cycles of CHOP21 + GCSF. In RSST (NCT00590447), patients in CR after restaging continued with four three-weekly courses of rituximab monotherapy while all others received 4 cycles of R-CHOP-21 + G-CSF. Inclusion criteria and follow-up schedule were identical; there were no significant differences in the transplant- and lymphoma-related baseline factors. Primary endpoint was treatment efficacy measured as response rates and response duration. Analysis was by intention to treat. 70 patients were treated in NCT01458548 and 152 in NCT00590447.

Results: 162/222 patients were male. 98/222 were kidney, 56 liver, 29 heart, 22 lung, 7 kidney/pancreas, 5 heart/kidney, and 4 heart/lung transplant recipients. Median age at diagnosis was 55 years. PTLD was late (> 1 year after transplant) in 173/222. 96/210 PTLD were EBV-

associated. 169/222 patients (76%) had monomorphic DLBCL-like PTLD, 23 polymorphic and 2 early lesion PTLD. The overall response rate (ORR) was 164/185 (89 %, CR: 128/185 [69 %]). Median follow-up was 4.6 years. Median duration of remission (DR) was not reached; the 3-year Kaplan-Meier estimate was 79%. Median time to progression (TTP) was not reached either. The 3-year Kaplan-Meier estimate was 75%. Median OS was 6.6 years with a 3-year estimate of 67%. There was no significant difference in ORR, DR or OS between EBV-positive and EBV-negative PTLD. On the other hand, response to 4 applications of rituximab was a highly significant predictor of overall survival, time to progression and progression-free survival despite introduction of treatment stratification in the 3rd amendment (all $p<0.001$). In an analysis limited to the most common transplanted organs (liver, kidney, heart, lung), there was a significant difference in OS ($p=0.004$) but not in TTP ($p=0.256$).

Conclusions: This pooled analysis of the two largest ever trial cohorts in PTLD to date demonstrates that sequential treatment strategies in PTLD are feasible, safe and effective in both EBV-positive and negative PTLD and across a range of transplanted organs. Nowadays many patients can be cured and treatment toxicity considerably is reduced by sequential treatment and risk stratification.





452.6

Cancer-related incidence and progression to mortality among kidney allograft recipients in England: a population-cohort analysis between 2003 and 2013

Francesca Jackson-Spence[1], Holly Gillott[1], Sanna Tahir[1], Jay Nath[3], Felicity Evison[2], Jemma Mytton[2], Adnan Sharif[3].
[1]Medical School, University of Birmingham, Birmingham, United Kingdom; [2]Department of Medical Informatics, Queen Elizabeth Hospital, Birmingham, United Kingdom; [3]Department of Nephrology and Transplantation, Queen Elizabeth Hospital, Birmingham, United Kingdom.

Background: Cancer-related incidence and mortality for kidney allograft recipients are raised compared the general population due to the burden of immunosuppression. While our understanding of cancer-related epidemiology has increased over the last decade, no study has ever documented the risk of cancer-incidence post kidney transplantation progressing to cancer-related mortality within the same cohort. In this population-based cohort study, we sought to understand the risk of cancer developing post-transplantation and how this relates to the risk of cancer progression to mortality (both all-cause and cancer-related deaths).

Methods: We obtained data from every kidney-alone transplant procedure performed in England between 2003 and 2013, collecting patient demographics that included age, gender, donor type (living or deceased), socioeconomic deprivation, transplant year, medical co-morbidities (using ICD-10 linked cancer codes) and ethnicity. Data was extracted from Hospital Episode Statistics, with linkage to the Office for National Statistics for mortality data (including causality from death certification).

Results: Data was available for 21,371 kidney allograft recipients who received a transplant in England between 2003 and 2013, with median follow up 6.3 years post-transplantation. After exclusions due to missing demographic data and patients who received combined transplants, we had 18,493 patients over the age of 18 for analysis. The mean age of the cohort was 47.6, 61.5% were male, 78.5% were of white ethnicity, 22.3% lived in the most socio-economically deprived area, 36.3% received a living-donor kidney, 2.8% were on a repeat transplant and pre-transplant cancer was diagnosed in 1.8% of patients. Post-transplant admissions with a cancer diagnosis occurred in 12.3% (n=2,273) of kidney allograft recipient. In total, all-cause (including cancer) and cancer-specific mortality occurred in 2,461 and 444 of kidney allograft recipients respectively at median follow up (up to October 2015). For patients with a cancer admission post kidney transplantation, by median follow up 19.5% had died from cancer-related deaths (n=444) and 10.6% had died from non-cancer related deaths (n=240. Skin cancer was the commonest occurring cancer (43.4% of all cancers), but was associated with mortality in only 4.9% of cancer-related deaths. Cancer sites with the greatest of site-specific deaths within our cohort were lung, digestive and mesothelial/soft tissue (all >40% risk of death by median follow up).

Conclusion: To our knowledge, this study is the first to highlight cancer occurrence post kidney transplantation and risk of progression to all-cause or cancer-related mortality. It demonstrates the competing risks for death for kidney allograft recipients after development of cancer and reinforces the need to further our understanding of cancer epidemiology post-transplantation to optimise care.

Impact of pulse pressure on patient and graft survival in renal transplant recipients: results from the Collaborative Transplant Study

Bernd Krüger[1], Bernd Döhler[2], Gerhard Opelz[2], Bernhard K.Krämer[1], Caner Süsal[2].
[1]Vth Medical Department, University Medical Center Mannheim, Mannheim, Germany; [2]Transplantation Immunology, Institute of Immunology, University of Heidelberg, Heidelberg, Germany.

Background: In kidney transplant patients, as well as in the general population, systolic blood pressure (SBP) and diastolic blood pressure (DBP) display important predictors for patient, and in the transplant population, graft survival. In addition, pulse pressure (PP), the difference between systolic and diastolic pressure, has been associated with cardiovascular and renal morbidity in the general population. Therefore we conducted the current analysis to test whether increased pulse pressure is associated with patient or graft survival in renal transplant recipients.
Methods: We included all adult patients receiving their first renal transplant from a deceased donor between 1995 and 2014 with both a functioning graft and an available blood pressure reading at year 1, in our analysis for graft and patient survival.
Results: We included 38,411 renal transplant recipients showing that a higher PP at year 1 was significantly associated with inferior death-censored graft survival. The extent of this association was comparable to the association of DBP and SBP with death-censored graft survival. In accordance lower patient survival was significantly associated with a higher PP in a linear fashion. However, in comparison to DBP or SBP this association was stronger for PP. If restricted to "death to cardiovascular disease", the analysis showed similar results for patient survival. Furthermore, we found no additional effect on death-censored graft survival for the different categories of PP when patients presented with a SBP >160 mmHg. In contrast, in patients presented with a SBP >160 mmHg as well as a PP >70 mmHg at year 1, an inferior death-censored graft survival could be shown.
Conclusions: In this large retrospective analysis of first renal transplant recipients receiving a deceased organ, based on prospectively collected data from CTS, we found convincing evidence that PP 1-year post transplant is a superior predictor of patient survival and a good predictor of death-censored graft survival.

Cardiac biomarkers correlate with changes in left ventricular mass index and diastolic dysfunction following renal transplantation.

Amy Crosthwaite[1,2], Matthew Roberts[3], Rosemary Masterson[4], Adam Hedley[1], Ruth Lim[5], Omar Farouque[2,6], Frank Ierino[1,2].
[1]Nephrology, Austin Health, Heidelberg, Australia; [2]Medicine, University of Melbourne, Melbourne, Australia; [3]Renal Medicine, Eastern Health Clinical School, Monash University, Melbourne, Australia; [4]Nephrology, Melbourne Health, Parkville, Australia; [5]Radiology, Austin Health, Heidelberg, Australia; [6]Cardiology, Austin Health, Heidelberg, Australia.

Background: Chronic and end-stage kidney disease (CKD/ESKD) is associated with profound increase in burden of Cardiovascular disease (CVD). This improves following kidney transplantation but remains a leading cause of death with a functioning graft. Asymptomatic elevation of cardiac biomarkers (high-sensitivity cardiac troponin T (hscTnT) and N-terminal proBNP (NT-proBNP)) and cardiac abnormalities detected by cardiac magnetic resonance imaging (cMRI) and transthoracic echocardiography (TTE) predict patient outcomes[1]. Early identification of abnormal cardiac biomarkers and imaging following transplantation may assist detection of early cardiac pathology and direct therapeutic strategies.
Aim: To define temporal changes in cardiac pathology demonstrated by cMRI, TTE, high-sensitivity cardiac troponin T (hs-cTnT) and NT-proBNP in incident renal transplant recipients (RTR).
Methods: cMRI and TTE were performed at enrolment and after 12 months in incident RTR (n=22). Cardiac imaging parameters measured were; Left ventricular mass index (LVMI), left ventricular ejection fraction (%EF) left atrial area (cMRI) and lateral Ee/e' (TTE). Serum was collected at 18 time points. hs-TnT and NT-proBNP (ECLIA Roche) were measured on a Roche Cobas e602 analyser. Skewed variables were log-transformed and the geometric mean compared using a paired t-test. Non-parametric variables were analysed by the Wilcoxon signed-rank test.

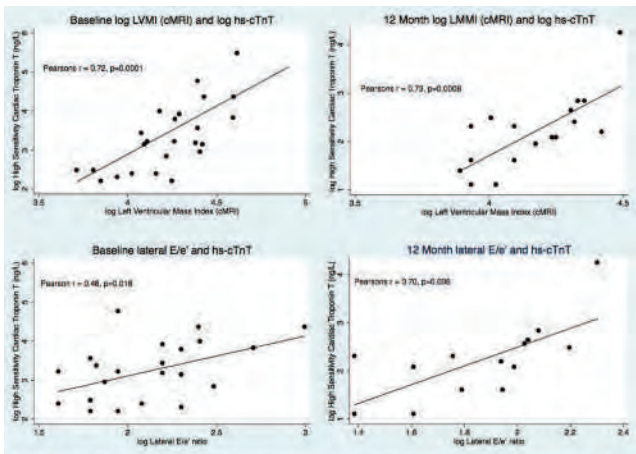

Figure 1. Correlation between high-sensitivity cardiac troponin T and baseline and 12 month (1) LVMI measured by cMRI and (2) lateral E/e' ratio measured by TTE.

Results: 22 RTR (Males 60%, age 48.1±14 years, live-donor transplant 17/22) completed follow up. No CVD clinical events were reported. After 12 months, a significant reduction in cMRI measured LVMI (69.4 g/m2 (95%CI 61-78) vs 63 g/m2 (95%CI 56-69) p=0.021), and lateral E/e' (8 (95%CI 7-9) vs 6 (95%CI 5-7), p=0.032) was demonstrated in RTR. There was a non-significant reduction in left atrial area (25cm2 (95%CI 23-27) vs 23 cm2 (95%CI 21-25), p= 0.080). Both hs-cTnT (median 27ng/L (IQR 18,40) vs 9ng/L (IQR 6,13) p<0.0001) and NT-proBNP (median 755ng/L (IQR 344,1657) vs 106ng/L (IQR 61,184) p<0.0001) were elevated at baseline and improved post transplant.

There was also continued significant decline in hs-cTnT ($p<0.0013$) and NT-proBNP ($p<0.0003$) following stabilization of GFR post transplantation. hs-cTnT demonstrated a strong correlation with LVMI (cMRI) and diastolic but not systolic dysfunction at baseline and 12 months post transplant (Figure 1). ROC analysis confirmed the ability of hs-cTnT and NT-proBNP to predict the presence of LVH (cMRI) and diastolic dysfunction (TTE) (Table 1).

Presence of Cardiac Imaging Abnormality	hs-Cardiac Troponin T		NT-proBNP	
	Baseline	12 months	Baseline	12 months
Left Ventricular Hypertrophy (ROC AUC and 95%CI)				
LVMI by cMRI	**0.85 (0.68-1.00)**	0.77 (0.29-1.00)	**0.88 (0.66-1.00)**	0.79 (0.56-1.00)
LVMI by TTE	0.46 (0.17-0.76)	0.67 (0.18-1.00)	0.64(0.34-0.94)	0.50 (0.00-1.00)
Left ventricular Systolic Dysfunction (ROC AUC and 95%CI)				
Systolic dysfunction by cMRI	0.72 (0.51-0.93)	0.65 (0.39-0.92)	0.63(0.34-0.91)	0.77 (0.48-1.00)
Systolic Dysfunction by TTE	0.55 (0.00-1.00)	0.68 (0.38-0.97)	0.76 (0.28-1.00)	**0.98(0.91-1.00)**
Diastolic Dysfunction (TTE) (ROC AUC and 95%CI)				
Diastolic Dysfunction	**0.81 (0.56-1.00)**	**0.82 (0.60-1.00)**	0.80 (0.57-1.00)	0.69 (0.09-1.00)

Table 1. AUC for Receiver Operating Characteristic (ROC) curve (95%CI) for ability of cardiac biomarkers to predict the presence of cardiac abnormalities.

Conclusion: This study demonstrates that LVMI, hs-cTnT and NT=proBNP reduce post renal transplantation. Higher hs-cTnT levels predict increased LVMI before and after transplantation. The strong association of the biomarkers with LVMI after restoring renal function suggests that increased LV mass stongly contributes to biomarker levels. The correlation of biomarkers with prognostic cardiac pathology indicates potential clinical utility in identifying RTR with early CVD.

Integrative, multi-cohort analysis of Epstein-Barr Virus (EBV)-positive and negative tumor samples to identify gene-signatures associated with EBV oncogenesis

Eden Maloney, Erika Bongen, Francesco Vallania, Nikesh Kotecha, Purvesh Khatri, Olivia MMartinez.
Stanford University School of Medicine, Stanford, CA, United States.

Introduction: EBV is linked to a variety of lymphoid and epithelial malignancies. In transplant recipients EBV is associated with the development of B cell lymphomas in post-transplant lymphoproliferative disorder (PTLD). We performed an integrative, multi-cohort analysis of EBV-positive and negative tumor samples to identify shared gene-signatures associated with EBV oncogenesis.

Methods: For our analysis, we selected three gene expression data sets (Gastric Cancer, PTLD, and Hodgkin's Lymphoma) that compared EBV-positive to EBV-negative tumors (n =170, collected from Gene Expression Omnibus). For each data set, we plotted the geometric mean of each gene probe to check for proper normalization and batch effects. The Hedges' g effect size, a measure of magnitude, was calculated for each gene in each dataset. To study the absolute change in expression of the three data sets, a meta-effect size was created by combining the gene effect sizes from each data set. Using a False Discovery Rate of < 0.05 and an Effect Size of 0.8, we utilized two meta-analysis methods, the random-effects model and the Fischer's sum-of-logs method. Leave-one-out validation was used to prevent bias from a large dataset. We validated the EBV-positive tumor signature with an independent gene expression data set (n = 8).

Results: We identified 30 human genes that were significantly up-regulated and five human genes that were significantly down-regulated in EBV-positive tumors. Of the top 15 most significant genes, nine have proposed roles in oncogenesis; for example, PMAIP1 is up-regulated in adult T cell leukemia and SESN2 contributes to p53 signaling. However, only FGR was previously shown to be up-regulated in EBV-associated tumors; thus, these genes provide potential novel mechanisms of EBV oncogenesis. Overall, of the 35 genes, 17 have known or proposed mechanisms in oncogenesis, six have unknown functions, eight are immune regulators, and four are cellular homeostasis enzymes. Of note, CD38 and TLR7, known targets in cancer therapy, were up-regulated in EBV-positive tumors indicating that this approach can identify viable therapeutics.

Receiver operating characteristic curves, violin plots, and forest plots demonstrated that the 35 genes were able to significantly distinguish EBV-positive from EBV-negative tumors in each dataset. Importantly, the EBV-specific gene signature was able to significantly separate EBV-positive and EBV-negative samples in a validation analysis of an independent Burkitt's Lymphoma cell line dataset.

Conclusion: An integrative, multi-cohort analysis of three gene expression datasets produced a gene signature of 35 genes that robustly discerns EBV-positive from EBV-negative tumors. These results suggest common underlying mechanisms of viral transformation in EBV-positive tumors and may identify new opportunities for drug targeting or predictive diagnostics.

The relative costs and health benefits of an age-matched deceased donor allocation algorithm compared to current practice

Vaishnavi Calisa[1], Jonathan Craig[1,4], Steve Chadban[1,3], Wai Lim[1,6], Kirsten Howard[1,4], Jeremy Chapman[1,2], Stephen McDonald[1,5], Germaine Wong[1,4].
[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [2]Centre for Transplant and Renal Research , The Westmead Institute for Medical Research, Sydney, Australia; [3]Royal Prince Alfred Hospital , Sydney, Australia; [4]Sydney School of Public Health, The University of Sydney, Sydney, Australia; [5]ANZDATA Registry, The University of Adelaide, Adelaide, Australia; [6]The University of Western Australia, Perth, Australia.

Introduction: Increasing demand for kidney donors in past decades has led to widespread use of expanded criteria donors (ECD), with variable outcomes for recipients. To ensure equity and utility in graft allocation, one proposed strategy is "age-matching", in which donor-recipient age mismatch is restricted. This approach may improve survival gains for younger recipients but may adversely affect survival and quality of life for older recipients due to the decreased availability of younger donor kidneys for this group. However, the extent to which health benefits occur across different age groups, under age-matching, is unknown. This study aimed to determine the incremental costs and benefits of an age-matched model of deceased donor kidney allocation, in comparison to current practice.
Materials and Methods: Probabilistic Markov models were created to determine the incremental healthcare costs and life years gained under age-matched practice, where donor-recipient age mismatch was ≤10 years, in comparison to current practice in the age groups, ≤30 years, 30 to 45 years, 45 to 60 years and >60 years. Mortality and graft survival estimates were sourced from the ANZDATA registry (1990–2012). Quality of life outcomes and direct healthcare costs were derived from published literature.
Results and Discussion: Compared to current practice, the incremental benefits and costs of age-matched allocation were 0.31 QALYs (SD: 1.95 QALYs) and -$78153 (SD: $146917) in younger recipients (≤30 years). This finding was consistent for recipients between 30 and 45 years. However, an age-matched system incurred negative benefits of 0.33 QALYs (SD: 1.38 QALYs) for those aged between 45 and 60. At a willingness-to-pay threshold of $50,000/QALY, the probability that age-matching was cost-effective compared to current practice was 77% and 63% amongst recipients aged ≤30 years and 30 to 45 years, respectively. Conversely, for those aged 45 to 60 years and over 60 years, these probabilities were reduced to 33% and 29%, respectively (Figure 1). Across all ages, an age-matching algorithm incurred a total loss of 0.16 QALYs (SD: 6.77 QALYs) in comparison to current practice.
Conclusion: At a population level, age-matched deceased donor algorithm did not incur any health benefits compared with current practice. At an individual level, the overall health benefits in the young were at best modest, and at the expense of a significant decline in survival and quality of life among the aged.

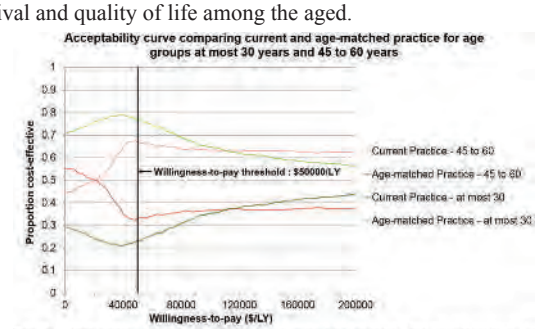

Figure 1: Cost-effectiveness acceptability curve comparing age-matched and current practice for those at most 30 years of age and those 45-60 years of age. The vertical black line indicates the standard willingness-to-pay threshold of $50,000/LY.

Donor-recipient age mismatches: the relative benefits and costs of waitlisting, transplantation and dialysis

Vaishnavi Calisa[1], Jonathan Craig[1,2], Steve Chadban[1,4], Wai Lim[1,6], Kirsten Howard[1,2], Jeremy Chapman[1,3], Stephen McDonald[1,5], Germaine Wong[1,2].
[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [2]Sydney School of Public Health, The University of Sydney, Sydney, Australia; [3]Centre for Transplant and Renal Research, The Westmead Institute for Medical Research, Sydney, Australia; [4]Royal Prince Alfred Hospital , Sydney, Australia; [5]ANZDATA Registry, The University of Adelaide, Adelaide, Australia; [6]The University of Western Australia, Perth, Australia.

Introduction: Increasing demand for kidney donors in past decades has led to widespread use of expanded criteria donors (ECD). In comparison to dialysis, the survival benefits of receiving an ECD graft are age-dependent, with limited gain in life years for younger compared with older recipients. This study aimed to determine the incremental benefits of listing and transplant with various donor-recipient age differences, in comparison to being on dialysis.
Materials and Methods: Using current outcomes for patients on dialysis and graft recipients with a range of donor-recipient age mismatches, probabilistic Markov models were created to compare the health and economic benefits of waitlisting and transplantation, with dialysis. Mortality and graft survival estimates were sourced from the ANZDATA registry (1990 – 2012). Quality of life outcomes and direct healthcare costs were derived from published literature.
Results and Discussion: Compared to dialysis, listing and transplantation was cost-saving by an average of -$105,035 (SD: $326,761). Incremental benefits decreased with increasing donor-recipient age mismatch across all age groups. Amongst the 45 to 60 year-olds, gains of at least 0.70 LYs (SD: 4.54 LYs) and 1.36 QALYs (SD: 2.39 QALYs) and up to 4.58 LYs (SD: 4.90 LYs) and 4.06 QALYs (SD: 3.29 QALYs), corresponding to donor-recipient age mismatches of -25 to -20 years and +15 to +20 years, respectively, were observed. Similar trends were observed for 30-45 year-olds, with incremental benefits decreasing from 6.94 LYs (SD: 5.32 LYs), for age mismatches of -10 to -5 years, to 3.68 LYs (SD: 5.28 LYs) for +20 to +25 years mismatch. For recipients over 60, this trend was less marked, with incremental benefits ranging between 0.72 LYs (SD: 4.37 LYs) and 3.26 LYs (SD: 4.76 LYs). An age mismatch over +27 years offered no survival benefit (Figure 1). At a willingness-to-pay threshold of $50,000/LYs, the probabilities that listing and transplantation was cost-effective compared to dialysis were 90.1% and 99.3% for age mismatches of at least 20 years and -30 to -25 years, respectively (Figure 2).
Conclusion: Minimising donor-recipient age mismatch improves incremental gains in survival for all recipients, in comparison to remaining on dialysis. This strategy will incur the greatest benefits for those under 45, many of whom, currently receive much older renal allografts.

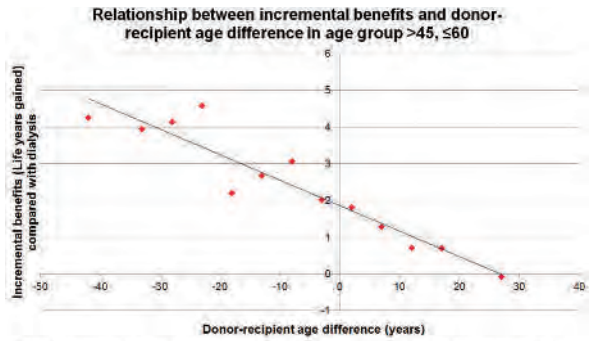

Figure 1 Association between life years gained being listed and transplanted and the donor-recipient age mismatch associated with the transplant

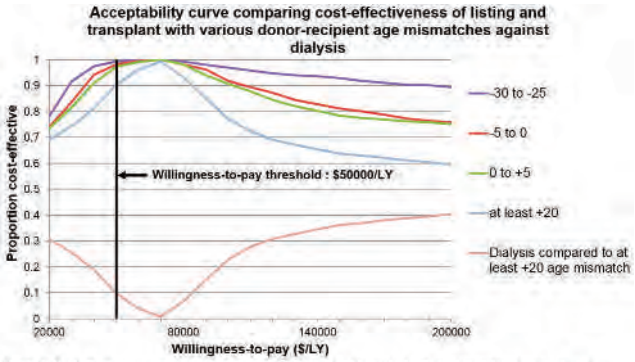

Figure 2. Cost-effectiveness acceptability curve comparing listing and transplant with a range of donor-recipient age mismatches against remaining on dialysis. The vertical black line indicates the standard willingness-to-pay threshold of $50,000/LY.

453.3

Scope and heterogeneity of outcomes reported in Cochrane systematic reviews of kidney transplantation

Benedicte Sautenet[1,2,3], Jonathan C.Craig [1,2], Nicole Evangelidis[1,2], Jeremy R.Chapman [4], John Gill [5], Germaine Wong [1,2,4], Allison Tong[1,2].
[1]Sydney School of Public Health, The University of Sydney, Sydney, Australia; [2]Centre for Kidney Research, The Children's Hospital at Westmead, Westmead, Australia; [3]University Francois-Rabelais, Tours, France; [4]Centre for Transplant and Renal Research, Westmead Hospital, Westmead, Australia; [5]Division of Nephrology, University of British Columbia, Vancouver, BC, Canada.

Aims: The heterogeneity and bias in selecting and reporting outcomes can limit the relevance and utility of systematic reviews (SRs) in informing shared decision-making. We aimed to assess the scope and consistency of outcomes reported in SRs for kidney transplant recipients.
Methods: The Cochrane Database of SRs was searched to November 2015 for published SRs of all interventions for kidney transplant recipients. All outcomes were extracted and clustered into domains, and the frequency of outcomes reported across all SRs was assessed.
Results: 30 SRs with 422 trials reported 1115 outcomes that clustered in 35 outcome domains. Only five outcome domains were reported in at least half of the SRs: mortality (29 SRs [97%]), graft function (25 [83%]), graft loss (24[80%]), graft rejection (17[57%]) and infection (15[50%]). The next three most frequently reported outcomes were cancer (14[47%]), cardiovascular diseases (13[43%]) and lipids (10[33%]). Patient-reported outcomes including mental health, health status, sleep, pain, physical function, were seldom reported (<20% of SRs). There was substantial variability in the tests, timing, and thresholds used to define and measure the outcomes.
Conclusions: Mortality and graft outcomes are frequently reported in Cochrane SRs of kidney transplantation, whereas other patient-centred outcomes including psychosocial status, mental and physical function are uncommon. These findings presumably reflect the outcomes reported in the corresponding trials. A standardised set of core outcomes based on the shared priorities of patients and health professionals in kidney transplantation may help maximise the value of SRs to inform clinical decision-making.

Timely transplantation: Improving access to early transplantation and active transplantation listing within six months of starting renal replacement therapy

Megan Brown, Kevan Polkinghorne, Orla Maney, John Kanellis. Nephrology, Monash Health, Clayton, Australia.

Introduction: Renal transplantation is the optimal therapy for end stage renal failure (ESRF). In this context, a Key Performance Indicator (KPI) was developed in Victoria measuring the proportion of new ESRF patients <65yo who either receive a transplant or are actively listed within three and six months of starting renal replacement therapy (RRT); with goals of 30% and 50% respectively. This study aims to identify the barriers to meeting this KPI within a single transplant service.

Materials and Methods: Patients <65yo commencing RRT between 01/01/2012 and 12/12/2014 were retrospectively analysed. Data was collected on demographics, dialysis factors, comorbidities, social and systemic factors. Patients were grouped according to whether they met the six month KPI or not. Those not meeting the KPI had their main barrier to listing categorised.

Table 1: Comparison of major factors between those who met the KPI and those who did not

	Listed within 6 months (N=63)		Not listed within 6 months (N=121)		P value
	Total no.	%	Total no.	%	P=
Patient Demographics					
Age at RRT	47	NA	42.8	NA	0.018

Non-Adherence	3	4.8%	47	38.8%	<0.001
Systemic issues					
Referred for transplant assessment before RRT	60	96.8%	50	40.9%	<0.001

Results:183 patients were included; 62/183 met the KPI, 121/183 did not. 27/62 (43.5%) who met the KPI were transplanted within six months, with 21/62 occurring pre-emptively. There were significant differences in the cause of ESRF and comorbidities between groups ($p<0.001$, table 1). Those not meeting the KPI were more likely to start RRT with temporary access and less likely to receive pre-dialysis education ($p<0.001$; table 1). Most delays were multifactorial, however 27/121 (22%) were limited by systemic factors alone. 96.8% who met the KPI were referred for transplantation assessment prior to RRT with a referral date of 12.8±8.8 (mean±SD) months pre-RRT.

Discussion: Multiple factors make timely transplantation and listing difficult. Living donor and pre-emptive transplants had a large role in allowing patients to meet the KPI, providing the greatest opportunity for early transplantation. Correcting systemic factors could increase the proportion of patients achieving the six month KPI to 48.6%. Other barriers are consistent across multiple units.

Conclusion: Many of the barriers identified are not easily modifiable, however systemic factors have the potential for significant improvement. This involves optimising both referral and workup processes. A state-wide evaluation may be useful to reassess the value of this KPI as an appropriate measurement tool, and to consider a shared approach to dealing with common barriers.

453.5

Roux-en-Y gastric bypass as a bridge to kidney transplantation: effective but how safe?

Ian Thomas[1], Nestor De La Cruz-Munoz[2], Tameka Joseph[3], Jeffrey Gaynor[1], Franco Cabeza[1], David Roth[1], Warren Kupin[1], Adela Mattiazzi[1], Linda Chen[1], George Burke[1], Gaetano Ciancio[1], Junichiro Sageshima[1], Rodrigo Vianna[1], Giselle Guerra[1].
[1]Kidney Transplant, Miami Transplant Institute, Miami, United States; [2]Surgery, University of Miami, Miami, United States; [3]Internal Medicine, University of Miami, Miami, United States.

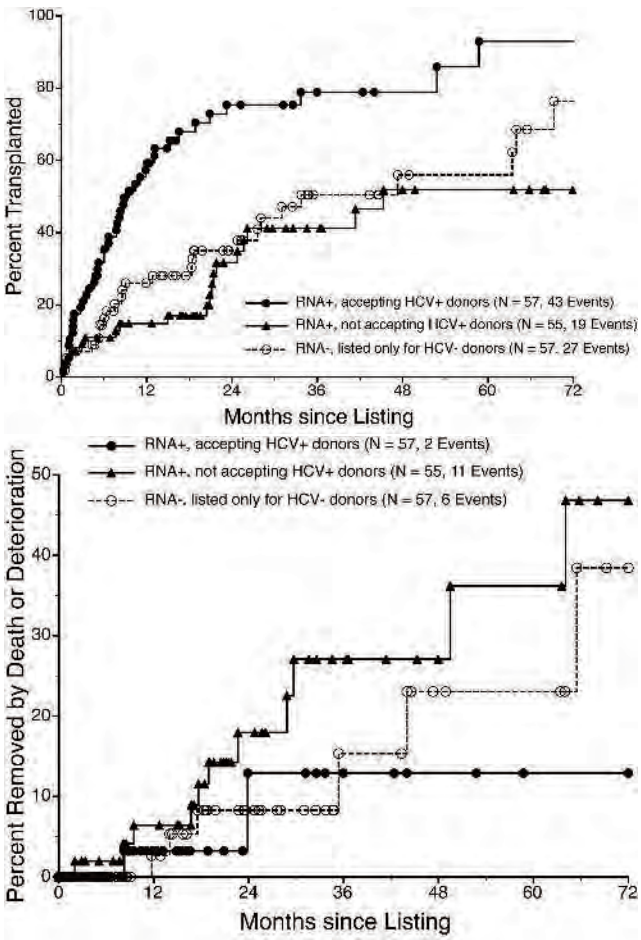
Introduction: Evaluation of body mass index (BMI) in potential kidney transplant recipients is an important component of the pre-transplant evaluation. A BMI greater than 40 kg/m2 (or in some centers more than 35 kg/m2) is considered a contraindication to transplantation due to an increased risk of wound complications, delayed graft function, venous thrombosis, new-onset diabetes after transplantation and cardiovascular complications. Roux-en-Y gastric bypass (RYGB) is frequently performed pre-transplant to help morbidly obese patients reach the target BMI. We sought to evaluate the pre-transplant outcomes for obese patients having RYGB and post-transplant outcomes in the subset of patients who were transplanted.
Materials and Methods: After reviewing the list of patients having RYGB at our institution between July 2009 and June 2014, the group of patients receiving kidney transplants after RYGB was extracted. A cohort of all patients (between March 2009 and June 2011) not having any bariatric surgery procedure with a BMI greater than 37kg/m2 at the time of kidney transplantation was used as a historical control group. The charts of both groups were reviewed to evaluate and compare pre-transplant outcomes after RYGB (where applicable) and post-transplant outcomes. These were followed until May 31, 2015.
Results: Complete anthropometric data were found for 31 of 33 kidney transplant candidates who had RYGB. 11 of these were subsequently transplanted up to the follow up period. 25 historical controls (non-RYGB obese group) were identified.
In the RYGB group, mean BMI (+ standard error) before gastric bypass was 43.5 + 0.7 kg/m2 (range: 35.4–50.5 kg/m2). A total of 87.1% (27/31) achieved a BMI <35 kg/m2. Observed mean percentage excess weight loss was 72.8% + 3.0%. The percentage having improved control of diabetes/hypertension was 29.0% (9/31); 25.8% (8/31) had complications (mostly minor) after gastric bypass.
After transplantation, no cases of new-onset diabetes or oxalate nephrolithiasis/nephropathy were observed. Biopsy-proven acute rejection was seen in 5/11 RYGB patients compared to 3/25 controls (P = 0.002). Infection requiring hospitalization was seen in 9/11 RYGB patients compared to 12/25 in the control group (P = 0.02). Death-censored graft loss occurred in the 2/11 of the RYGB group compared to 3/25 in the control group (P=0.05). No mortality was observed in the RYGB group. 4 deaths with functioning graft occurred in the non-RYGB group, p =0.2. Morbidly obese kidney transplant patients that did not have bariatric surgery before transplantation seem to have a higher mortality than the RYGB group.
Conclusion: RYGB has been successfully used as a bridge to transplantation at our center. The vast majority of patients having this procedure pre-transplant will reach the target weight allowing them to be listed for transplantation in hope of improving patient survival. Moreover, the reported complications of bariatric surgery are usually self-limited and minor. The increased rates of biopsy-proven acute rejection and borderline higher rate of death-censored graft loss may result from changes in pharmacokinetics of immunosuppressant drugs within this population. Further studies assessing this and other variables such as newer bariatric surgery procedures are warranted for short and long-term analysis.

453.6

Hepatitis C RNA-positive patients who are willing to accept hepatitis C seropositive kidneys have better transplant access and favorable waitlist outcomes

Junichiro Sageshima[1], Angelo de Mattos[2], Chandrasekar Santhanakrishnan[1], John McVicar[1], Mehul Gandhi[2], Muna Alnimri[2], Brian Gallay[2], Christoph Troppmann[1], Richard Perez[1].
[1]Surgery, University of California, Davis, Sacramento, CA, United States; [2]Internal Medicine, University of California, Davis, Sacramento, CA, United States.

Background: kidney transplantation from hepatitis C seropositive (HCV+) donors may benefit hepatitis C RNA-positive (RNA+) candidates, but it is not clear how the acceptance/listing status of such kidneys affect waitlist and transplant outcomes.
Methods: In a single-center retrospective analysis, HCV+ transplant candidates (N=169) who were placed on the deceased donor kidney waitlist from March 2004 to February 2015 were evaluated for waitlist and posttransplant outcomes. All RNA+ candidates were offered the option to be listed for HCV+ donors (in addition to HCV seronegative [HCV-] donors) in UNet after informed consent was obtained. RNA- candidates were listed only for HCV- donors.
Results: Fifty-seven patients (51% of all RNA+) were willing to accept HCV+ kidneys and listed both for HCV+ and HCV- donors. During 6-yr follow up, 43 of 57 (75%) RNA+ patients accepting HCV+ donors vs. 19 of 55 (35%) RNA+ patients not accepting HCV+ donors received a deceased donor kidney transplant with median waiting time of 9 mo vs. 45 mo, respectively (P<.0001).



Multivariable analysis demonstrated that HCV listing status (P=.0005) and waiting time (P<.0001) were associated with receiving a transplant. More patients not accepting HCV+ donors (vs. accepting HCV+ donors) were removed from the list due to death or deteriorated medical condition (20% vs. 4%, P=.0046).
Posttransplant patient survival rates were similar for patients accepting vs. not accepting HCV+ donors (70% vs. 67% at 6 yrs, P=.55). On multivariable analysis, donor HCV status did not impact posttransplant patient or graft survival. Patient and graft survival rates for HCV+ vs. HCV- donor transplants at 6 yrs were 74% vs. 59% (P=.93) and 59% vs. 52% (P=.43), respectively.
Conclusion: HCV RNA+ patients significantly benefit if they are willing to accept HCV+ kidneys as they have superior waitlist and equivalent transplant outcomes.

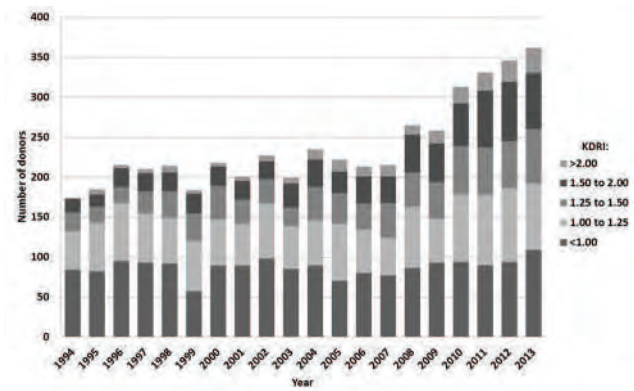
Change in deceased kidney donor characteristics and kidney donor risk index (KDRI) in Australia and New Zealand over twenty years

Samuel Chan[1,2,3], Scott B. Campbell[1,2,3], Phillip A.Clayton[4,5], David W.Mudge[1,2,3], David W.Johnson[1,2,3], Ross Francis[1,2,3].
[1]Queensland Renal Transplant Service, Princess Alexandra Hospital, Brisbane, Australia; [2]School of Medicine, The University of Queensland, Brisbane, Australia; [3]Department of Nephrology, Princess Alexandra Hospital, Brisbane, Australia; [4]Central Northern Adelaide Renal and Transplantation Service, Royal Adelaide Hospital, Adelaide, Australia; [5]ANZDATA, Australia and New Zealand Dialysis and Transplant Registry, Adelaide, Australia.

Aim: To review changes in deceased kidney donor characteristics in Australia and New Zealand between 1994 and 2013
Methods: A retrospective analysis of all deceased kidney donors in Australia and New Zealand between 1 January 1994 and 31 December 2013 using data from the Australia and New Zealand Organ Donor Registry using the Kidney Donor Risk Index (KDRI) as a surrogate measure of donor quality
Results: Of 4,689 deceased donors, 57% were male and 89% were from Australia. Annual donor numbers increased from 158 in 1994 to 360 in 2013. Mean donor age increased from 35.7 ± 16 years to 46.1 ± 17.6 years over time. As the primary cause of death, motor vehicle accidents reduced from 16.5% to 3.5% and cerebral pathology increased from 52% to 64%. There was an increase in the proportion of donors with hypertension (11.4% to 24.2%) or diabetes (1.3% to 7%) between 1994 and 2013. The proportion of donors who were overweight or obese increased from 38.5% to 58.4%. These changes in donor characteristics were reflected by a rise in the median KDRI from 1.01 ± 0.29 to 1.22 ± 0.4 (slope for linear regression of log-transformed KDRI = 0.009 (95% CI 0.007 to 0.010, p<0.001). When divided into 5 categories of KDRI, the proportion of higher risk donors has increased over time (Figure 1).



Conclusions: As deceased kidney donor numbers have increased, the range of donor quality has increased, with an increase in the proportion and number of high-risk donors, and a decrease in donor quality. These data highlight the need for kidney allocation algorithms to evolve to ensure appropriate allocation of deceased donor kidneys.

453.8

99-100% cPRA deceased donor kidney transplants pre and post new kidney allocation system (KAS) - a single center perspective

Hasan Khamash, Kunam S.Reddy, Marcelo Pando Rigal, Andrew Singer, Raymond Heilman.
Transplant Center, Mayo Clinic Arizona, Phoenix, United States.

The new Kidney Allocation System (KAS) in the United States was implemented on December 4th 2014 with goals of increasing allocation fairness and providing transplant opportunities for difficult to match candidates including the highly sensitized. Prior to KAS candidates with cPRA 99-100% had dismal transplant rates of <3% that increased nationally to >14% due to regional and national priority allocation.
We wanted to assess in our center the percentage and group characteristics of deceased donor kidney alone recipients with cPRA 99-100% pre and post KAS following one complete year of implementation.
We included all kidney alone deceased donor transplants between January 1st 2010 and December 4th 2015. 871 patients were identified, and out of this cohort 30 recipients had cPRA of 99-100% prior to transplant with follow up through January 2016. Prior to KAS 13 patients were transplanted out of 634 deceased kidney transplants(2 %) compared to 17 out of 237 (7.2%) in the year following KAS implementation. The sensitized cohort was mostly female 19/30 (63%), with a history of previous transplants 18/30 (60%) and mostly on dialysis 29/30 (97%) prior to transplant. 20/30 (67%) received rATG induction and all were maintained on 3 drug immunosuppression including prednisone.
We compared the sensitized groups pre and post KAS. They had similar age, demographics, retransplant rates and Kidney Donor Profile Index. They significantly differed in the number of HLA mismatches and the wait time on the list. Table. The increase in wait post KAS is likely due to the roll back of wait time to dialysis start date. Number of HLA mismatches (ABDR) was significantly lower pre KAS with higher percentage of 0 mismatch transplants compared to post KAS.There were 4 cases of rejection in the pre KAS group with one antibody mediated. Only one cellular rejection case post KAS and no graft loss in either group.

	Pre-KAS(13)	Post-KAS(17)	p
Age(yr)	48±12	51±14	.6
Retransplants	8(62%)	10(59%)	.9
Wait Time(days)	1434±1235	2418±1169	.03
HLA mismatches	0.9±1.5	3±1.5	.001
0 mismatch	9(69%)	2(12%)	.001

Conclusion: We demonstrate at the center level the increased transplant percentage for candidates with cPRA 99-100% through regional and national priority allocation of deceased donor kidneys.

453.9

A retrospective cohort study on the association between donor kidney KDRI score and re-hospitalization in transplant recipients

Wilson Lin, Yuliana Noah, Colin Dunn, Stuart Greenstein.
Albert Einstein College of Medicine, Bronx, NY, United States.

Introduction: Although kidney transplantation is considered the best treatment for end stage renal disease, the number of kidneys available for transplantation each year is insufficient to reduce the number of patients on the waiting list. One strategy to expand the kidney donor pool has been to incorporate the use of non-ideal donor kidneys, such as those from hypertensive or cardiac death donors. Several scoring systems exist to assess the quality of these 'marginal' kidneys. While Expanded Criteria Donor (ECD) status has been mainly used in the past, the Kidney Donor Risk Index (KDRI) has recently come to be regarded as a better measurement, since it incorporates more donor factors and is a continuous score rather than a binary indicator. However, studies evaluating its capability to predict recipient outcomes are scarce. This study seeks to determine the degree of correlation between KDRI values of donor kidneys and incidence of re-hospitalization in transplant recipients.
Materials and Methods: A cohort of 526 deceased donor kidneys transplanted between 2003 and 2013 was retrospectively examined. Cox proportional hazards modeling was used to determine the association between KDRI and the occurrence of at least one recipient re-hospitalization within the first two years post-transplant. Poisson regression analysis was used to assess the relationship between KDRI and total number of re-hospitalizations within the first two years post-transplant, as well individually for the first year and the second year. Both analyses were adjusted for the covariates that significantly affected re-hospitalization: time on dialysis, presence of psychiatric illness, and use of mycophenolate mofetil. The Poisson regression analysis only incorporated 471 recipients due to insufficient follow-up duration (< 2 years).
Results and Discussion: The recipient cohort was 42.1% Black, 36.6% Hispanic, and 21.3% White/Other; the mean age was 52.7, mean time on dialysis was 4.61 years, and mean BMI was 27.4. The mean donor kidney age was 43.9; KDRI values ranged from 0.639 to 2.80, with a mean of 1.29. Cox proportional hazards modeling revealed a hazard ratio of 1.180 ($p=0.1609$), meaning the hazard rate increased by ~18% with each unit increase in KDRI. Poisson regression analysis indicated that the expected log count increase in total number of re-hospitalizations per unit increase in KDRI is 0.3006 ($p<0.001$). The increase was 0.3253 ($p<0.001$) during the first year post-transplantation, and 0.2654 ($p=0.002$) during the second year.
Conclusion: KDRI did not correlate significantly with the occurrence of recipients being re-hospitalized at least once ($p=0.1609$). However, it was a significant predictor of total number of re-hospitalizations ($p<0.001$), with a greater impact during the first year post-transplant than the second year (0.3253 versus 0.2654).

454.1

Assessment of immune mediators in plasma for detection of chronic rejection after heart transplantation

Christoph Bara[1], Bianca Przybylek[1], Anneke Neumann[1], Axel Haverich[1], Christine Falk[2].
[1]Department of Cardiothoracic, Transplantation and Vascular Surgery, Hannover Medical School (MHH), Hannover, Germany; [2]Institute of Transplant Immunology, IFB-Tx, Hannover Medical School (MHH), Hannover, Germany.

Purpose: Typical manifestation of chronic rejection in transplanted heart is onset of so called cardiac allograft vasculopathy (CAV) in the coronary arteries. It remains a common cause of death after heart transplantation (HTx) and one of the most limiting aspects for long-term graft survival. The inflammatory process is supposed to be one of the central factors in the pathogenesis of CAV. Immune mediators, which are part of an inflammatory immune response, are serologically detectable in various cardiovascular diseases, including native coronary artery disease and myocardial infarction. Therefore, we hypothesized that certain mediators, being present in blood in higher amounts than others, may serve as non-invasive biomarkers for CAV.
Methods: In order to investigate the cytokine microenvironment in these patients, we performed profiling of plasma samples of patients after HTx (n=31) with angiographic confirmed moderate or severe CAV (ISHLT 2 or 3) and a control group of patients without CAV (ISHLT 0, n=23) at least 5 years after HTx. We focused on IL-4, IL-6, IL-10, IL-17, IL-21, IL-23, IL-31, IL-33, IFN-g, TNF-α and sCD40L in order to uncover potential changes in the Th1/2/17 balance. Furthermore, we compared the plasma levels among themselves and correlated the increase or decrease of each of them with another one.
Results: There were no significant differences between the groups for IL-6, IL-23, IL-33, IFN-g and sCD40L concentrations. Although IL-4, IL-21 and IL-31 concentrations were higher in CAV sera, they did not show any statistical significance (p=0,058 – 0,067). However, IL-10 and TNF-α concentrations were significantly elevated in plasma of CAV patients (p<0,05). Eleven combinations of mediator levels correlated with each other in both - the CAV and non-CAV group. There were 15 combinations that correlated with each other in the non-CAV patients but only two of them (IL-21 vs. IL-33 and IL-6 vs. sCD40L) could be found solely in the CAV patients.
Conclusion: The detection of higher IL-10 and TNF-α concentrations in plasma of CAV patients indicates a systemic pro-inflammatory process associated with chronic rejection and the development of CAV. The simultaneous increase of IL-21 and IL-33 or IL-6 and sCD40L may support an acceleration of this process. Thus, cytokine quantification could be helpful to identify the patients with increased risk of developing CAV after HTx.

Air pollution can support a chronic rejection after heart transplantation

Christoph Bara, D. Böthig, Y. Scheibner, B. Przybylek, A. Haverich.
Department of Cardiothoracic, Transplantation and Vascular Surgery, Hannover Medical School (MHH), Hannover, Germany.

Purpose: The main clinical form of chronic rejection after heart transplantation (HTx) is the development of cardiac allograft vasculopathy (CAV). It is the most limiting factor leading to reduced graft function and one of the most common causes of death in long-term follow-up after HTx. Despite the development of novel immunosuppressive regimes, the prevalence of CAV has not significantly been reduced. A number of studies have shown the association between exposure to air pollution and the development of cardiovascular disease. The impact of air pollution on chronic rejection after lung transplantation has been demonstrated. Therefore, we hypothesized that air pollution could also affect the development of CAV after HTx.
Methods: In order to assess the potential impact of air pollution on CAV, we selected 50 consecutive patients with angiographic-confirmed moderate or severe CAV (ISHLT 2 or 3) that visited our out-patient clinic and 55 consecutive patients without CAV (ISHLT 0). All patients were at least 5 years post-HTx. Based on air pollution data published by the German Environment Office, we estimated the exposure to particulate matter (PM) of different sizes (eg. PM2.5 and PM10). Various dichotomization values for both available PM concentrations were entered into series of Kaplan Meier freedom from CAV estimations to maximize the contrast between the resulting groups. Statistical differences between the curves were assessed with log rank, Breslow-, and Tarone-Ware tests.
Subsequently, a Cox regression model was formed including the potential risk factors i.e. body mass index, CMV-infection, postoperative need for dialysis, diabetes, and hypertension. In order to take into account potential factors with non-proportional hazards, the product of event times and potential factors were also included in the model.
Results: There were no statistically significant differences between patients with or without CAV concerning age, body mass index, donor and recipients' CMV-antigen status, previous CMV-infection, number of previous organ rejections, diabetes, or hypertension. However, the most contrasting air pollution indicator threshold was more than 15 µg/m³ of PM sized 2.5 µm: According to the log rank test, the error probability was 6.5%, Breslow estimated 3.3% and Tarone Ware 4.3%. The stepwise backwards Cox regression resulted in considering the same pollution indicator as the only remaining significant risk factor (p=1.9%, HR = 2.44). Including PM2.5 as a continuous variable, PM2.5 concentration was also a significant independent risk factor for CAV development (p=0.039, HR = 1.155).
Conclusion: Air pollution should be considered as an additional risk factor in the development of CAV after heart transplantation. Further investigations are necessary to confirm these observations in a larger study population and to identify the underlying pathological mechanisms.

Pre-sensitized immune condition of host exaggerates prolonged cold ischemia-mediated injury of cardiac graft involving in regulatory T cells

Weihua Gong[1], Fangmin Ge[1], Baoqing Liu[2].
[1]Surgery and Medicine, Second Affiliated Hospital of Zhejiang University, Hangzhou , People's Republic of China; [2]Zhejiang University, Hong Kong, Hong Kong.

Background: The detrimental effect of prolonged cold ischemia time (PCI) on pre-sensitized transplanted graft is conceivable, but impact of pre-sensitization status of recipient on PCI-mediated graft injury and inflammation is not well-defined.
Methods: Allogeneic skin grafts from Balb/c donors were transplanted into C57BL/6 recipients for pre-sensitization. Syngeneic or allogeneic heterotopic heart transplantations with PCI were performed using C57BL/6 or BALB/c donors for these recipients through different treatments.
Results: We revealed that PCI could not affect isograft survival but significantly shortened allograft survival in the pre-sensitized recipients. Depletion of regulatory T cells (Tregs) starting 1 day before and after heart transplantation with anti-CD25 mAb remarkably induced intragraft Foxp3 gene expression, worsened architecture damage and subepicardial and intramuscle inflammatory cellular infiltration, and caused a dramatic fall of intragraft CD4+/CD8+ ratio, while adoptive transfer of exogenous wild-type Tregs or endogenous Tregs promoted by Rapamycin had a beneficial effect on preventing the infiltration of T lymphocytes and Gr-1+ neutrophils, reversed intragraft CD4+/CD8+ ratio, preserving cardiac graft architecture. However, their distinct protective mechanisms showed that Rapamycin treatment mainly diminished CD4+ T cells infiltration. Nevertheless, CD4+ still outnumbered CD8+ T cells in the graft, while adoptive transfer of Tregs expanded both CD4+ and CD8+ T cells, particularly CD8+ T cells.
Conclusion: Allogeneic immunoresponses synergistically enhanced PCI effect under pre-sensitized condition. PCI could affect subsequent immunoresponses. Tregs were closely involved in this pathophysiological process. Our data may pave the way to utilize Tregs as a novel therapeutic approach to prevent PCI-mediated injury in the pre-sensitized transplant recipients.

Altered immunogenicity of porcine hearts via ex vivo perfusion

William Critchley[1,2], John P.Stone[1,2], Parminder Chaggar[1,2], Qiuming Liao[4], Guangqi Qin[4], Rajamiyer Venkateswaran[3], Trygve Sjöberg[4], Stig Steen[4], James Fildes[1,2].
[1]Manchester Collaborative Centre for Inflammation Research, University of Manchester, Manchester, United Kingdom; [2]The Transplant Centre, University Hospital of South Manchester, Manchester, United Kingdom; [3]Department of Cardiothoracic Surgery, University Hospital of South Manchester, Manchester, United Kingdom; [4]Department of Cardiothoracic Surgery, Lund University, Lund, Sweden.

Introduction: Graft rejection is a major barrier to heart transplantation success and fundamentally requires the activation of recipient immunity. Many donor organs a contain significant leukocyte reservoirs, which, upon transplantation, are able to migrate to recipient lymph nodes and prime recipient allospecific T cells, initiating a rejection response. We aimed to profile the donor myocardial leukocyte content and to determine whether ex vivo perfusion of the heart promotes immune migration into the circuit and thus immunodepletion of the donor organ prior to transplantation.
Methods: Six isolated porcine hearts were attached to an ex vivo circuit and underwent hypothermic, cardioplegic perfusion for 8 hours. Biopsy samples were taken both pre- and post- perfusion. Perfusate samples were taken before organ attachment, and at 2, 4, 6 and 8 hours. Leukocyte populations were quantified in biopsy and perfusate samples by flow cytometry. In perfusate samples, cell-free DNA and 13 cytokines were quantified via PCR and Luminex respectively. A targeted proteomic approach was used to assess the state of the tissue on a molecular level.
Results: Ex vivo perfusion results in the significant depletion of leukocytes from myocardial tissue ($p=0.003$, $p=0.023$, $p=0.024$, $p=0.043$, $p=0.003$ and $p=0.042$ for neutrophils, basophils/eosinophils, classical monocytes, macrophages, NK cells and B cells respectively). The perfusate displayed a selective, pro-inflammatory pattern during perfusion with steadily increasing concentrations of IFN-γ ($p=0.003$, peaking at >8000pg/ml), GM-CSF ($p=0.021$), IL-8 ($p=0.001$), IL-18 ($p=0.001$) and TNF-α ($p=0.001$) detected. Within the perfusate, an increasing concentration of cell-free genomic DNA ($p=0.037$) and mitochondrial DNA ($p=0.063$) was detected. Diminished expression of 9 pro-apoptotic proteins (heme oxygenase 1, death receptor 5, Bad, Bcl-x, pro-caspase-3, claspin, clusterin, serine 46 phosphorylated p53 and TNF receptor 1) was demonstrated in the tissue following perfusion. Stable expression was observed for a further 26 cell death and apoptosis related proteins.
Discussion: We demonstrate for the first time that the donor myocardium contains a significant immune population with the potential to elicit a strong recipient alloresponse. Furthermore, ex vivo perfusion significantly reduces the immunogenicity of the donor heart via the profound loss of resident donor leukocytes, which is likely to reduce direct allorecognition. This novel process may be magnified by active migration in response to inflammatory cytokines in the circuit, particularly IFN-γ, which reaches an extremely high concentration. Despite this pro-inflammatory environment, we also demonstrate a pro-survival profile in the tissue at 8 hours, indicating that myocardial status is significantly improved by perfusion. Preservation of donor hearts via hypothermic, cardioplegic perfusion may therefore provide significant benefit for both organ viability and immunogenicity.

454.5

C4d positive staining is a poor prognostic indicator in cardiac transplant recipients

Carmela D. Tan, E. Rene Rodriguez.
Anatomic Pathology, Cleveland Clinic, Cleveland, OH, United States.

Introduction: The current diagnostic criteria for antibody-mediated rejection (AMR) in heart transplant recipients are based on a combination of histologic and immunopathologic features as recommended in the International Society for Heart and Lung Transplantation (ISHLT) working formulation. Despite published criteria, there are still considerable variations in the technical aspects of diagnosing AMR amongst transplant centers. In this study, we sought to evaluate the clinical significance of C4d staining by immunofluorescence technique in the clinical outcome of heart transplant patients.
Materials and Methods: The study population included 296 adults patients transplanted between January 2006 through March 2012 and who survived more than a year posttransplant. Patient demographics and clinical data including recipient age at the time of transplantation, cytomegalovirus (CMV) status, pre-transplant panel-reactive antibody (PRA), history of cardiovascular surgery or mechanical circulatory support, and immunosuppression at the time of discharge were obtained from the electronic medical record. All endomyocardial biopsies were routinely processed as frozen sections for evaluation of acute cellular rejection (ACR) and AMR by staining for C4d and C3d.
Results: Complement staining was positive in 70 of 296 patients. Fifty-one (17%) of patients were C4d+ on the index biopsy while 19 (6%) of patients were C4d+C3d+. Eleven of 51 (22%) C4d+ patients converted to C4d+C3d+ over an average of 10 month follow-up. C4d+ biopsies occurred mostly as asymptomatic single events that resolved without therapy. At the end of an average length of 73 month follow-up (range: 34-110 months), 38% (15/40) of patients from the C4d+ group died. Mortality in the C4d+C3d+ group was 37% (1/19), in the C4d+ converters 36% (4/11) and only 11% (25/226) in the control group. In a multivariable model, the significant variables that were associated with decreased survival were the presence of complement deposition on biopsy and the use of cyclosporine as maintenance immunosuppression. The results of a multivariable backward Cox proportional hazards regression indicated that the hazard ratios for all three patient groups relative to the control group were significant.
Discussion: Our results show an inferior survival for all patients with evidence of any complement staining in their biopsies. While a high short-term mortality in patients with overt clinical AMR having C4d+C3d+ biopsies and allograft dysfunction is known, this study shows that the poor survival rate of patients with subclinical AMR having C4d+ biopsies without allograft dysfunction was comparable to clinical AMR patients on longer follow-up.
Conclusion: Positive C4d staining in surveillance endomyocardial biopsies is a strong prognostic indicator of worse survival. The optimal management of subclinical AMR however is not yet established.

454.6

Calcineurin inhibitor (CNI) delay with ATG induction: Teaching an old dog, new tricks

Arezu Z. Aliabadi[1], Johannes Goekler[1], Olivia Salameh[1], Thomas Haberl[1], Barbara Steinlechner[2], Phillip Opfermann[2], Alexandra Kaider[1], Keziban Uyanik-Uenal[1], Guenther Laufer[1], Andreas O.Zuckermann[1].
[1]Cardiac Surgery, Medical University of Vienna, Vienna, Austria; [2]Cardiothoracic and Vascular Anesthesiology, Medical University of Vienna, Vienna, Austria.

CNI delay early after heart transplantation is a recommended therapeutic option according to ISHLT guidelines. However, there exist only few published data on feasibility of CNI delay. The aim of this single center retrospective study was to analyze safety and efficacy of CNI delay with ATG induction therapy.
A total of 706 patients were transplanted at our center from 1/96-9/14. All patients received thymoglobuline induction therapy for 1-10 days. CNI therapy was started after the end of ATG-induction. Patients were grouped according to CNI start day (0-1, 2-3, 4-5, 6-7, >7). Freedom from rejection at 1 and 12 months was analyzed in each group by Kaplan-Meier analysis with log-rank test. Changes of creatinine levels (Crea) pre-transplant (preTX) vs. 7 days post-transplant (7d PostTX) were compared in all groups and in sub-groups with crea preTX levels >1.5mg/dl. Differences were analyzed with paired t-test. P-values <0.05 were defined as significant.
Group 0-1 consisted of 20 patients (Crea>1.5mg/ml: n=8; 40%), 2-3: n=173 (n=30, 17%), 4-5: n=219 (n=53; 24%), 6-7: n=224 (n=64; 29%), >7: n=70 (n=25; 36%). Freedom from acute rejection at 1 and 12 months post transplant were: 0-1: 100%, 95%; 2-3: 92.4%, 88.4%; 4-5: 95%, 91.3%; 6-7: 93.3%, 87.5% and >7: 88.6%, 82.9%; p=0.282). Whereas there was no significant change between preTX Crea and 7d postTX in the 0-1 (1.68±1.11 vs. 1.69±1.18) and >7 groups (1.59±1.02 vs. 1.32±0.8), there was significant improvement in groups 2-3 (1.35±0.82 vs. 1.18±0.61; p<0.001), 4-5 (1.43±0.85 vs. 1.21±0.46; p<0.001) and 6-7 (1.42±0.63 vs. 1.18±0.56; p<0.001). In patients with preTX crea >1.5 there was also significant improvement in crea 7d postTX in most groups. 2-3 (2.15±1.52 vs. 1.71±1.00; p<0.01), 4-5 (2.13±1.32 vs. 1.41±0.48; p<0.001), 6-7 (2.02±0.78 vs. 1.48±0.50; p<0.001), >7 (1.78±0.51 vs. 1.42±0.50; p<0.01). Only group 0-1 showed no improvement (2.55±1.35 vs. 2.38±1.54; p=n.s.).
CNI delay of 2 to even >7 days in combination with ATG induction seems to be associated with low rejection rates and improvement of early renal function. Prospective studies are needed.

454.7

Cellular rejection beyond 2 years after cardiac transplantation

Christian Heim, Johannes Roesch, Michael Weyand, Rene Tandler.
Cardiac Surgery, University of Erlangen, Erlangen, Germany.

Introduction: Endomyocardial biopsy (EMB) is widely used for routine surveillance of cardiac allograft rejection. The need for continued EMB beyond the first year after cardiac transplantation is controversial. EMB is performed through the jugular or femoral veins and is associated with a complication rate of less than 1%. The aim of this study was to investigate the use of EMB in monitoring long term surviving heart transplant recipients.
Methods: We conducted a retrospective chart review of all patients at our center 2 years or more after heart transplantation. 154 HTx patients between 2000-2012 were included in this study. Significant cellular rejection was defined as grade 2R or 3R using ISHLT nomenclature. Patients were analyzed assessing immunosuppressive regimen and procedural related complications.
Results: Of 154 cardiac transplant patients, 110 (71.4%) had a follow-up of more than 2 years. 17 of these long-term survivors of cardiac transplantation developed at least 1 episode of significant late (>2 years after Tx) cellular rejection (15.5%). Analyzing the respective immunosuppressive regimen showed increased number of calcineurin inhibitor (CNI)-free regimen (64.7%) in patients rejecting late after heart transplantation. Only 35.3% of late cellular rejections occurred in patients treated with Ciclosporin A or Tacrolimus. The overall incidence of procedural related complications was low (1.0%) and none was life threatening.
Conclusion: The above data demonstrates that endomyocardial biopsies continue to detect clinically significant rejection beyond 2 years after cardiac transplantation. Late rejection was not depending on previous episodes of early cellular rejections. Therefore, we recommend routine endomyocardial biopsies in cardiac transplant recipients even though late after transplantation.

455.1

Survival benefit of liver transplantation for HIV+ candidates

Allan B. Massie[1], Christine M. Durand[1], Jayme E. Locke[2], Rhiannon D. Reed[2], Brittany A. Shelton[2], Andrew M. Cameron[1], Dorry L. Segev[1].
[1]Surgery, Johns Hopkins, Baltimore, United States; [2]Surgery, University of Alabama at Birmingham, Birmingham, United States.

In the modern era of antriretroviral therapies, HIV-positive patients are living longer and end-stage renal disease is increasing in this population. Many seek liver transplantation. However, the survival benefit of liver transplantation in HIV+ patients is unknown.
Materials and Methods: We linked SRTR data (comprehensive national registry for transplant patients in the United States) on liver transplant candidates March 2002-Dec 2014 to pharmaceutical claims from IMS Health (a major commercial dataset covering 65% of liver candidates during the study period). HIV status was ascertained by prescription fills of medications specific to HIV. We modeled relative risk of waitlist mortality and post-transplant mortality in HIV+ patients vs HIV- patients using Cox regression, adjusting for MELD score, age, and sex. We modeled benefit of transplant in HIV+ patients in various MELD strata using Cox regression, with transplant date as time of origin for patients who received a transplant, and the date of the earliest MELD score in the stratum for patients who did not receive a transplant in that MELD stratum.
Results and Discussion: Among 71,561 waitlist candidates, 607 (0.8%) were HIV+ at time of listing. In the first 30 days after listing, HIV infection was associated with 6.7-fold risk of waitlist mortality (aHR=$_{4.6}$ 6.7 $_{10.0}$, p<0.001), an added mortality risk equivalent to 9.3 MELD points (Figure, upper panel). Thereafter, HIV was associated with 60% higher risk of waitlist mortality (aHR=$_{1.4}$ 1.6 $_{1.9}$, p<0.001, HIV/time interaction p<0.001), an added mortality risk equivalent to 2.4 MELD points. Waitlist mortality risk associated with HIV was consistent across the range of MELD (MELD/HIV interaction p=0.6). One, three, and five-year post-transplant patient survival rates were 82%, 67%, and 62% for HIV+ recipients vs 92%, 84% and 77% for HIV- recipients (Figure, lower panel). Among transplant recipients, HIV was associated with threefold risk of mortality in the first 6 months post-transplant (aHR=$_{2.1}$ 3.1 $_{4.4}$, p<0.001) and 40% increased risk thereafter (aHR=$_{1.1}$ 1.4 $_{1.9}$, p<0.01, HIV/time interaction p<0.001). Nevertheless, liver transplantation was associated with substantial survival benefit for recipients with MELD of 20 and above (aHR of transplantation = $_{0.5}$ 0.8 $_{1.4}$, p=0.4 for MELD 6-12; $_{0.4}$ 0.7 $_{1.1}$, p=0.1 for MELD 13-19; $_{0.3}$ 0.5 $_{0.8}$, p=<0.01 for MELD 20-29; and $_{0.1}$ 0.2 $_{0.3}$, p=0.<0.001 for MELD 30-40; aHR less than 1 indicates survival benefit from liver transplantation).
Conclusion: Despite increased risk of post-transplant mortality (particularly in the short-term post-operative period), HIV+ transplant recipients in this US-based cohort had high rates of five-year survival and received substantial survival benefit from liver transplantation, suggesting that liver transplantation is a viable treatment for HIV+ patients with end-stage liver disease.

Treatment of HCV-recurrence after liver transplantation with sofosbuvir/ledipasvir: the role of ribavirin

Dennis Eurich[1], Brigitta Globke[1], Raschzok Nathanael[1], Eva Teegen[1], Iman Dimrah[1], Eckart Schott[3], Johann Pratschke[1,2].
[1]General, Visceral and Transplant Surgery, Charité Campus Virchow, Berlin, Germany; [2]General, Visceral, Thoracic and Vascular Surgery, Charité Campus Mitte, Berlin, Germany; [3]Gastroenterology and Hepatology, Charité Campus Virchow, Berlin, Germany.

Introduction: HCV-recurrence after liver transplantation used to be a hard and sad issue in the era of interferon-based treatment. Since the introduction of modern direct acting antivirals, treatment became easier and shorter. According to published data, antiviral treatment duration with sofosbuvir (SOF) und ledipasvir (LDV) may be shortened to 12 instead of 24 weeks using ribavirin (RBV) additionally in the natural course of hepatitis-C-infection. Furthermore, the question, if ribavirin is really necessary in a 12-week SOF/LDV-treatment in transplant setting, is still unanswered.
Patients and Methods: 98 liver transplant patients with HCV-recurrence underwent interferon-free sofosbuvir-based treatment at our institution. 51 genotype 1 and 4 patients were included in the analysis of antiviral efficacy of SOF/LDV with or without RBV. Group A with the shortest and simplest treatment (SOF/LDV for 12 weeks) comprised 29 patients with histologically proven low stage fibrosis (F0-2) and was compared to 22 individuals in the group B (SOF/LDV with RBV or 24 weeks treatment), which comprised 15 patients treated with SOF/LDV with RBV for 12 weeks, 5 patients treated with SOF/LDV and RBV for 24 weeks and 2 patients treated with SOF/LDV for 24 weeks predominantly in case of advanced fibrosis stages (F3-4).
Results: All patients demonstrated a rapid decline of HCV-rna that was measured once a week. By the end of week 4, all patients had HCV-rna-concentration below the limit of detection. All 51 patients achieved ETR and SVR 12 disregarding the treatment mode, previous treatment history and transplant fibrosis stage. No patient in any treatment group had virological breakthrough during the treatment and relapse after treatment. The highest prevalence of adverse events that was significantly different among the groups A and B was observed in the group B with RBV or prolonged treatment regimen (27.6% vs. 86.4%; $p<0.001$). In 55% (n=11) of 20 patients with RBV-comedication RBV-dose had to be reduced and in 40% (n=8) of 20 patients RBV-therapy had to be stopped due to adverse events predominantly due to significant anemia with hemoglobin concentrations lower than 10g/dl in 11 (21.6%) patients. No acute cellular rejection episodes occurred during the treatment and the observation period.
Conclusion: SOF/LDV-combination is a reliable therapy of recurrent HCV-infection after liver transplantation. It is easy to administer and to achieve SVR in immunocompromised patients without interactions with the immunosuppressive medication. Regarding the high rate of adverse events, frequent RBV-treatment discontinuation and 100%-SVR in patients with advanced fibrosis stages, there is no need for RBV in the 12 week SOF/LDV-regimen after liver transplantation.

455.3

Interferon-free antiviral treatment of HCV-recurrence with sofosbuvir containing regimen: evaluation of kidney function

Dennis Eurich[1], Eva Teegen[1], Brigitta Globke[1], Nathanael Raschzok[1], Iman Dimrah[1], Eckart Schott[3], Johann Pratschke[1,2].
[1]General, Visceral and Transplant Surgery, Charité Campus Virchow, Berlin, Germany; [2]General, Visceral, Thoracic and Vascular Surgery, Charité Campus Mitte, Berlin, Germany; [3]Gastroenterology and Hepatology, Charité Campus Mitte, Berlin, Germany.

Background: Since the introduction of directly acting antiviral drugs (DAAs), treatment of hepatitis-c before and after liver transplantation has finally become a highly effective procedure with a low risk profile. The use of sofosbuvir (SOF) is limited to patients with all stages of hepatic and transplant fibrosis and is not recommended for patients with glomerular filtration rate (GFR) lower than 30ml/min, thus denying this HCV-positive subpopulation with renal insufficiency stage IV and V an effective antiviral therapy. Therefore, we performed a retrospective analysis of SOF-based antiviral treatment after liver transplantation especially focusing on kidney function in order to deliver some additional data on this topic.
Patients and Methods: 98 patients were identified who underwent a virologically successful interferon-free, SOF-based antiviral treatment of HCV-recurrence after liver transplantation at our institution. The indication for antiviral treatment was based on viral genotype, transplant fibrosis stage and urgency. Apart from virological and biochemical data renal function (creatinine, GFR) were assessed before, during and after antiviral treatment.
Results: SOF-based antiviral treatment in full dose (400mg/d) was performed with ledipasvir in 52 (53.1%), daclatasvir in 21 (21.4%), simeprevir in 22 (22.4%) and ribavirin (RBV) in 3 (3.1%) genotype 2 patients. There were 3 patients on dialysis (stage V), 3 patients in stage IV, 34 patients in stage III of renal insufficiency and 2 patients after liver and kidney transplantation. The antiviral therapy was well tolerated although no dose reduction was performed and no SOF-related adverse events occurred during and after the treatment. Mean GFR did not show any significant differences at the moment of treatment initiation 64.3ml/min at the end of treatment 63.8ml/min and 12 weeks after treatment 63.1ml/min. Stages of renal insufficiency were equally distributed before and after the antiviral treatment.
Conclusion: Although SOF-based treatment is not recommended in patients with severely impaired kidney function (stages IV-V), no further deterioration of kidney function could be observed in the present analysis suggesting that SOF may be used as a therapy backbone without dose reduction in this specific, difficult to treat, liver transplant population.

A closing chapter – therapy of HCV genotype III recurrence in liver transplants

Eva Teegen[1], Brigitta Globke[1], Eckart Schott[2], Johann Pratschke[1], Dennis Eurich[1].
[1]Department of General, Visceral and Transplantation Surgery, Charité, Berlin, Germany; [2]Medical Department, Division of Hepatology and Gastroenterology, Charité, Berlin, Germany.

Introduction: Historically, HCV-genotype (GT) 3 was not as hard to treat as genotype-1 HCV-infection using interferon-based therapy. Nowadays, GT-3-HCV-infection can easily be assessed using interferon-free regimes such as the combination of sofosbuvir (SOF) and daclatasvir (DCV) as a highly successful and reliable therapeutical option.
We report a successful antiviral treatment of our last 10 GT-3 patients suffering from HCV-recurrence after liver transplantation with SOF/DCV.
Patients and Methods: This report presents a descriptive analysis of 10 patients who were transplanted due to a GT-3 cirrhosis in our center. Only two of them were naïve for any antiviral therapy. All of them received antiviral treatment with SOF/DCV for 12 weeks after liver transplantation; in one case ribavirin was additionally applied. The endpoint was HCV-RNA free survival after 12 weeks of therapy. Secondary endpoints were preservation of renal and liver function and incidence of adverse events.
Results: All patients were free of HCV-RNA at the latest from 8 weeks of therapy. Elevated transaminases and gamma-glutamyl transferase at the beginning of therapy normalized during the therapy. Bilirubin and alkaline phosphatase were stable at all dates. There were no severe side effects especially on renal function or blood count. Sustained virological response rates at week 12 were achieved in all 10 patients.
Conclusion: HCV could be eliminated in all patients after liver transplantation by antiviral treatment of SOF/DCV over 12 weeks. SOF/DCV is a safe and reliable antiviral therapy of recurrent GT-3 HCV-infection that allowed us to close the chapter of HCV-recurrence after liver transplantation in our outpatient clinic.

455.5

The use of hepatitis B core antibody positive donors for liver transplantation does not lead to inferior survival

Tiffany C.L. Wong[1], James Y.Y. Fung[2], See Ching Chan[1], Chung Mau Lo[1].
[1]Surgery, The University of Hong Kong, Hong Kong, Hong Kong;
[2]Medicine, The University of Hong Kong, Hong Kong, Hong Kong.

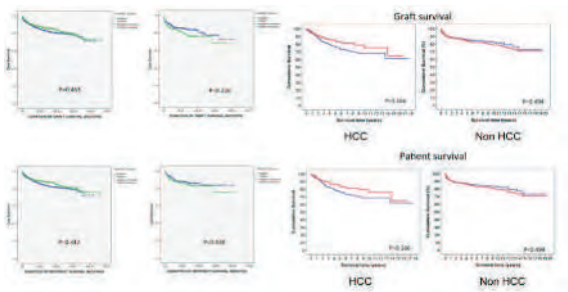
Introduction: It is still controversial whether the use of hepatitis B core antibody (HBcAb) positive graft would lead to an inferior survival after liver transplantation (LT). Consensus is lacking regarding the optimal regimen of anti-viral prophylaxis in these patients and the reported risk of de novo hepatitis B (HBV) infection ranged from 0-14%. It was suggested that such risk was higher especially when HBcAb positive grafts were transplanted to non-HBV recipients. Our study aims to evaluate the long-term outcomes and risk of de novo HBV in using HBcAb positive grafts.
Method: We evaluated all patients who were transplanted in our center from 1996 to 2015. All data was retrieved from a prospectively collected database.
Results: There were 1004 adult LT and 438 grafts (43/6%) were from HBcAb positive donors and 326 (74.4%)of these grafts were transplanted to HBV recipients while 112 (25.6%) were transplanted to non-HBV recipients. All recipients received oral antiviral prophylaxis only and had no hepatitis B immunoglobin (HBIG). Table 1 showed the clinical characteristics of donors and recipients as related to HBcAb status.
Figure 1 showed the use of HBcAb positive grafts to HBV and non-HBV recipients. In fact the long-term patient and graft survival at 10 years are >80% for both group. The use of HBcAb positive graft in patients with and without hepatocellular carcinoma did not influence long-term graft and patient survival either.

Table 1. Clinical characteristics of donor and recipient as related to HBcAb status

Donors	HBcAb+ graft (n=438)	HBcAb- graft (n=566)	P value
Age	47 (12 – 77)	35 (2 – 84)	0.000*
% Male	202 (46.1%)	270 (47.7)	0.618
BMI	22.5 (12.9 – 35.2)	22.2 (12.8 – 35.6)	0.079
Cold ischemic time	160.5 (60 – 924)	133 (53 – 742)	0.001*
Warm ischemic time	52 (25 – 146)	51 (24 – 151)	0.043*

Recipients	HBcAb+ graft (n=438)	HBcAb- graft (n=566)	P value
Age	51 (17 – 69)	52 (16 – 73)	0.210
% Male	325 (74.2%)	407 (71.9%)	0.418
HCC vs. non HCC	330 : 308	161 : 405	0.669
BMI	23.8 (15.1 – 47.7)	24.2 (15.4 – 42.9)	0.627
MELD	22 (6 – 59)	21 (6 – 53)	0.702
LDLT vs. DDLT	218 : 220	339 : 227	0.001*

In fact, there was no difference in outcomes when HBcAb positive grafts were used in living donor vs. deceased donor LT; recipient MELD <30 vs. ≥30 and MELD <45 vs. ≥45.
Among the 112 non-HBV patients who received a liver graft from HBcAb positive donors, only 1/112 (0.9%) developed de novo HBV. HBV DNA was 179.3 copies/ml at time of HBV recurrence and liver biopsy showed graft fibrosis and had graft failure.
Conclusion: Our study has demonstrated the outcomes of HBcAb positive grafts in LT were excellent with minimal risk of de novo HBV. The use of oral antiviral therapy alone is adequate to prevent de novo HBV. The use of HBcAb positive grafts in non-HBV recipients is also safe.



455.6

Hepatitis B vaccination in patients receiving antiviral monotherapy after liver transplantation for chronic hepatitis B

Tiffany Wong[1], James Y.Y.Fung[2], See Ching Chan[1], Chung Mau Lo[1].
[1]Surgery, The University of Hong Kong, Hong Kong, Hong Kong;
[2]Medicine, The University of Hong Kong, Hong Kong, Hong Kong.

Introduction: Life long antiviral prophylaxis is required for patients who are transplanted for hepatitis B (HBV). Our study aimed to determine if a double-dose pre-S containing HBV vaccination (Sci-B-VacTM) could elicit an adequate and sustainable immune response in HBV patients who developed previous hepatitis B surface antibody (Anti-HBs) response after liver transplantation (LT).
Method: All patients who were transplanted for HBV related disease for >1 year with normal graft function and hepatitis B surface antigen (HBsAg) seronegativity were evaluated. They were recruited to receive a 40mcg pre-S containing HBV vaccine if they were responders in our previous vaccine trial, or anti-HBs was positive for >1 year after LT or a peak anti-HBs at any time point after LT was >100mIU/ml. All patients received oral antiviral therapy as prophylaxis, none of them had hepatitis B immunoglobulin (HBIG) at any time point before or after LT. Primary endpoint was the development of anti-HBs ≥10mIU/ml from previous negative value or a 1-log increase from baseline. Anti-HBs up to 32 months after vaccination was monitored.
Results: Eighty-six patients were recruited; 5 were responders from previous trial; 45 patients had detectable anti-HBs >1 year after LT and 36 patients had an anti-HBs >100mIU/ml. Figure 1 showed the anti-HBs response of all responders. All (5/5,100%) previous responders responded to booster vaccination and all demonstrated a positive response 2 weeks after vaccination with median anti-HBs of 638 (range 146-1000)mIU/ml. Anti-HBs remained detectable in all patients at 32 months followup. For the remaining 81 patients, 10/81 (12.3%) responded. Table 1 showed the characteristics between responders and nonresponders in the 81 patients. Majority (8/10, 80%) of them developed a positive response at 2 weeks after vaccination; the remaining 2 patients responded at 1 month and 3 months after vaccination. At 32 months after vaccination, anti-HBs remained detectable in 3/10 (30%) patients.
Conclusion: All previous responders responded to booster vaccination, implying durability and memory of HBV immune response, which is an important prerequisite for definitive host immunity for HBV. In patients who had spontaneous and significant anti-HBs production after LT, a single HBV vaccination can induce response in 12.3% of patients which was higher than that reported in literature. The fact that none of our recipient received HBIG, and anti-HBs persisted up to 32 months in 8 patients after vaccination, demonstrating a spontaneous production of anti-HBs which is independent of adoptive immunity transfer from donor and passive immunity. This group of patients might be potential target for anti-viral prophylaxis withdrawal.

Figure 1. Anti-HBs response in responders. a) Previous responders b) Patients who had persistent anti-HBs >1 year after LT or peak anti-HBs >100mIU/ml

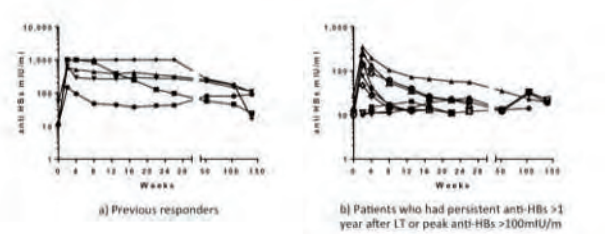


Table 1. Baseline characteristics of patients

	Responders n=10	Non-responders n=71	P value
Age	48.5 (27-63)	52 (24-67)	0.31
Sex (n, % male)	8 (80)	60 (84.5)	1.00
Disease indication			
Acute/acute on chronic	3 (30)	9(12.7)	
Cirrhosis	3 (30)	35(49.3)	
Hepatocellular carcinoma	4 (40)	27 (38)	0.46
Graft type			
LDLT vs. DDLT (n,%)	8 (80): 2 (20)	41(57.7): 30 (42.3)	0.32
Time from LT to current study (months)	131.5 (62.5-155.6)	105.1 (57.4-163.2)	0.11
Antiviral therapy			
Lamivudine	8 (80)	29 (40.8)	
Lamivudine + adefovir	0 (0)	11 (15.5)	
Lamivudine + tenofovir	1 (10)	4 (5.6)	
Entecavir	1 (10)	26 (36.6)

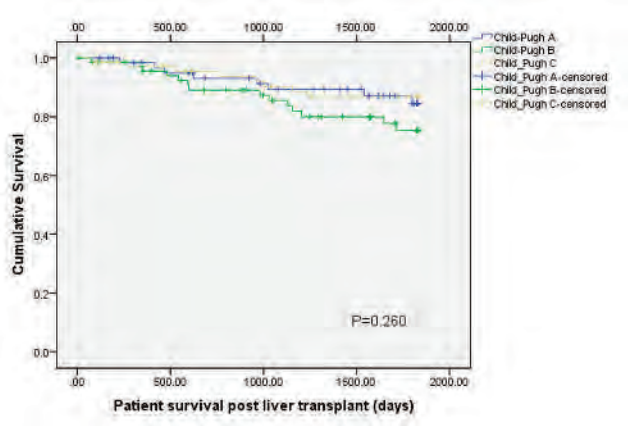
Duration of antiviral therapy before LT (months)	0.1 (0-82.2)	1.3 (0-131.5)	0.06
HBeAg seropositive before LT	1 (10)	24 (33.8)	0.25
HBV DNA at LT (copies/ml)	15x 10^3 (35-7.2x 10^6)	12x 10^3 (0-4.2x 10^6)	0.84
Presence of HBV mutant (n,%)	0 (0)	14 (19.7)	0.27
Time for HBsAg seroconversion after LT (months)	0.7 (0-1.2)	0.8 (0-14.8)	0.16
Peak anti-HBs after LT	61 (11-342)	165 (20-1000)	0.09
Donor anti-HBc (n,%)	5 (50)	42 (59.2)	0.70
Donor anti-HBs (n,%)	7 (70)	63 (88.7)	0.04

455.7

Child-Pugh classification cannot predict survival of hepatocellular carcinoma patients after liver transplantation

Walid Elmoghazy[1,2], Norman Kneteman[1].
[1]Department of Surgery, Hepatobiliary, Pancreatic Surgery, and Transplantation, University of Alberta Hospital, Edmonton, AB, Canada; [2]Department of Surgery, Sohag University, Sohag, Egypt.

Background: According to Barcelona clinic algorithm for management of hepatocellular carcinoma (HCC) patients, patients who are classified Child-Pugh class (CPC) C, should be offered only palliative care. So, we aimed to study patients who were transplanted at our institution due to HCC and to assess impact of CPC on their prognosis after transplant.
Patients and Methods: A retrospective analysis of 202 patients with non-incidental HCC transplanted between October 1990 and October 2013 was done. The end point was 5-year survival after liver transplantation. Comparison of survival according to CPC was done using log-rank test.
Results: Over a period of 20 years, 202 patients with non-incidental HCC were transplanted in our center with a mean follow-up of 4.5 years. Mean age at time of transplant was 55.5 ± 8.3 years and 164 (81.2%) patients were males. HCV-related cirrhosis represented the underlying pathology in 107 patients (53%). Patients with CPC classes A, B, and C were 63 (31.2%), 70 (34.6%), and 69 (34.2%), respectively. The 5-year survival was 85.1% while the overall patient survival was 70.6% during the follow-up period. The 5-year survivals for patients with Child-Pugh classes A, B, and C were 87.3%, 80%, and 88.4%, respectively with no significant statistical difference (P = 0.26) (figure 1).
Conclusions: Child-Pugh classification could not stratify the outcome of patients undergoing liver transplantation for hepatocellular carcinoma and should not be used in selection of patients.



455.8

Hepatic epithelioid haemangio-endothelioma and adult liver transplantation: Extra-hepatic disease is not a contraindication to liver transplantation. Report of the European liver transplant registry including 149 patients

Quirino Lai[1], Estelle Feys[1], Vincent Karam[2], Rene Adam[2], Jurgen Klempnauer[3], Martin Oliverius[4], Vincenzo Mazzaferro[5], Andreas Pascher[6], Piotr Remiszewski[7], Helena Iesoniemi[8], Jacques Pirenne[9], Aksel Foss[10], Bo GEriczon[11], Sasa Markovic[12], Jan Lerut[1].
[1]UCL, S. Luc Hospital, Brussels, Belgium; [2]Liver Transplant Unit, Centre Hépatobiliaire Paul Brousse, Paris, France; [3]Liver Transplant Unit, Medizinsche Hochschule Hannover, Hannover, Germany; [4]Liver Transplant Unit, Transplancenter IKEM, Prague, Czech Republic; [5]Liver Transplant Unit, Istituto Nazionale Tumori, Milan, Italy; [6]Liver Transplant Unit, Charité Campus Virchow Klinikum, Berlin, Germany; [7]Department of General Transplant and Liver Surgery, Medical University of Warsaw, Warsaw, Poland; [8]Liver Transplant Unit, UCJ Helsingfors, Helsinki, Finland; [9]Liver Transplant Unit, Universitaire Ziekenhuizen Gasthuisberg KULeuven, Louvain, Belgium; [10]Liver Transplant Unit, Oslo Universitetssykehus, Oslo, Norway; [11]Liver Transplant Unit, Karolinska University Hospital, Stockholm, Sweden; [12]Liver Transplant Unit, University Medical Centre Ljubljana, Ljubljana, Slovenia.

Background: Hepatic epithelioid haemangio-endothelioma (HEHE) is a rare vascular tumour with an intermediate aggressiveness. Due to its rarity, the surgical management is still not yet standardized despite the fact that liver transplantation (LT) has been valued in its treatment even in the presence of extrahepatic disease (EHD). The aim of the present study is to further define the value of LT in the current management of HEHE and to identify risk factors for recurrence after LT.
Methods: outcome of one hundred forty-nine patients collected in the European Liver Transplant Registry (ELTR) during the period November 1984-May 2014 has been analysed. Median follow-up after LT is 7.6 years (IQR; 2.8-14.4).
Findings: At Cox regression analysis, only macro-vascular invasion (hazard ratio 4.8; p-value < 0.001) and waiting time before LT ≤ 120 days (HR: 2.6; p-value: 0.01) were significant risk factors for recurrence. Hilar lymph node invasion and LT performed during the period 1984-2003 almost reached significance (p-values 0.07 and 0.12, respectively). Importantly, pre-LT EHD was not a risk factor for post-transplant recurrence.
Five-year disease-free survival rates were 84.7 vs. 44.0% in patients without or with macro-vascular invasion (p-value < 0.001) and 86.7 vs. 73.3% in patients without or with WT ≤ 120 days (p 0.02).
Interpretation: The detailed analysis of this worldwide largest cohort of adult liver recipients transplanted because of HEHE clearly confirms the value of LT in the treatment of this rare vascular hepatic disease. EHD is not a contraindication to transplantation. Tissue examination of lymph nodes and tissues, including Factor VIII antigen immunohistochemistry staining, are needed in order to stage the real disease extension. This information is of importance as it will allow to better appreciate the risks for tumour recurrence after (partial as well as total) hepatectomy.

455.9

Liver transplantation and liver resection for treatment of hepatoblastoma: 10-years single-center experience

Oleg Kotenko, Marat Grigiryan, Denis Fedorov, Alexander Grinenko, Alexander Korshak, Alexey Popov, Andrey Gusev, Alexander Ostapishen, Artem Minich.
Liver Surgery and Transplantation, National Institute of Surgery and Transplantology, Kiev, Ukraine.

Introduction: Hepatoblastoma is the most common malignant liver tumor in childhood. Achievement of complete surgical resection is the mainstay of multimodal treatment for hepatoblastomas. Overall, outcomes have greatly improved because of advances in chemotherapy and innovations of surgical technologies, including the liver transplantation.
Materials and Methods: The aim of this study was to retrospectively review our results of hepatoblastoma surgical treatment. The medical records of patients with hepatoblastoma, treated in our institution from 2005 to 2015, were reviewed. 60 children with a hepatoblastoma have entered the study. The age range at surgery was 8 months to 5.6 years (median 28 months), with a male to female ratio of 3:1. The patients were classified according to the pretreatment extent of disease (PRETEXT) grouping system. 3 patients (5%) were PRETEXT group I, 19 (31,6%) group II, 30 (50%) group III and 8 (13,4%) group IV. 12 patients PRETEXT I-II underwent primary surgery. 48 patients were treated with preoperative chemotherapy. 51 patients received postoperative chemotherapy. The standard perioperative treatment is 4 cycles of preoperative chemotherapy followed by surgical treatment and 2 postoperative cycles of chemotherapy («PLADO» or «superPLADO»). Patients with PRETEXT IV tumors, multifocal tumors and tumors invading major vessels of the liver underwent liver transplantation. Surgical procedures performed included: right trisectionectomy (N.23), left trisectionectomy (N.7), right hemihepatectomy (N.9), left hemihepatectomy (N.4), left lateral sectionectomy (N.3), mesohepatectomy (N.1) , central and anterior bisegmentectomy (N.5), living donor liver transplantation (N.7), living donor liver transplantation with total pancreatectomy, splenectomy, gastroduodenectomy, mesenterico-caval shunting, cavoportal transposition (N.1) in one case hepatoblastoma with portal vein and splenic vein invasion and tumor thrombosis.
Results: The overall 1-,3- and 5-year survival rate for 52 patients after liver resection and for 8 patients after LDLT in the study was 90,4%, 82,7%, 71,1% and 100%, 87,5%, 75%, respectively. Recurrence-free 1-,3- and 5-year survival rate for 52 patients after liver resection and for 8 patients after LDLT in the study was 86,5%, 76,9%, 69,2% and 100%, 87,5%, 75%, respectively. Operative morbidity and mortality after liver resection and after LDLT were 17,3% and 12,5%, 9,6%, and 0%, respectively. 5 patients died after extended hepatectomies. After a median follow-up of 3.8 years (range 1.5-5.3 years), 42 (70%) of the patients were tumor-free in remission and 18 (30%) had died.
Conclusion: Favorable long-term outcome could be expected for hepatoblastoma with multidisciplinary treatment involving neoadjuvant chemotherapy, surgical treatment with complete tumor excision followed by adjuvant chemotherapy. Liver transplantation is a successful treatment option for children with unresectable hepatoblastoma.

456.1

Characterization of hematopoietically-derived CNS macrophages following bone marrow transplantation

Kurt Pruner, Zachary Heroux, Matthew DeFazio, Marina Rocha, Todd Williams, Josef Kurtz.
Department of Biology, Emmanuel College, Boston, MA, United States.

Microglia/macrophages of the central nervous system (CNS) consist of a heterogeneous population, although unlike other tissue-specific macrophages, post-fetal microglial populations have been observed to undergo self-renewal in the brain parenchyma, and limited contribution from hematopoietically-derived monocytes in the absence of an inflammatory state has been described. We have previously described the appearance of a small, but readily observable population of hematopoietically-derived CNS macrophages that demonstrate similar characteristics to resident microglia (both by flow cytometry within the CD11b+/CD45mid population and by immunofluorescence microscopy of Iba1^{+} cells with ramified morphology) following syngeneic bone marrow transplantation.

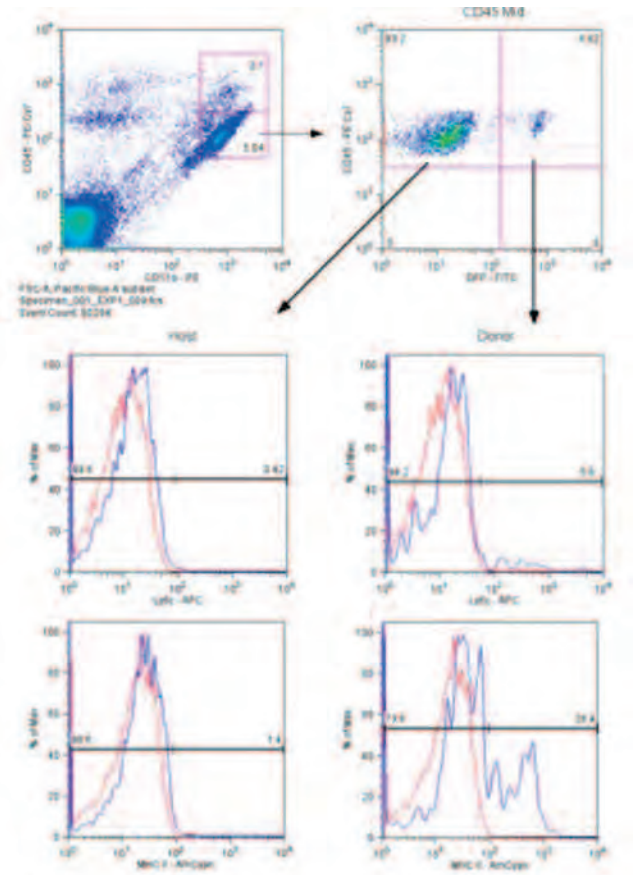


Figure 1. Pseudo-dot plots of data obtained by flow cytometry isolate cell populations characterized by positive expression of CD11b and mid expression of CD45 in the brains of mice 29 weeks post-BMT. These cells are further characterized by donor specific expression of GFP. Histograms compare the expression of Ly6c and MHC II among these CD11b^{+} CD45^{mid} GFP^{+} (donor) and GFP^{-} (host) populations.

To further investigate the phenotype of these CNS infiltrating macrophages, recipient C57BL/6 mice were treated with a (previously described) non-inflammatory myeloablative busulfan regimen followed by a bone marrow transplantation from syngeneic green fluorescent protein (GFP)-expressing C57BL/6 donors. Analysis by flow cytometry of a CNS macrophage phenotype population (CD11b^{+}/CD45^{mid}) in chimeric mice demonstrated that 1-5% of these cells were GFP^{+} at 7 post-BMT, although no significant further increase in percentages were observed at later time points (up to 52 weeks post-BMT). Interestingly, no GFP^{+} cells were detected before 7 weeks post-BMT, suggesting that the recruitment/migration of circulating blood monocytes into the CNS was not due to an acute inflammation process in response to busulfan conditioning. Analysis of Ly6C expression found that Ly6c^{low} cells were observed in the GFP^{-}/CD11b^{+}/CD45^{mid} resident population, but Ly6c^{hi} cells were observed in the peripheral circulation as well as in the GFP^{+}/CD11b^{+}/CD45^{mid} CNS population, suggesting recent migration from blood into the CNS. Interestingly, analysis of MHC class II expression revealed that only the hematopoietically-derived GFP^{+}CD11b^{+}/CD45^{mid} population expressed surface MHC class II, in contrast to no expression by resident (GFP^{-}) populations, suggesting that these cells may have an immune function upon migration into the CNS.

Additionally, immunofluorescence (IF) microscopy identified Iba-1^{+}/GFP^{+} CNS macrophages at 8 weeks post-BMT, however they did not demonstrate a ramified morphology until ~ 13 weeks post-BMT, suggesting that these cells (as detected by flow cytometry) are not merely in transit through the blood. Finally, IF microscopy confirmed the presence to GFP^{+}/Iba1^{+}/MHC class II^{+} cells.

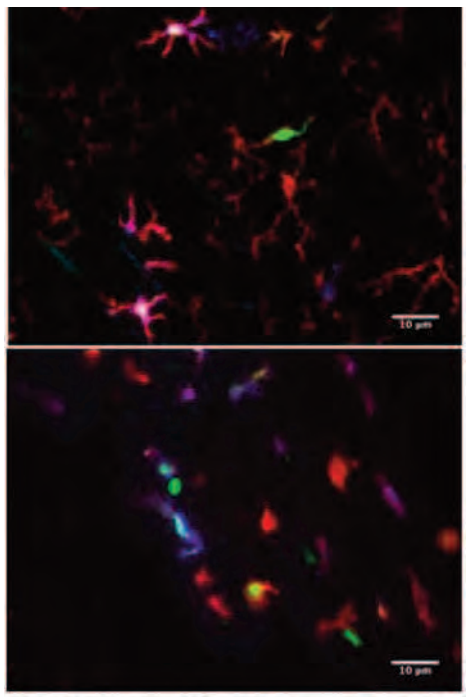

Figure 2. IF imaging of 13µm thick sections of the brains of mice 29 weeks post-BMT assess MHC II (blue) expression of Iba1^{+}(red) macrophages from GFP^{+} donor (green) and GFP^{-} host populations. 40x imaging of the lateral ventricle depicts amoeboid shaped macrophages of donor origin with MHC II expression located in the choroid plexus. 40x imaging of cerebral cortex reveal ramified 'microglia-like' macrophages of donor origin expressing MHC II in the parenchyma.

Together, these data suggest a possible continuum of cells that originate as hematopoietically-derived monocytes into CNS macrophages, with potential immune surveillance function, and further investigations into the mechanisms of recruitment will be important in understanding the interplay between the traditional CNS and immune systems.

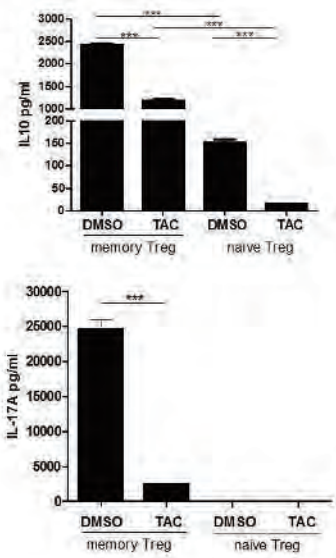
CD45RA identifies TSDR demethylated regulatory T cells with a stable phenotype and suppressive cytokine profile

Rebeca Arroyo Hornero[1], Gareth J.Betts[1], Birgit Sawitzki[2], Katrin Vogt[2], Paul N.Harden[3], Kathryn J.Wood[1].
[1]Transplant Research Immunology Group, Nuffield Department of Surgical Sciences, University of Oxford, Oxford, United Kingdom; [2]Institute for Medical Immunology, Charité University of Medicine, Berlin, Germany; [3]Oxford Kidney Unit, Churchill Hospital, Oxford, United Kingdom.

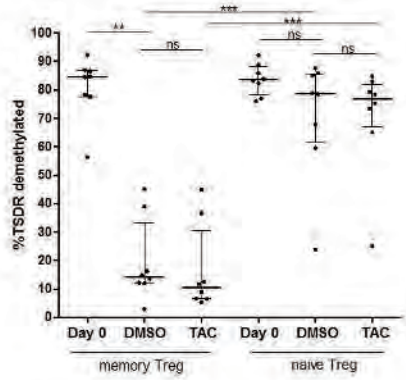
Introduction: Regulatory T cell (Treg) therapy is a promising strategy to induce transplant tolerance and may permit a reduction of IS chemotherapy and its toxic side effects[1]. The ONE study clinical trial is currently examining Treg cell therapy in combination with low tacrolimus (TAC) in living donor kidney recipients. Therefore, Treg populations that are able to survive, expand and remain suppressive in the presence of TAC may be critical to the therapy's success. Stable *bona fide* Tregs may be accurately identified through measurement of the methylation status of their Treg-specific demethylated region (TSDR) on the FOXP3 promoter[2]. While useful as a research technique, TSDR cannot assist in identification of cells for therapy. The identification of cell surface markers sufficient to isolate Treg that remain stable after expansion is therefore key. We focussed on distinct Treg subpopulations using CD25, CD127 and CD45RA cell surface markers[3],[4].

Materials and Methods: Total Tregs ($CD4^+CD127^{lo/-}CD25^+$); $CD127^{lo/-}CD25^{hi}CD45RA^-$($CD25^{hi}$memoryTreg); $CD127^{lo/-}CD25^{int}CD45RA^-$($CD25^{int}$memoryTreg); and $CD127^{lo/-}CD25^{int}CD45RA^+$(naiveTreg) were sorted from PBMC and expanded *in vitro* for 14 days using αCD3/αCD28 coated beads. Cells were expanded in the presence of a therapeutic concentration of TAC (8ng/ml)[5],[6] or control DMSO for the final 7 days of culture. FOXP3 expression, TSDR demethylation, suppressive function and IL-10, IL-17 and IFN-γ production were analysed after expansion.



IL-10 and IL-17A production by expanded Treg subsets.
IL-10 and IL-17A production by memory Tregs and naive Tregs after *in vitro* expansion in the presence of TAC or DMSO was determined in triplicate wells. 1 representative donor of 2 different donors IL-17 production by naive Tregs was under the detection limit. Bars represent means with SEM (***p<0.001).

Results: TAC reduced $CD25^{int}$memoryTreg and naiveTreg expansion equally, whilst $CD25^{hi}$memoryTreg were highly anergic and did not proliferate, even in the absence of TAC. FOXP3 expression after expansion was higher in naiveTregs than in memoryTregs, and was reduced by TAC. Importantly, naiveTregs had a stable demethylated TSDR following *in vitro* expansion whilst memoryTregs lost their demethylated phenotype.
This effect was independent of their exposure to TAC. Suppressive capacity of memoryTreg and naiveTreg was similar in the absence of TAC; however, naiveTregs had partially reduced suppressive function following exposure to TAC in 4/5 donors, compared to 1/6 donors for memoryTregs. MemoryTregs produced substantially more IL-10, IL-17 and IFN-γ than naiveTregs, however this production was reduced by TAC.



Demethylation status of the TSDR region of expanded Treg cell subsets.
Percentages of TSDR demethylation (n=8 donors) before (day 0) and after expansion in the presence of DMSO control or TAC. For statistical analysis, Wilcoxon-matched pair test was performed comparing TSDR demethylation between the same Treg population and the Mann-Whitney test was used to compare between cell populations (*p<0.05, **p<0.01, ***p<0.001). Median with interquartile range is represented.

Discussion: Suppressive mechanisms of naiveTregs and memoryTreg may differ given their differential susceptibility to TAC and levels of cytokine production.

Conclusion: Although memoryTregs retained a greater suppressive capacity when expanded with TAC, the marked loss of TSDR demethylation highlights the potential for loss of stability of these cells after infusion into transplant recipients. By contrast, expanded naiveTregs were still highly suppressive, retained TSDR demethylation and did not produce IL-17, suggesting that this $CD4^+CD127^{-/lo}CD45RA^+$Treg population is a promising candidate for Treg therapy and should be studied further.

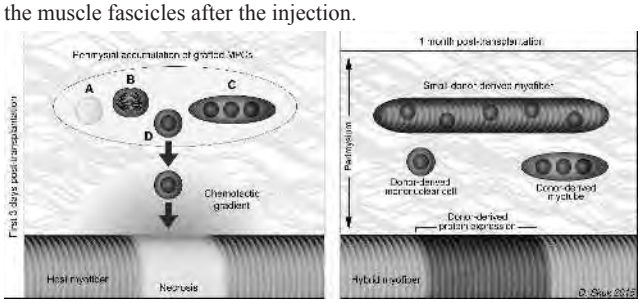
The early behavior of muscle-precursor cell transplantation in skeletal muscles and how this conditions the outcome of the graft: A study in non-human primates

Daniel Skuk, Jacques P.Tremblay.
Axe Neurosciences, Research Center of the CHUQ, Québec, QC, Canada.

Introduction: Transplantation (Tx) of muscle-precursor cells (MPCs) has potential applications in the treatment of skeletal muscle disorders. Clinical results must be improved[1],[2], but this must be based on adequate knowledge of what happens to the MPCs after Tx, which is not sufficiently known. To clarify this issue in a model extrapolable to human, we conducted a study in nonhuman primates.
Material and Methods: MPCs proliferated in vitro and labeled with ß-galactosidase (ß-Gal) were injected in muscle regions of 1 cm^3 in macaques immunosuppressed with tacrolimus. The MPC-grafted regions were biopsied at post-Tx periods of 1 hour, 1, 3, 7 days and 3-4 weeks and analyzed by histology.
Results and Discussion: One hour post-Tx, grafted cells formed compact accumulations randomly in the perimysium. Few cells remained in the trajectories of injection in the muscle fascicles. On days 1, 3 and 7, there was a progressive depletion of the grafted cells in the perimysium, some of which fused between them to form myotubes. Paralelly, there was necrosis (day 1), phagocytosis (day 3) and regeneration (day 7) of the myofibers damaged by the injections. At day 7, regenerating myofibers began to express ß-Gal. At 3-4 weeks, regeneration was completed and ß-Gal was mostly in the myofibers of the muscle fascicles, reproducing the injection trajectories. Few ß-Gal+ elements remained in the perimysium as myotubes, small myofibers or mononuclear cells. Necrosis was observed in several grafted cells at day 1 by immunodetection of intracellular complement deposition, while immunodetection of active caspase 3 suggests that some grafted cells undergo apoptosis. Proliferating cell nuclear antigen immunodetection evidenced proliferation in the grafted-cell collections during the first week.
We interpret that the cell suspension leaks from the muscle fascicles and dissects the perimysium to accumulate there. In these cell accumulations, MPCs have different fates (figure). Some die by necrosis and probably by apoptosis (A). Some survive and proliferate (B), fuse between them to form myotubes (C) or migrate towards damaged myofibers to participate in regeneration (D). After 1 month (figure), the process is complete: the accumulations of grafted cells disappeared leading to few graft-derived elements in the perimysium: mononuclear cells, myotubes and small myofibers. ß-Gal+ myofibers in the fascicles occur more likely by MPCs that migrated from the perimysial accumulations than by the few MPCs that remained within the muscle fascicles after the injection.



Conclusion: The primary distribution of the grafted cells depends on the physical properties of the host tissue components and the cell suspension, while the graft outcome depends on different interacting biological factors: cell death vs proliferation, and local fusion vs migration to participate in myofiber regeneration.

Mobilized human peripheral blood mononuclear cells (PBMCs) contain higher proportion of IL-10 producing B cells in CD8+TCR- facilitating cell population than non-mobilized PBMCs

Yujie Wen, Esma S.Yolcu, Yiming Huang, Larry E.Kahn, Suzanne T.Ildstad.
Institute for Cellular Therapeutics, University of Louisville, Louisville, KY, United States.

Introduction: We recently reported that facilitating cell (FC) enriched hematopoietic progenitor stem cell (HSPC) allografts (FCRx) induced tolerance without graft-versus-host disease (GVHD) or engraftment syndrome in HLA-mismatched living donor renal transplant recipients. Recent studies suggest that dysfunction of B cells that maintain homeostasis may play a role in the pathogenesis of chronic GVHD after HSPC transplantation and alterations in B cells may be a biomarker for transplantation tolerance in kidney transplant recipients.
Materials and Methods: We analyzed B cell progenitors and interleukin 10 (IL-10)-producing B cell subsets in FC obtained from mobilized peripheral blood mononuclear cell (mPBMC) for clinical transplantation, control un-mobilized PBMC and G-CSF mPBMC from healthy volunteer donors. Clinical donors received 9 doses of 10 µg/Kg G-CSF plus 1 dose of Plerixafor while volunteer donors received 4 doses of 10 µg/Kg G-CSF (q.d. for 4 days).
Results and Discussion: FC obtained from mPBMC for FCRx contained significantly more $CD19^+CD24^{hi}CD27^+$ activated B cells and memory B cells ($p<0.01$; n=7-15) and $CD19^+CD24^{hi}CD27^+CD38^{-/lo}IgM^+$ memory IL-10-producing B cell subsets ($p<0.05$; n=7-15), but contained a similar proportion of B cell progenitor subsets (Pro-B $CD34^+CD19^+CD38^+CD10^+IgM^-$, Pre-B $CD34^-CD19^+CD38^+CD10^+IgM^-$ and Immature B $CD34^-CD19^+CD38^+CD10^+IgM^+$) compared to the two control groups. The percentage of $CD8^+TCR^-$ FC in the lymphoid gate was 9 fold less than that of the Non-FC cell population (reverse gate of $CD8^+TCR^-$) in mPBMC for FCRx. However, the FC population contained a significantly higher proportion of activated and memory B cells ($p<0.05$, n=7) and IgM^+ memory IL-10-producing B cell subsets ($p<0.01$, n=7) compared to the Non-FC cell population. We then evaluated the impact of depleting $CD19^+$ FC on in vivo engraftment of mPBMC in a non-obese diabetic / severe combined immune deficiency mutation and IL2 receptor gamma chain deficiency (NSG) mouse model. NSG mice were conditioned with 325 cGy TBI and transplanted with 50-70 x 106 mPBMC for FCRx with or without $CD19^+$ FC. Depletion of $CD19^+$ FC resulted in a significant impairment in engraftment (6 % vs. 14 %; p = 0.03, n = 6) compared to mPBMC for FCRx containing $CD19^+$ FC.
Conclusion: In summary, our results suggest that $CD8^+TCR^-$ facilitating cells in mPBMC from clinical donors for FCRx are enriched with IL-10 producing B cell subsets, which may contribute to the prevention of GVHD and the induction of transplantation tolerance.

Therapeutic benefit of adipose-derived stem cell transplantation in rats of acute-on-chronic liver failure

Cheng-Maw Ho[1,2], Ya-Hui Chen[3], Chin-Sung Chien[2], Shu-Li Ho[1,3], Chih-Chiang Hsiao[4], Jung-Cheu Chen[4], Hui-Ling Chen[2,3], Daniel Tzu-bi Shih[4], Po-Huang Lee[1,2].

Background: Acute-on-chronic liver failure resulted in high mortality. Adipose-derived stem cells (ADSCs) hold promise to complement cell therapy for this dread syndrome. The aim of this study is to demonstrate the therapeutic benefit of CD34 expressed cells derived from adipose tissue in complementing hepatocyte transplantation for acute-on-chronic liver failure in rats.
Methods: Acute-on-chronic liver failure was induced by temporary bile duct obstruction (for 2 weeks) and D-galactosamine (350mg/kg, one day before transplantation) in Sprague-Dawley (SD) rats. Donor hepatocytes were freshly isolated from green fluorescent SD rats by in situ liver perfusion and collagenase digestion before transplantation. ADSCs of stromal vascular fraction were freshly isolated from human adipose tissue and cryopreserved for future transplantation. Three groups, CD34+, CD34-, and unsorted ADSCs were classified based on cell sorting. Rat hepatocytes (1 x 10^7/1ml) were transplanted intraportally into rats of acute-on-chronic liver failure, followed by ADSCs (1 x 10^6/0.5 ml, PKH 26 Fluorescent-labeled) 1 hour later. Animals were sacrificed in 1 and 2 weeks after transplantation, if survived. Liver fibrosis, donor cell identification, serologic tests, immunohistopathological examination, were analyzed.
Results: Acute-on-chronic liver failure was evidenced by the development of acute coagulopathy and hepatocyte necrosis in fibrotic livers. Transplanted ADSCs were found universally in the periportal connective tissue. Rats of CD34+ group exhibited better resolution of obstructive jaundice and biliary fibrosis, followed by those of unsorted and CD34- groups. Ductular reaction, marked by CK19+ progenitor cells, was prominent in CD34- group, and less so in unsorted and CD34+ groups. The CK19+ progenitor cells were not co-localized with transplanted ADSCs. Rats of unsorted group had the trend of superior survival benefit than the other two groups (unsorted vs. sorted, p=0.087).
Conclusions: Co-transplantation of CD34+ ADSCs and hepatocytes resulted in significantly better amelioration of liver fibrosis and ductular reaction in rats of acute-on-chronic liver failure, compared to CD34- ADSCs, although co-transplantation with non-sorted ADSCs instead showed potential survival benefit.

Tracking of Iron nano-particle labelled Mesenchymal stem cells in Ovine heterotopic kidney transplantation

Bron Lett[1,4], Kisha NSivanathan[1,4], Dyane Auclair[3], Julie Johnston[1,4], Christine HRussell[2], Santosh Olakkengil[2], Raj Perumal[3], Chris Drogemuller[1,2,4], Patrick TCoates[1,2,4].
[1]School of Medicine, University of Adelaide, Adelaide, Australia; [2]Renal Department, Royal Adelaide Hospital, Adelaide, Australia; [3]Large Animal Research and Imaging Facility, Adelaide, Australia; [4]Center for Clinical and Experimental Transplantation, Royal Adelaide Hospital, Adelaide, Australia.

Mesenchymal stem cells (MSCs) are a potent group of non haematopoietic progenitor cells with the hallmark qualities of differentiation into bone, cartilage and fat cells. They also possess immunomodulatory and immunosuppressive properties. Given these traits they are a promising candidate for cellular therapy with potential use in solid organ transplantation.
Applying these potential therapeutics to large animal models is essential for understanding their mechanism of action and improving their eventual clinical application. To this end we have a developed an Ovine model of kidney transplantation and tracked the in vivo movement of these cells using MRI.
Methods: Bone marrow aspirate was isolated from the iliac crest and MSCs were selected for by washing off the non adherent cells 7 days after plating. The MSCs were characterised by their ability to differentiate into bone, cartilage, and fat cells as well as flow cytomertry staining. The immunosuppressive abilities of these cells were assessed via mixed lymphocyte reaction.
In order to track the cells in vivo we use an iron nano particle, resovist. To ensure that this did not interfere with the function of the cells, MSCs were labelled and characterised again.
The transplant model can be either an autograft or an allograft and involves the heterotopic transplantation of the donor kidney into the neck of the recipient sheep. The renal artery undergoes end to end anastamosis with the left carotid artery and the renal vein undergoes end to side anastamosis with the jugular vein. The ureter is then passed through the skin flap that covers the kidney and catheterised to allow urine flow and collection.
Heparinised and labelled mesenchymal stem cell suspension (1x106 cells/kg in volume) was infused directly into the renal graft artery immediately prior to completion of the anastomosis, with additional vascular clamps used to prevent loss of solution at the anastomosis. Alternatively the cells were given at the time of the arterial anastamosis via a central venous line. The animals then underwent MRI scans to try and locate the iron labelled cells in the graft.
Results: Differentiation potential, cell surface markers, and immunosuppressive abilities of the MSCs were comparable between unlabelled and resovist labelled cells with no significant difference being observed in any of the assays.
MRI imaging of the transplanted kidney allowed for the detection of iron labelled MSCs up to 7 days post infusion, the distribution of which was confirmed histologically using Prussian blue staining.
Conclusion: In conclusion, these translational studies provide techniques to label large animal MSCs and follow the distribution of these cells within a living kidney using non-invasive MRI scanning. The heterotopic transplant model should allow testing of the effectiveness of MSCs as a cell therapy and provide a tool for refinement of their application.

Ex-vivo expansion of human alloantigen-reactive regulatory T cells using monocyte-derived dendritic cells versus CD40L-stimulated B cells

Hong Zhang[1], Yifei Zhao[1], Qizhi Tang[2], Mohammed Ezzelarab[1], Angus Thomson[1].
[1]Surgery, University of Pittsburgh, Pittsburgh, PA, United States; [2]Surgery, UCSF, San Francisco, CA, United States.

Introduction: Alloantigen-reactive murine and human CD4+CD25+FOXP3+ regulatory T cells (arTreg) are more potent in promoting long-term allograft survival than polyclonal Treg in experimental models. Dendritic cells (DCs) are well known professional antigen-presenting cells (APC) specialized to initiate and regulate immunity. CD40L-stimulated B cells (CD40L-sBc) have been reported to expand human arTreg. However, no direct comparison of the ability of these different APCs to expand arTreg has been reported. In order to establish a protocol to generate large numbers of human arTreg with potent allospecific suppressive capacity for therapeutic application, we compared immature monocyte-derived DC (mono-DC), LPS-matured DC, and CD40L-sBc for their ability to expand arTreg.
Materials and Methods: To generate mono-DCs, immunobead-selected peripheral blood CD14+ cells were cultured with GM-CSF and IL-4 for 7 days. To mature the mono-DCs, LPS was added for the last day of culture; to make CD40L-sBc, flow-sorted CD20+ cells were cultured with irradiated 3T3-CD40L cells, IL-4 and cyclosporine A for 7 days before restimulation with CD40L-3T3 and IL-4 for an additional 3 days. The APCs were irradiated and co-cultured with flow-sorted peripheral blood CD4+CD25+CD127- Tregs and IL-2 for 12 days. To test their function, the expanded arTreg were co-cultured with Teff from same Treg donor at different ratios under stimulation of allo-sBc or anti-CD3/CD28 beads. % of suppression of proliferation correlates with suppressive capacity of the arTreg.

Figure 1. (A) Phenotype of CD40L-stimulated B cells (sBc), monocyte-derived DC (untreated DC), and LPS-treated DC (LPS-DC). (B) Expansion kinetics of arTreg stimulated by sBc, DC, or LPS-DC

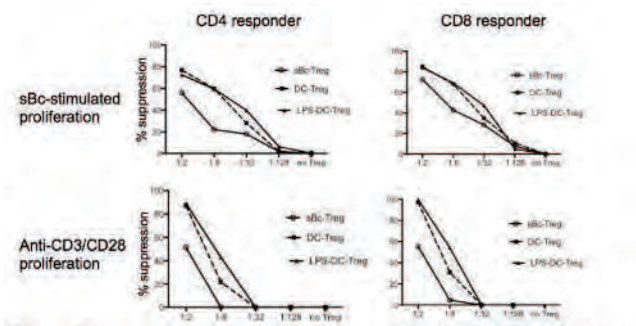

Figure 2. Human arTreg flow-sorted and expanded with allo-sBc, unstimulated DC, or LPS-DC were co-cultured with VPD450-labeled CD4+CD25- Teff from the Treg donor at the indicated ratios under stimulation of allo-sBc (top) or anti CD3/CD28 beads (bottom) for 4 days. % of suppression of proliferation is shown..

Results and Discussion: We observed that LPS-matured DC expressed higher levels of co-stimulatory CD80 and CD86 than immature DC and CD40L-sBc (Figure 1A), suggesting a stronger stimulatory capacity. Treg cultured with LPS-matured DCs were expanded ~40 fold, while those cultured with immature DC or CD40L-sBc were expanded 10- to 20- fold (Figure 1B). Expression of FOXP3 and CTLA-4 was higher

in Treg expanded by either DCs or LPS-matured DCs. In addition, Treg expanded by DCs were superior suppressors of effector T cell proliferation stimulated by either anti-CD3/CD28 beads or allo-sBc (Figure 2). T cell receptor diversity analysis of expanded arTreg is currently being performed to ascertain and compare the clonality of arTreg expanded by the different types of allo-APCs.
Conclusion: LPS-matured human mono-DCs are superior to immature DC and CD40L-sBc in their ability to expand functionally suppressive FOXP3+ Treg. Given the importance of Treg specificity in their in vivo efficacy, our data and ongoing studies will allow determination of which APC is optimal for expansion of human arTreg for in vivo therapy.

De- and recellularization of porcine pancreas

Erik Elebring[1], Bengt Gustafsson[2], Niclas Kvarnström[2], Suchitra Sumitran-Holgersson[1].
[1]Laboratory for Transplantation and Regenerative Medicine, Department of Surgery, University of Gothenburg/Sahlgrenska Academy, Gothenburg, Sweden; [2]Sahlgrenska University Hospital, Gothenburg, Sweden.

Introduction: Diabetes mellitus is a global metabolic disease affecting endocrine pancreas with extremely high prevalence worldwide[1]. The currently available treatments for diabetes mellitus are not adequate[2],[3]. A technique with the potential to improve therapies that has evolved over the last decade is whole organ perfusion decellularization and recellularization. The ultimate goal of decellularization is to, with the help of different agents, remove cell material from the organ without negatively affecting the extracellular matrix (ECM) scaffold[4]. An innate ECM scaffold has the basic biomolecules, preservation of scaffold-bound growth factors and cytokines, an intact vascular structure and the ability to direct cell differentiation during recellularization.
Apart from endocrine tissue, pancreas also consists of exocrine tissue[5]. The release of digestive enzymes from exocrine tissue during decellularization results in a damaged ECM structure. Therefore an alternative decellularization method is presented, where cold temperature is used to keep activity of digestive enzymes low for preservation of ECM structure.
Materials and Methods: Porcine pancreata were dissected with duodenum and aorta intact. The aorta was cannulated and the portal vein was kept open, while all other vessels were ligated. Organs were washed with cold PBS with heparin for 2 hours and then frozen until use. When ready for decellularization the organ was placed at +4°C and perfused with 4% sodium deoxycholate and 6% Triton X-100 in distilled water for 8 hours. Lastly, the organ was washed by perfusion with distilled water for a minimum 120 hours. The outcome of decellularization was characterized using histological and, immunohistochemical stainings for ECM components, quantification of ECM components and quantification of DNA. 0.5 cm3 pieces of decellularized scaffolds were recellularized by seeding cells isolated from human fetal small intestine.
Results and Discussion: After decellularization, pancreata look pale in comparison to normal (Figure 1). Histology results showed that decellularization protocol at +4°C can effectively remove nuclei and other cellular remnants while affecting the ECM minimally (Figure 2). Pancreata decellularized at cold temperature had a much more conserved ECM structure compared to pancreata decellularized at room temperature. DNA quantification confirmed removal of nuclei material during decellularization. Results of recellularization with human fetal small intestine cells will be presented.
Conclusion: Porcine pancreas can be effectively decellularized in a cold surrounding using detergents, while preserving the ECM structure.

Figure 1. Gross anatomy of normal and decellularized porcine pancreas.

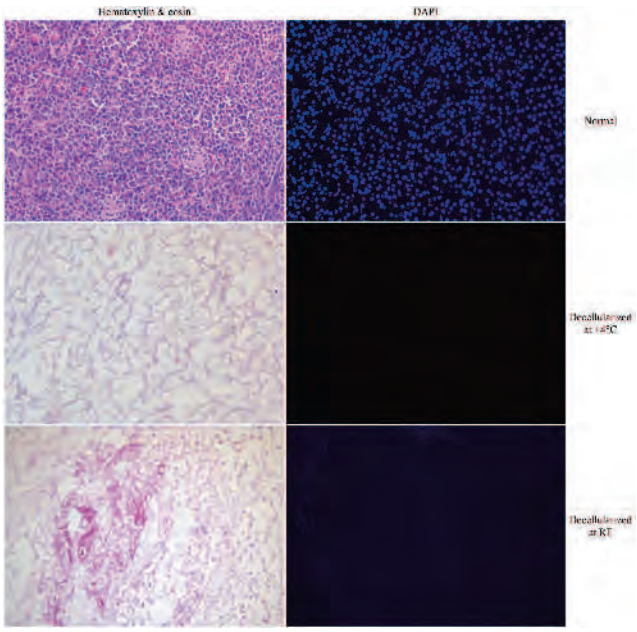

Figure 2. Histological characterization of normal and decellularized pancreata. H&E is used to characterize the ECM while DAPI is used to characterize nuclei.

Stem cell therapy as an emerging modality for post-traumatic paraplegia and for renal parenchymal diseases

Umang G. Thakkar[1], Hargovind L. Trivedi[1,3], Aruna V. Vanikar[1,2]. [1]Department of Regenerative Medicine and Stem Cell Therapy, Institute of Kidney Diseases & Research Centre (IKDRC) - Institute of Transplantation Sciences (ITS), Ahmedabad, India; [2]Department of Pathology, Laboratory Medicine, Transfusion Services and Immunohematology, Institute of Kidney Diseases & Research Centre (IKDRC) - Institute of Transplantation Sciences (ITS), Ahmedabad, India; [3]Department of Nephrology and Transplantation Medicine, Institute of Kidney Diseases & Research Centre (IKDRC) - Institute of Transplantation Sciences (ITS), Ahmedabad, India.

Background: Stem cell therapy (SCT) holds promise for spinal cord injury (SCI) and renal parenchymal diseases (RPD).[1][2] We present experience of co-infusion of autologous adipose-derived neuronal differentiated mesenchymal stem cells (N-AD-MSC)+ hematopoietic stem cells (HSCs) in post-traumatic paraplegia (PTP), and allogenic AD-MSC+ HSC in RPD.

Materials and Methods: Informed consent forms of these prospective, non-randomized, open-labeled studies were approved by Institutional Review Board. Study-1 was carried out in 10 PTP patients (8 males, 2 females) with mean age of 28 years and mean injury duration, 3.42 years, from January,'09 to March,'12. Seven patients had SCI at dorsal level and 3, at lumbar level. Spine-fixation was performed in 7 patients. All patients had bowel-bladder incontinence, sexual dysfunction, 8 had neurogenic pain and pressure sores, 6 had kyphosis/scoliosis, 4 had recurrent urinary tract infections, 1 had bladder calculi, and 5 were depressed. Nerve-conduction studies showed motor axonopathy in 4, upper motor neuron lesion in 2 and radiculoneuropathy in 4 patients. Mean Hauser Ambulation index (HAI) was 9. American Spinal Injury Association (ASIA) score was "A" in all.

Seven steroid-resistant RPD patients (5 males, 2 females) in study-2 underwent SCT from May,'13 to March,'14. Mean patient age was 29.85 years with disease duration, 5.43 years, 24-hours proteinuria, 1.45 gm, serum Creatinine (SCr), 1.17 mg/dL and serum albumin (S.alb), 3.08 gm/dL. Three patients had primary focal segmental glomerulosclerosis, 2 had lupus nephritis, and 1 each had primary IgA nephropathy and mesangio-proliferative glomerulonephritis.

MSCs were generated in vitro from abdominal fat and differentiated into neuronal cells. HSCs were generated from bone marrow. N-AD-MSCs, 2.08 ml (expressing beta-3 tubulin and glial fibrillary acid protein, Figure-1) and HSCs, 1.96 ml, with mean nucleated cell counts of $2.0\times10^2/\mu L$, and $4.5\times10^4/\mu L$ respectively were infused into cerebrospinal fluid below injury site.

In study-2, AD-MSCs + HSCs were infused by femoral catheterization into bilateral renal arteries, portal circulation and thymus. Mean counts of MSC and HSC were 33.79 $x10^4$ and 4.86x 10^8/Kg BW respectively with mean $CD34^+/CD90^+/CD73^+$ of 0.81%/ 37.95% /20.6%.

Results and Discussion: SCT was safe and uneventful.

In study-1, over mean 4.95 years follow-up, ASIA score improved to B in 6, C in 3, D in 1; HAI improved to 7.4, with subjective improvement. Muscle power improved to grade-2 in 6 patients. Touch and pressure sensation regained in 4 and 3 patients respectively. The required natural recovery period is ≈1-year, suggesting positive role of SCs here.

In study-2, over mean 23.57 months follow-up, there was sustained reduction in proteinuria to 0.48 gm/day, decreased SCr to 0.81 mg/dL (Figure-2) and increased S.alb to 3.54 gm/dL. Remission was found in all with absence of relapse in 5 patients.

MSCs promote recovery via angio/neuro/synaptogenesis and axonal remodeling. Demyelinated axons are re-myelinated by SCs releasing various trophic factors and induce endogenous mechanisms of tissue repair.[3] HSCs help in angiogenesis and remodeling. MSCs facilitate immunomodulation and regeneration.

Conclusion: Co-infusion of N-AD-MSC+ HSC in CSF for SCIs, and AD-MSC+ HSC infusion in portal, thymic and renal circulation for remission of RPD is safe and viable.

Macrophage-specific deletion of mTOR inhibits chronic allograft rejection and induces long-term heart allograft survival

Yue Zhao, Wenhao Chen, Wentao Liu, Malgosia Kloc, Rafik Ghobrial, Peixiang Lan, Xian C. Li.
Immunobiology and Transplant Research Center, Houston Methodist Hospital, Houston, United States.

Most transplants are eventually lost to chronic rejection under broad immunosuppression therapies where activation of innate immune cells is suspected to play a major role in graft loss. Indeed, monocytes and macrophages are major cell types infiltrating the chronically rejected allografts, but the molecular mechanisms governing macrophage activities in the grafts are poorly understood. In the present study, we generated mTOR-conditional knockout mice in which deletion of mTOR in macrophages was driven by LyzM-Cre and used this model to examine the role of mTOR in regulating innate immunity in chronic allograft rejection. We observed in a heart transplant model that treatment of wild type C57BL/6 mice with CTLA-4Ig prevented acute rejection of Balb/c heart allograft, but allowed chronic rejection to develop. There was an extensive macrophage infiltration in chronically rejected heart allografts, and the graft infiltrating macrophages preferentially expressed markers associated with M2 phenotype. Interestingly, treatment of macrophage specific mTOR deleted mice with CTLA4-Ig showed that neointima formation and M2 infiltration were marked ameliorated in the grafts, and as such, the graft survival was marked prolonged (>100 days). Mechanistically, we found that deletion of mTOR in macrophages resulted in an impaired induction of M2 cells, but M1 polarization was intact, and this impaired M2 induction was related to reduced STAT6 activation. These findings highlight the importance of mTOR in regulation of macrophages in chronic rejection and provide potential new therapeutic targets for treatment of chronic graft loss.

Systemic therapy of regulatory dendritic cells derived form induced pluripotent stem cells allows allogeneic cardiac grafts acceptance

[1]Division of Transplantation Immunology, National Research Institute for Child Health and Development, Tokyo, Japan; [2]Department of Advanced Technology for Transplantation, Osaka University Graduate School of Medicine, Osaka, Japan; [3]AIDS Research Center, National Institute of Infectious Diseases, Tokyo, Japan; [4]Department of Immunology, Lerner Research Institute, Cleveland Clinic, Cleveland, United States.

Backgroud: Regulatory dendritic cells (DCreg) play an essential role in inducing and maintaining immune tolerance, representing a potential therapeutic tool for organ transplantation.
Methods: In the present study, we attempted weather systemic administration of donor-type iPSCs derived DCregs (iPS-DCregs) could lead to permanent acceptance of fully MHC-mismatched murine allogeneic cardiac grafts[1]. We used the mouse cardiac transplantation model (C57BL/6, H-2Kb into CBA/N, H-2Kk) to test the hypothesis.
Result: Recipients (CBA/N) pretreated with donor-type (C57BL/6, B6) iPS-DCregs accepted B6 cardiac grafts but rejected third-party (BALB/c, H-2Kd) grafts. The number of graft infiltrating CD8+ T cells in iPS-DCregs treated recipients was significantly decreased compared with no-treat group, and the Foxp3+ T cells were significantly increased. Further, the naïve secondary recipients (CBA/N) treated with the adoptive transfer of splenocytes from iPS-DCregs treated primary recipients on POD100 accepted B6 cardiac grafts but rejected BALB/c grafts. Dramatically, the above effects were reversed by infusion of anti-TGFβ or anti-CD25.
Conclusion: Our data indicated that preconditioning of donor-type iPS-DCregs to recipients generated antigen-specific Tregs in association with TGFβ. These findings highlight the iPS-DCregs will be a key cell therapy in clinic transplantation.

Human regulatory macrophages are capable of suppressing the allogeneic response in vitro via soluble molecules

Yuanfei Zhao[1,2], Yixiong Tan[1,2], Fei Guo[1,2], Dandan Huang[1,2], Min Hu[1,2], Wayne J.Hawthorne[1,2], Shounan Yi[1,2], Philip J.O'Connell[1,2]. [1]Centre for Transplant and Renal Research, The Westmead Institute for Medical Research, Sydney, Australia; [2]The University of Sydney, Sydney, Australia.

Introduction: Human regulatory macrophages (Mreg) have been shown to suppress mitogen-driven T cell proliferation in vitro and are under evaluation as a cellular therapy in renal transplantation in THE ONE STUDY clinical trial. In this study we investigated whether human Mreg were capable of suppressing the allogenic response in vitro and the mechanisms involved.
Methods: Human CD14+ cells were isolated from healthy donor peripheral blood monocytes (PBMC) using CD14 magnetic beads. Mreg induction was performed by culturing CD14+ cells with macrophage colony-stimulating factor (M-CSF) for 6 days. On day 6 cells were stimulated with IFN-γ for a further 24 hr. The phenotype of Mreg were characterized by flow cytometry, and their suppressive activity was tested by mixed-lymphocyte reaction (MLR) using human PBMC as responder cells, autologous Mreg as suppressor cells and irradiated allogeneic PBMC as stimulator cells. In a separate transwell MLR setting, responder and allogeneic stimulator cells were cultured in the upper chamber and autologous Mreg were seeded in the lower chamber. Supernatants collected from MLR cultures were used for cytokine detection using cytokine beads array and ELISA kits and IDO activity assay by HPLC, respectively.
Results: The resulting induced human Mreg demonstrated a typical Mreg phenotype, CD14low CD80low CD86+ HLA-DR+ CD83low CD16-, and as a result, potent suppression of proliferating alloreactive PBMC even at Mreg: responder cells ratios >1:16. Separation of Mreg from responder and allogeneic stimulators in a transwell MLR system had mild impact on their suppressive potency in the allogeneic response at all ratios of Mreg:responder cells tested. Upregulated levels of Mreg function related molecules TGF-β and IDO were detected in the supernatants collected from both non-transwell and transwell MLR cultures containing Mreg.
Discussion: In vitro induced human Mreg showed capacity to suppress the allogeneic response in vitro and Mreg-mediated suppression was not cell-cell contact dependent.
Conclusions: This study suggested soluble molecules TGF-β and IDO involved mechanisms used by human Mreg to suppress the allogeneic response in vitro. The requirement of these soluble molecules for Mreg-mediated immunomodulation of the allogeneic response is being under further investigation by blockading TGF-β and IDO activity in MLR assays.

Anti-A immune response in mice to ABO-blood carbohydrates antigen is T cell dependent

Ibrahim Adam[1,4], Bruce Motyka[2,4], KeSheng Tao[2,4], Lori West[1,2,3,4]. [1]Medical Microbiology & Immunology, University of Alberta, Edmonton, AB, Canada; [2]Pediatrics, University of Alberta, Edmonton, AB, Canada; [3]Surgery, University of Alberta, Edmonton, AB, Canada; [4]Alberta Transplant Institute, University of Alberta, Edmonton, AB, Canada.

Background: ABO-incompatible heart transplantation (ABOi HTx) is safe during infancy and allows increased access to donors. B-cell tolerance develops to donor A/B antigen(s) (Ag) following ABOi HTx, but mechanisms of tolerance are not well-defined. Using a recently developed A-transgenic (A-Tg) mouse on B6 background (express A Ag on vascular endothelium and erythrocyte (RBC)), we investigated the role of CD4+ T-cells in anti-A antibody (Ab) production.
Methods: Wild-type C57BL/6 mice (WT) were injected i.p. 3x, 1 week apart with human blood group A (n=3) or A-Tg (n=12) RBCs and adjuvant. Four weeks later, mice injected with A-Tg RBCs were injected i.p. with human A-RBCs. Anti-A Ab in serum was measured by hemagglutination and ELISA (both IgG and IgM). To deplete CD4+ T-cells, rat anti-mouse Ab (GK1.5) was used, 3x 1 week apart, pre and post human A-RBC injection (n=5). To study the effect of antigens on human RBCs, human group-O and A-Tg RBCs were mixed, injected i.p. 3x, 1 week apart in WT (n=5), then anti-A IgM titer was measured.
Results: Despite comparable A-Ag expression, A-Tg RBCs did not induce anti-A Ab in WT mice (titer ≤1:2), in contrast to human A-RBCs (titer=512). Four weeks after A-Tg RBC injection, human A-RBC injection induced anti-A Ab (median titer=256). Human A-RBC injection following CD4+ T-cell depletion did not produce anti-A Ab to human A-RBCs (titer <4). Moreover, co-injection of A-Tg and human O-RBC into WT mice did not induce anti-A Ab (titer ≤1:2).
Conclusions: Administration of A-Ag alone (A-Tg RBC) to WT mice was not sufficient to induce an anti-A Ab response. In contrast, human A RBC (A antigen plus foreign glycoproteins/glycolipids) induced a strong anti-A Ab response which was CD4+ T cell-dependent. The lack of an anti-A Ab response following co-injection of A-Tg RBCs and human O RBC is consistent with a requirement for a chemical linkage of foreign protein/lipid with A-antigen. Administration of A-antigen alone (A-Tg RBC) did not induce tolerance inasmuch as subsequent administration of human A RBC elicited anti-A Ab.

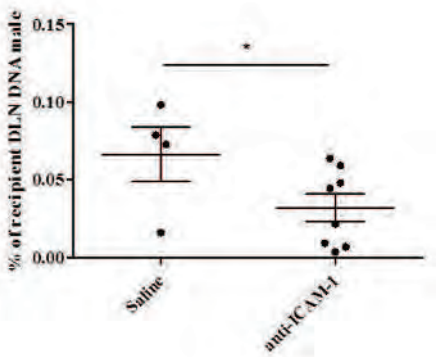
Anti-ICAM-1 treatment hinders lymphatic trafficking of donor passenger leukocytes and prolongs murine kidney allograft survival

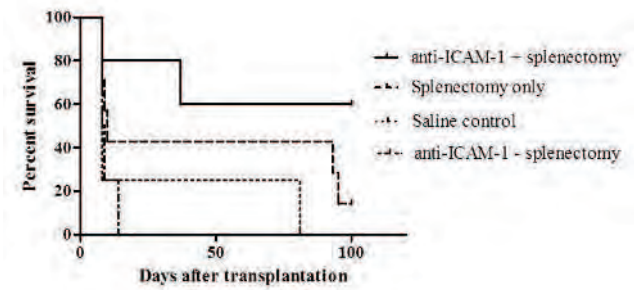
Lucy Meader, Lindsey A.Edwards, Anna Nowocin, Kathryn Brown, Wilson Wong.
Medical Research Council (MRC) Centre for Transplantation, King's College London, London, United Kingdom.

The immune response to an allograft is initiated when donor-derived foreign antigen is recognised by the host immune system, leading to the priming of graft-destructive T cells. This process relies on efficient trafficking of donor passenger leukocytes (DPL) out of the graft to secondary lymphoid organs, i.e. the local draining lymph nodes and spleen, via lymph and blood, respectively. This provides a suitable niche for interactions between antigen presenting cells and alloreactive T cells. The lymphatic vasculature permeates tissue and provides a conduit for immune surveillance. It is now known that lymphatic endothelial cells (LEC) play an active role in the adaptive immune response as they can; present antigens to T cells, affect dendritic cell function and alter the inflammatory milieu by secreting cytokines and chemokines. In addition to this; during inflammation LEC upregulate adhesion molecules important for DC transmigration, such as ICAM-1. We hypothesised that blocking ICAM-1 in a transplant model would hinder DPL trafficking to draining lymph nodes, and thus dampen the rejection process.

Fully allogeneic male BALB/c mouse kidneys were transplanted into female C57BL/6 recipients. Recipient mice were treated with either saline control, or a single dose of 200µg anti-ICAM-1 on the day of transplantation to inhibit transmigration of DPL across the lymphatic endothelium, and thus their passage to the local draining lymph nodes. Recipient spleens were removed to exclude this alternative route of T cell priming. Real-time quantitative PCR, for a donor male specific HY gene, was used to quantify donor passenger leukocytes in recipient draining lymph nodes.

Trafficking of DPL to recipient draining lymph nodes, in the initial post-transplant period, was reduced in anti-ICAM-1 treated recipients compared to saline treated controls. Figure 1 shows that the proportion of recipient draining lymph node DNA that was donor derived was significantly higher in saline treated recipients (0.06%) than anti-ICAM-1 treated recipients (0.03%) (p=0.0375), 24 hours after transplantation. In addition, graft survival was prolonged in anti-ICAM-1 treated splenectomised recipients, with 60% of recipients surviving indefinitely, compared to 14% in the splenectomy only group, and zero in both the saline control and anti-ICAM-1 only groups (figure 2).





These results demonstrate the effect of anti-ICAM-1 treatment on lymphatic trafficking of DPL in the immediate post-transplant period, and highlight the importance of interactions between antigen presenting cells and recipient T cells within secondary lymphoid organs to the rejection process.

Soluble fibrinogen-like protein 2 regulates differentiation and enhances immunosuppressive function of myeloid-derived suppressor cells in allograft immunity

Cheng Yang[1], Lingyan Wang[2], Ming Xu[3], Tongyu Zhu[3].
[1]Plastic Surgery, Zhongshan Hospital, Fudan University, Shanghai, People's Republic of China; [2]Biomed Research Center, Zhongshan Hospital, Fudan University, Shanghai, People's Republic of China; [3]Urology, Zhongshan Hospital, Fudan University, Shanghai, People's Republic of China.

Soluble fibrinogen-like protein 2 (sFGL2) is a novel immunoregulatory molecule, secreted mainly by regulatory T cells. CD11b+ Gr1+ myeloid-derived suppressor cells (MDSCs) are an important regulatory innate cell population and have significant inhibitory effect on T cell-mediated responses. Here, we synthesized murine full length sFGL2 by eukaryotic expression system, and investigated the impact on differentiation and function of MDSCs. Bone marrow cells from BABL/c mice were cultured with or without 10 μg/ml sFGL2 for 3 days and 5 days under 10 ng/ml GM-CSF stimulation. Compared with PBS, sFGL2 significantly induced CD11b+Ly6G-Ly6Chigh MDSC (MO-MDSC) differentiation but inhibited CD11b+Ly6G+Ly6Clow MDSC (PMN-MDSC) differentiation. The sFGL2-induced MO-MDSCs significantly inhibited T cells proliferation compared with those induced by PBS. Besides, sFGL2-induced MO-MDSCs demonstrated higher expression of arginase-1 and iNOS at both mRNA and protein level. Furthermore, adoptive transfer sFGL2-induced MO-MDSCs prolonged the skin allograft survival in mice. In the sFGL2-induced MO-MDSCs infusion group, the transplanted skin allograft showed mild inflammatory immune cell infiltration, less apoptosis and necrosis, and lower pro-inflammatory cytokines expression. T cells in the recipient mouse displayed a lower autoimmune phenotype (lower TCR+ CD44high CD62low cells). Taken together, our results indicate sFGL2 prompts MO-MDSCs differentiation and enhances their immunosuppressive function.

Reduction in CXCL9–CXCR3 signals diminishes TRAIL-expressing liver NK cells in partially hepatectomized mice under depressed immune status

Takuya Yano, Masahiro Ohira, Ryosuke Nakano, Hideki Ohdan.
Department of Gastroenterological and Transplant Surgery, Hiroshima University, Hiroshima, Japan.

Introduction: Liver resident natural killer (NK) cells express the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), a critical molecule for NK cell-mediated anti-tumor cell killing. However, dynamics of the TRAIL-expressing NK cells after partial hepatectomy (PH) or liver transplantation (LT) is unknown. In the present study, we used a mouse model to evaluate the effect of PH on the number and function of TRAIL-expressing NK cells in the liver.
Methods: To quantify the number and function of NK cells after PH, the liver was perfused and lymphocytes were purified using a density gradient. Flow cytometry revealed the changes in surface phenotype and intracellular protein production.
To assess the anti-tumor activity in vivo, Hepa1-6 cells were injected intra-portally into C57BL/6 mice following a 70% hepatectomy.
To investigate the liver environment during hepatectomy, cytokines and chemokines in the liver and their corresponding receptors on liver NK cells were measured.
Results: The expression of TRAIL in liver NK cells was temporarily down-regulated after a 70% PH (7 mice experiments; $p < 0.01$ for day 3 vs control). Although PH allowed tumor growth in the liver, adoptive transfer of TRAIL-expressing liver NK cells prevented the spread of metastases.
After PH, mRNA and protein levels of CXCL9 and interferon (IFN)-gamma significantly decreased in the liver (Fig 1A). Comprehensive analysis of chemokine receptors revealed that CXCR3, which is the receptor of CXCL9, was strongly expressed by TRAIL-expressing NK cells (98.8% ± 0.1 %) but not by TRAIL-negative NK cells (20.4% ± 2.3 %), (n = 5, p = 0.008) (Fig1B 1C 1D). Augmentation of CXCL9 in the liver by injecting poly I:C into mice maintained the TRAIL-expressing NK cells in the liver even after a 70% PH (Fig2A 2B 2C). Analysis of intracellular flow cytometry results showed that Kupffer cells extensively produced CXCL9 in response to IFN-gamma in various liver component cells.

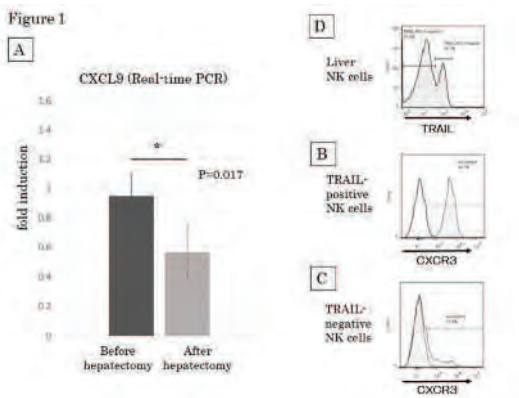

Figure 2

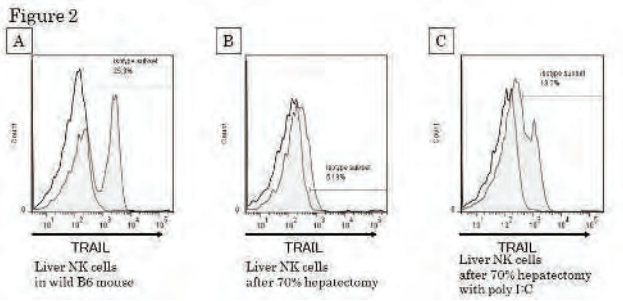

Discussion: In this study, we have shown that the number of TRAIL-expressing NK cells and anti-tumor activity in the liver decreased after 70% PH. The depressed immune status including activity of liver resident NK cells caused hepatocellular carcinoma (HCC) recurrence after PH or LT. The CXCL9-CXCR3 pathway in the liver is the possible molecular mechanism causing the recurrence. Since CXCL9 decreased after PH, TRAIL-expressing NK cells that had CXCR3 could not be maintained in the liver. Furthermore, intrahepatic IFN-gamma regulated Kupffer cells to produce CXCL9.
Conclusion: Significant reduction in TRAIL-expressing NK cells in the liver after 70% PH is associated with the impaired intrahepatic CXCL9–CXCR3 pathway. Our results suggest the possibility of developing strategies to augment CXCL9 levels in the liver to prevent HCC recurrence after PH or LT, i.e., the combination of immunotherapy using TRAIL-expressing NK cells and chemokine CXCL9.

NK cells promote kidney graft rejection through evasion of cyclosporine a therapy

Muhammad Imtiaz Ashraf[1], Thomas Resch[2], Cornelia Fabritius[2], Susanne Ebner[2], Paul Ritschl[1], Vanessa Mellitzer[2], Julia Günther[2], Felix Aigner[1], Johann Pratschke[1], Katja Kotsch[1].
[1]Department of General, Visceral, and Transplantation Surgery, Experimental Surgery and Regenerative, Charité-Universitätsmedizin Berlin, Berlin, Germany; [2]2Department of General, Visceral, and Transplantation Surgery, Innsbruck Medical University, Innsbruck, Austria.

Background: Despite advances in immunosuppressive regimens having significantly increased short-term graft outcome, overall long-term graft survival has not dramatically changed. Frequently used immunosuppressive drugs e.g. calcineurin inhibitors (CNI), either cyclosporine A (CsA) or tacrolimus (Tac) are primarily targeting T cells, whereas their efficacy in suppressing other immune subsets such as NK cells might be limited, which may explain the incomplete long-term benefits. As NK cells have recently been recognized as key players in chronic allograft failure comprehensive studies are required to address whether NK cells can escape conventional immunosuppressive regimens and play a role in recurrence of allograft rejection.
Methods: We characterized the effects of cyclosporine A (CsA) in vitro and ex vivo on human and murine NK cells and further assessed its functional influence on NK cells during transplantation using a murine model of allogenic KTX (Balb/C to C57Bl/6). Immunophenotyping of NK cells and other graft infiltrating lymphocytes was performed by flow cytometry. Allograft function was assessed by measuring serum creatinine and urea levels. For histology tissue sections were stained with HE and PAS and evaluated according to the Banff criteria. Expression of cytokines and inflammatory markers was performed by RT-qPCR.
Results: In vitro, human NK cells treated with CsA concentrations (5-1000 ng/ml over 1-3 days) were insensitive concerning viability, expression of activation markers (CD16, NKp30, NKp44, NKp46), pattern of differentiation (CD65dim/CD56bright) and IFNγ production. Concordantly, ex vivo, CD3-NKp46+ NK cells isolated from CsA treated C57BL/6 mice (10 mg/kg for 7 days) revealed normal function regarding degranulation and IFNγ production, whereas CD8+ T cells were functionally impaired. In vivo, application of CsA to C57BL/6 recipients of fully allogeneic Balb/C kidneys resulted in a significant reduction of creatinine levels at day 7 (KTX: 35.6±4 vs. KTX+CsA: 19.8±4 mmol/L; $p<0.05$). Flow cytometric analysis revealed a CsA mediated reduction of intragraft CD4+ and CD8+ T cells by halve, whereas intragraft NK cell frequencies significantly increased (KTX: 10±0.4 vs. 17.5±1.5; $p<0.01$) and remained unaffected within the spleen or liver. Importantly, the additional depletion of NK cells (anti-NK1.1 Ab) resulted in a further improvement of kidney function (12±0.5 mmol/L; $p<0.01$) associated with reduced intragraft and splenic IFNγ expression levels ($p<0.05$, respectively).
Conclusion: CsA insufficiently targets human and murine NK cell function ex vivo and fails to affect NK cells in vivo. We show for the first time that NK cell depletion combined with CsA synergistically improves graft function in an acute transplantation setting, suggesting that selective NK cell targeting might constitute a novel approach to ameliorate outcomes after KTX in the long-term.

Klotho deficiency aggravates tacrolimus-induced renal injury via the PI3K-Akt-FoxO pathway

Jian Jin, Longt Jin, Chul Woo Yang, Kang Luo, Sun Woo Lim.
Seoul St. Mary's Hospital, The Catholic University of Korea 641 Banpo-ro, Seocho-Ku, Seoul 137-040, Korea, Seoul, Korea.

Background: Klotho is highly expressed in the kidney, is present in the circulation and urine, and has protective effects against various renal injuries. We examined whether reduced Klotho expression affects tacrolimus (Tac)-induced renal injury in an experimental model of chronic Tac nephropathy.
Methods: First, we evaluated the association between the Tac dose and Klotho expression by giving different doses of Tac (0.25, 0.5, and 1 mg/kg) to wild-type (WT) mice for 4 weeks. Second, we compared Klotho levels, renal function, fibrosis, and apoptosis between WT mice and Klotho heterozygous (HT) mice in an experimental model of chronic Tac nephropathy. Third, we examined whether the oxidative stress and signaling pathway is involved in the protection by Klotho against Tac-induced renal injury.
Results: Klotho levels in renal tissue and urine were reduced in a dose-dependent manner in Tac-treated WT mice. Tac-treated HT mice showed lower levels of Klotho in the renal cortex and urine, and higher serum creatinine level, fibrosis, and apoptosis compared with WT mice. Treatment of Tac to WT mice increased markers of oxidative stress such as PI3K–Akt and FoxO3a phosphorylation but decreased FoxO1 dephosphorylation. These effects were greater in HT mice. HT mice exhibited a much lower level of manganese superoxide dismutase level and higher level of Bim, target genes of FoxOs, compared with the levels in WT mice.
Conclusion: Reduced Klotho expression aggravates Tac-induced renal injury via the PI3K–Akt–FoxO pathway.

VDJ immune repertoire sequencing predicts patients at risk of alloimmune injury

Marina Sirota[1], Tara Sigdel[1], S. Boyd[2], A. Fire[2], Minnie Sarwal[1].
[1]University of California San Francisco, San Francisco, CA, United States; [2]Stanford University, Stanford, CA, United States.

Background: The complex repertoire of immune receptors generated by B cells enables allo-recognition in the context of transplantation across HLA barriers, and is a major contributor for the persistence of unrecognized, sub-clinical lymphocyte immune activation, resulting in acute and chronic immune mediated graft injury. High-throughput DNA sequencing technologies have been advancing at an extremely rapid pace and are transforming our understanding of humoral immune responses.
Methods: DNA sequencing of rearranged immune receptor loci was performed in 99 serial blood samples, collected at 0, 6, 12 and 24 months after transplantation in 36 unsensitized kidney transplant recipients with and without acute rejection and progressive chronic injury. Matched, centrally scored, histopathology compartment scores and graft function were also obtained on all patients at all time points. We used a series of redundant primers to amplify diverse DNA rearrangements, and the resulting mixtures of barcoded amplicons were sequenced using long-read ultra-deep sequencing. Individual DNA molecules were then characterized on the basis of DNA segments that were joined to make functional (or nonfunctional) immune effectors.
Results: Nearly 600,000 sequences were generated across 99 samples resulting in roughly 200,000 unique clones, defined by the VDJ recombination patterns and the CDR3 region sequence. We observed significantly more B-cell sequences and clones present in the acute rejection group in comparison to the other sub-groups (ANOVA p= 0.0006545), with greater expansion also seen in the patients with greater biopsy chronicity at 24 months (ANOVA p=5.016e-05). Importantly, in the acute rejection group B cell sequences and clones were expanded across all time points, inclusive of the pre-transplant sample. Longitudinal analysis tracking clones across the various time points observed similar and related clones across different people.
Conclusions: VDJ sequencing demonstrates expansion of specific B-cell clones prior to transplantation, even in the absence of allo-sensitization. This B cell clonal expansion is highly predictive of acute rejection and accelerated chronic rejection. B cell immune priming is currently unrecognized, and maybe harnessed for immunosuppressive drug selection at engraftment.

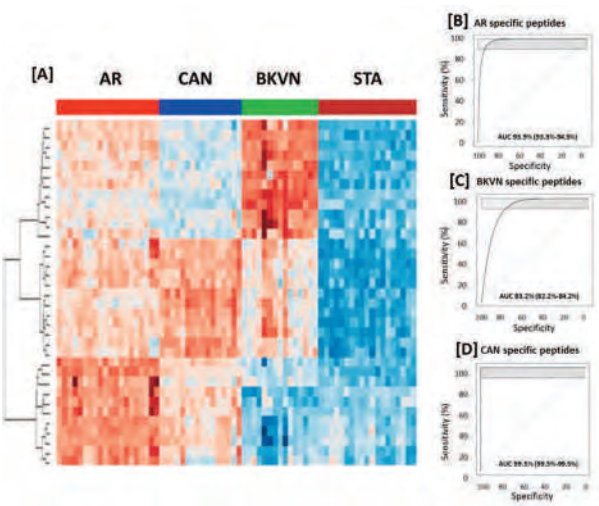
Mining the human proteome for monitoring renal transplant injury

Tara Sigdel[1], Y. Gao[2], J. He[2], A. Wang[1], C. Nicora[2], D. Smith[2], W. Qian[2], D. Camp[2], Minnie Sarwal[1].
[1]Surgery, University of California San Francisco, San Francisco, CA, United States; [2]Pacific Northwest National Laboratory, Richland, CA, United States.

The human urinary proteome reflects systemic and inherent renal injury perturbations and can be harnessed to define biomarkers for different kidney transplant injury states. Through a NIH-funded study, we sought to identify and validate panels of urine proteins that could serve as non-invasive surrogate biomarkers for kidney transplant injuries.
396 unique urine samples were collected contemporaneously with an allograft biopsy from 396 unique kidney transplant recipients. Centralized, blinded histology on the graft phenotyped matched urine samples into categories of acute rejection (AR), chronic allograft nephropathy (CAN), BK virus nephritis (BKVN), and stable (STA). A strategy involving liquid chromatography–mass spectrometry (LC-MS) based shotgun proteomics using iTRAQ based discovery (n=108) to quantify pooled samples and global label-free LC-MS analyses of individual samples (n=137) and targeted validation with selected reaction monitoring (SRM; n=151) was applied to identify and validate minimal urine protein/peptide biomarkers to accurately segregate organ injury causation and pathology. The panel of peptides was selected with an algorithm called LASSO and its extension elastic net.
A total of 958 proteins were initially quantified by iTRAQ, 87% of which were also identified among 1574 urine proteins detected in label-free LC-MS validation. 103 urine proteins were significantly ($p<0.05$) perturbed in graft injury and enriched for humoral immunity, complement activation and lymphocyte trafficking. A set of 131 peptides corresponding to 78/103 proteins were measured by SRM and validated as significant in an independent sample cohort. A rigorous A minimal set of 35 peptides mapping to 33 proteins, were modeled to segregate different injury groups (AUC =93% for AR, 99% for CAN, 83% for BKVN) [Fig1].



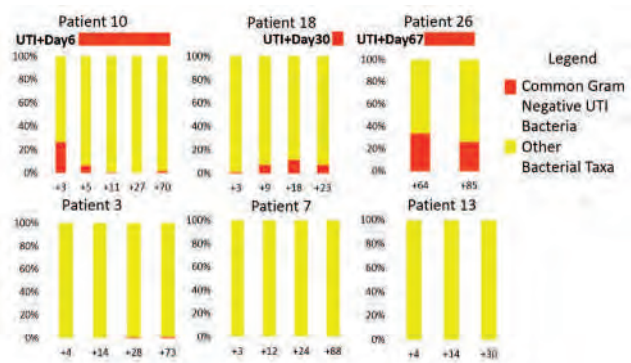
This translational research used biomarker discovery and validation used mass spectrometry based urinary proteomics and has identified urine protein fingerprints for non-invasive differentiation of kidney transplant injuries, thus opening the door for personalized immune risk assessment and therapy.

458.3

Gut microbial composition predictive of gram-negative urinary tract infections in kidney transplant recipients

John Lee[1], Muthukumar Thangamani[1], Darshana Dadhania[1], Lilan Ling[2], Matthew Magruder[1], Eric Pamer[2], Manikkam Suthanthiran[1].
[1]Medicine/Nephrology and Hypertension, Weill Cornell Medicine, New York, United States; [2]Medicine/Infectious Diseases, Memorial Sloan Kettering Cancer Center, New York, United States.

Introduction: Disturbance in the gut flora (i.e. antibiotic administration) is a known risk factor for development of *Clostridium difficile*, but its relationship to other infectious bacterial complications is not well defined. We reported that fecal *Enterococcus* abundance precedes and/or is associated with development of *Enterococcus* urinary tract infections (UTI) in kidney transplant recipients[1]. In this cohort of transplant recipients, we examine the relationship between the gut microbiota and common gram-negative UTIs in kidney transplantation.
Methods: We prospectively enrolled 26 kidney allograft recipients from 2011 to 2012 and collected serial fecal specimens during the first three months after kidney transplantation (N=85 specimens). We characterized the gut microbiota in all 85 fecal specimens using 16S rRNA deep sequencing of the V4-V5 hypervariable region. We evaluated whether the fecal abundance of common gram-negative UTI bacteria (defined by the following genera: *Escherichia*, *Klebsiella*, *Pseudomonas*, *Enterobacter*, *Citrobacter*, and *Proteus*) was associated with common gram-negative UTIs.
Results: Three of the 26 recipients developed common gram-negative UTIs (*Escherichia coli*, *Klebsiella oxytoca*, and *Proteus mirabilis*) and had available fecal specimens during the time frame of the UTI. Figure 1 shows the 3 recipients with UTI and 3 representative recipients who never developed common gram negative UTIs. In this figure, the gut microbial composition as a percentage of common gram-negative UTI bacteria is shown on the y axis and post transplantation days when the fecal specimens were collected for microbial composition analyses are shown on the x axis. The 3 transplant recipients who developed UTIs had a higher fecal abundance of common gram-negative UTI bacteria at the time of UTI (median, 7.3% [range: 6.5% to 33.6%]) than the 23 transplant recipients who did not develop common gram negative UTIs (time-matched specimens, median 0.4% [interquartile range: 0% to 1.5%]) (P=0.005, Wilcoxon rank sum test).



Conclusions: Fecal abundance of common gram-negative UTI bacteria is associated with common gram-negative UTIs, highlighting a novel interplay between the gut microbiota and urinary tract infections, and importantly the potential for personalized infection prophylaxis.

Host microbiota of cardiac allograft recipients is durably altered by fecal microbiota transplant and these changes correlate with allograft outcome

C. Colin Brinkman[1], Lauren Hittle[2], W. Florian Fricke[2], Emmanuel F.Mongodin[2], Jonathan Bromberg[1].
[1]Surgery, Microbiology and Immunology, University of Maryland School of Medicine, Baltimore, MD, United States; [2]Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, MD, United States.

Hypothesis: We previously presented highly significant differences in the bacterial community structures of human renal allograft recipients as a result of transplantation and attendant medications that persisted over time. These results suggest that longitudinal changes in each individual's microbiota have the potential to be indicative of health or disease in the context of transplantation. We also found that murine normal, colitic, and pregnant fecal samples influenced murine cardiac allograft survival and were markedly distinct from each other in bacterial composition and community structure, notably, in the abundance of Bifidobacterium. We hypothesized that these differences persist after fecal microbiota transplant (FMT) into mice with cardiac allografts and that they correlate with allograft outcome.
Methods: Mice were fed antibiotics (kanamycin, gentamicin, colistin, metronidazole, vancomycin) ad libitum in drinking water on days -6 to -1 before transplant. On d0 C57BL/6 mice received BALB/c hearts. Fecal samples from healthy C57BL/6, female mice on d11-12 of pregnancy, colitic T cell receptor transgenic mice that spontaneously develop colitis, or cultured Bifidobacterium pseudolongum (ATCC25526) were also transferred on d0 by gavage. Mice received daily immunosuppression: tacrolimus (2 mg/kg/d sc d0-40 or 3 mg/kg/d sc d0-60) starting on day 0. Fecal pellets and intestinal tissue were collected from transplanted mice, and analyzed via 16S rRNA gene sequencing and RNA-Seq. Cardiac allografts were assessed for survival, harvested at d40, 60, or rejection, and stained with H&E and Masson's Trichrome.
Results: 16S rRNA gene analysis of transplant recipient stool samples revealed highly significant differences in the bacterial community structures of recipients of normal, colitic, and pregnant FMT, and cultured B. pseudolongum, as determined by bacterial composition and relative abundance, principle component analysis and hierarchical clustering. Bacteria from the genus Bifidobacterium were absent in colitic, yet present in normal and pregnant source samples and remained fairly abundant in pregnant transplanted samples for at least 40 days. In general the microbiota of recipients of normal, colitic, and pregnant fecal samples converged over time, but remained distinct for at least 40 days. Mice receiving pregnant FMT or B. pseudolongum had the highest graft survival rates, and least histological evidence of graft inflammation and fibrosis indicating a possible anti-inflammatory effect of Bifidobacterium bacteria.
Conclusion: FMT of pro- and anti-inflammatory fecal microbiota and specific components of the microbiota result in durable changes to host microbiota. These changes correlate with alterations in systemic immunity with consequences for graft survival, rejection, and inflammation.

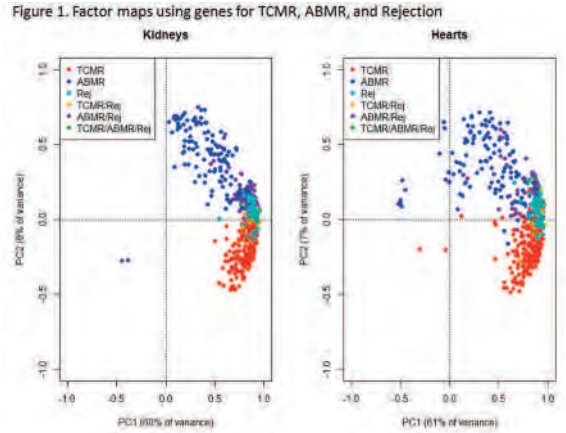
A molecular microscope diagnostic system (MMDx) for heart transplant biopsies developed from the molecular phenotypes of rejection in kidney transplants.

Philip Halloran[4], Daniel Kim[4], Alexandre Loupy[2], Jean-Paul Duong Van-Huyen[2], Patrick Bruneval[3], Luciano Potena[1], Ornella Leone[1], Jeff Reeve[4].
[1]University of Bologna, Bologna, Italy; [2]Necker Hospital, Paris, France; [3]Hôpitaux de Paris, Paris, France; [4]University of Alberta, Edmonton, AB, Canada.

The diagnosis of heart transplant rejection by histology in endomyocardial biopsies (EMB) is challenging. A molecular system (MMDx) has been developed to assess both T cell-mediated (TCMR) and antibody-mediated (ABMR) rejection in kidney transplant biopsies. The present project adapted the MMDx derived in kidney transplant biopsies to heart transplant EMBs. We collected a single bite from 331 standard-of-care EMBs from three centers and processed them on Affymetrix microarrays. EMB diagnoses were assessed by histology using ISHLT guidelines. To develop diagnostic tests for EMBs, the genes most highly associated with Rejection, ABMR, and TCMR in kidney transplants were used to perform semi-supervised clustering on the EMBs. Figure 1 shows that the multivariate distribution of these genes was highly conserved between kidney biopsies (left panel) and heart biopsies (right panel).

Figure 1. Factor maps using genes for TCMR, ABMR, and Rejection



The biopsies segregated into three overlapping molecular clusters in the discovery set, roughly corresponding to histologic diagnoses of TCMR, ABMR, and No Rejection (figure 2). Some histology ABMR and TCMR (particularly TCMR1) biopsies were molecularly No Rejection. Two-thirds of the biopsies were used as a discovery set, and the remaining third as a validation set. A predictive model for probability of ABMR, TCMR, or no rejection, based on the molecular distribution of biopsies in the discovery set, was used to assign scores to the biopsies in the validation set. These were distributed similarly to those in the discovery set. Biopsies designated as ABMR by the molecular test showed reasonably good agreement with histology, and were highly associated with HLA antibody. There was considerable less agreement between molecular and histologic TCMR, supporting concerns that the current histologic ISHLT assessment of EMBs is poorly predictive of true TCMR. We conclude that the MMDx can interpret rejection in EMBs, and the results show strong molecular similarity to rejection in kidney biopsies. The results also raise concerns about the accuracy of histologic assessment, particularly of TCMR, but open the possibility of using the molecular classification as a reference standard to improve conventional assessments of EMBs.

We and others have previously analysed rare kidney transplant recipients (KTR) that are operationally tolerant in that they have retained their transplant despite stopping all immunosuppression. These studies described a signature that displayed over-expression of B-cell-related genes and a relative expansion of the transitional-Bcell subset size. A key question confounding these studies was whether the features seen in the tolerant patients merely reflected the fact that they were not taking immunosuppression (IS), unlike all the comparator patient groups.
We re-analysed microarray data from our previous study, and validated on an independent cohort of 250 KTR on IS and 14 newly identified tolerant recipients.
We demonstrate that many of the genes with altered expression between tolerant subjects and the other KTR are influenced by IS. Additionally, flow-cytometry analyses show that IS drugs affect transitional B-cells in a way that mirrors their effects on gene-expression, but not other lymphocyte subsets as much. To address this problem, we have used a regression approach to obtain IS-independent expression and define a new unbiased signature of tolerance, using elastic-net regularized regression tuned via cross-validation. The new IS-independent signature was validated with AUC=0.93, and also differentiated tolerant patients from healthy controls. The statistical results are validated by a proof of concept prospective study that demonstrates that the IS-independent signature is robust to actual changes in IS, and remains stable when comparing samples before and after steroid withdrawal.
Conclusion: We report on a validated and highly accurate gene-expression signature that could be used reliably to identify patients suitable for IS reduction, irrespective of the IS drugs they are receiving. Only this approach will make the conduct of pilot clinical trials for IS-minimization safe, and hence allow critical improvements in kidney post-transplant management.

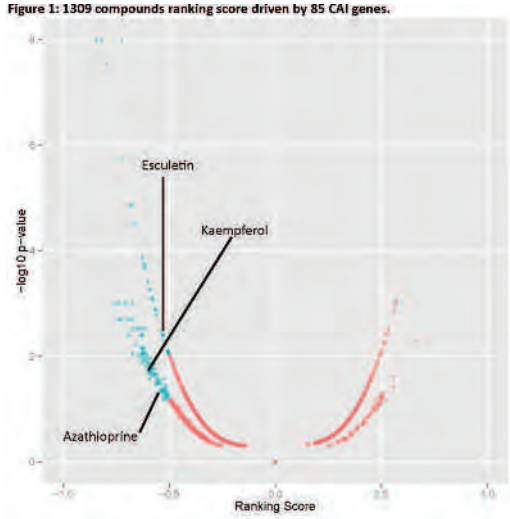
Identification of novel therapeutics and targets for chronic allograft injury using integrative informatics approach

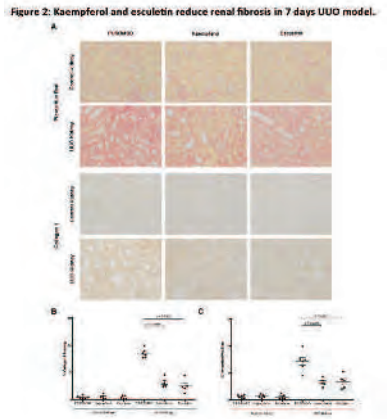
Li Li[1], Ilana Greene[2], Benjamin Readhead[1], Brian Kidd[1], Andrew Uzilov[1], Madhav Menon[2], Bernd Schroppel[2], John Cijiang He[2], Rong Chen[1], Joel Dudley[1,3], Barbara Murphy[2].
[1]Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, United States; [2]Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, United States; [3]Health Policy and Research, Icahn School of Medicine at Mount Sinai, New York, NY, United States.

Background and Hypothesis: Chronic allograft injury (CAI) is a leading cause of allograft failure and significantly impacts with long-term allograft survival[1]-[3]. Few effective therapeutic options are available to prevent or revert the progression of CAI. In this study, we aimed to identify novel therapeutic targets to potentially ameliorate CAI through an integrative computational framework. We hypothesized that a robust molecular signature from a meta-analysis of multi-center independent gene expression data sets integrated with a computational drug repurposing approach would suggest novel therapeutic targets for rational drug discovery and design.
Methods: We developed a computational framework to identify novel therapeutic targets with potential to ameliorate CAI. Our analysis utilized six independent microarray datasets comprising 275 samples generated by ourselves and others from Gene Expression Omnibus (GEO) as well as chemogenomic profiles of 1,309 compounds from the Connectivity Map[4]. We applied a meta-analysis approach to identify the gene signature specific to CAI, which was used as input for computational drug repurposing analysis. We hypothesized that if a CAI state is signified by a specific set of genome-wide transcriptional expression changes, and if exposure to a particular drug causes the reverse set of changes in a model cell line, then that drug has the potential to have a therapeutic effect on CAI. We used human kidney 2 (HK2) cells and mouse unilateral ureteric obstruction (UUO) model to validate the cellular pathways and study the development of renal interstitial fibrosis that were perturbed by the predicted drugs.
Results: We identified 85 genes that were associated with CAI. We thus generated a ranked list of potential treatments for CAI from compounds predicted to induce an anti-correlated state to CAI ($P \leq 0.05$)[5],[6]. Among the top ranked compounds predicted to be therapeutic for CAI were azathioprine (score=-0.53, p=0.04), a drug to prevent acute rejection in renal transplantation[7] and treat pulmonary fibrosis[8], and kaempferol (score=-0.57, p=0.02) and esculetin (score=-0.52, p=0.01), two drugs not previously described to have efficacy for CAI (Figure 1).

Figure 1: 1309 compounds ranking score driven by 85 CAI genes.



In UUO model, kaempferol reduced the expression of *Snai1* (p=0.04); esculetin reduced the expression and protein levels of *cyclin D1* (p=0.004). In HK2 cells, kaempferol attenuated TGF-b1 induced fibrotic and inflammatory mechanisms, as measured by reduction in the phosphorylation of *SMAD3* (p=0.01), NFkB *P65* (p=0.02), and reduction in expression of *SNAI1* (p=0.01) and *CDH1* (p=0.045). Esculetin attenuated Wnt-induced fibrotic mechanism, as measured by reduction in protein levels of *CCND1* (p=0.005) and reduction in expression of *CCND1* (p<0.0001) and *MYC* (p=0.01). Kaempferol and esculetin reduced fibrosis as compared with PBS/DMSO vehicle in UUO model as measured by collagen I immunohistochemistry and picrosirius red staining. Histology confirmed significantly abrogated fibrosis by kaempferol (p<0.0001 and p=0.0009) and esculetin (p<0.0001 and p=0.001) (Figure 2).



Conclusion: We developed and applied an integrative computational approach to identify kaempferol and esculetin as putatively novel therapies for CAI and provided experimental evidence for their therapeutic activity in vitro and in vivo using preclinical models. The findings suggest that both drugs might serve as therapeutic options for CAI.

First clinical results of a saliva testing for monitoring after renal transplantation

Dietmar Abendroth[1], Jürgen Kaden[2], Michael Marzinzig[1], Manfred J.Stangl[3].
[1]Center of Surgery, University of Ulm, Ulm, Germany; [2]Clinical Chemistry, Vivantes-Klinikum Friedrichshain, Berlin, Germany; [3]Transplant Center Munich-Großhadern, Ludwig-Maximilians-University, Munich, Germany.

Introduction: There remains a need for biomarker in transplantation for monitoring and early identification of rejection episodes. We developed a test using a colorimetric assay to detect kynurenine (Kyn) changes in serum and saliva. Kynurenine is generated downstream in the tryptophan metabolism and one of the key players concerning inflammatory response and known for immune-modulation not only on T-regulatory and NK cells. Furthermore, we developed a monoclonal antibody against kynurenine for application in a lateral-flow-test (LFIA) especially in saliva.

Materials and Methods: Blood samples were measured retrospectively from 442 renal transplant patients (Gr.1, 69 rejection episodes) (n=5210) and prospectively from 116 patients (Gr.2) after renal transplantation (n=803). 296 healthy blood donors served as normal controls. Serum (B) **and** saliva (S) were compared in normal controls and in Gr.2 with 24 rejection episodes (BPAR).

Results: Test-recovery rate was 97-99,8%, intra-assay variance 1,53% and inter-assay variance 2,77% (B) and 94,6-97,9%, 2,24% and 3,26% for (S). Values in normal controls were 2,7±0,4 µM for serum and 0,7±0,4 µM for saliva. Mean values in patients with rejection (BPAR) was 17,4±8,4 µM in (B) and 4,7±1,6 µM in saliva (S) compared to uneventful patients 4,4±1,5 µM (B) and 1,3±0,6µM (S). The proportion rate was equal between normal controls, uneventful patients after transplantation and rejection (3,8:1). We found a) a significant correlation of Kyn and rejection episodes (BPAR) early in the beginning without a false negative result (B+S), b) a predictive information concerning the long-term run of the transplant (n=138; up to 144 mos, only B) and c) excellent tool for monitoring therapeutic interventions. In (B) testing we could differentiate significantly between steroid-sensitive, steroid-resistant and antibody mediated rejection and infection (CMV). There was no difference concerning age, gender and circadian behavior.

Conclusion: This test fulfills the given prerequisites for a biomarker especially under screening test conditions. It is a safe and reliable method, is easy and quick to perform and not costly. The LFIA set-up is under evaluation and further development. A first prospective clinical observational and interventional study is underway. This test is an opportunity for a tailored immunosuppressive therapy.

Molecular and functional immune assays as non-invasive diagnostic tools to assess the risk of acute subclinical rejection after kidney transplantation

Oriol Bestard[1,2], Tara Sigdel[1], Silke Roedder[1], Elena Crespo[2], Josep Cruzado[2], Szu-Chuan Hsieh[1], Tim Tran[1], Josep Grinyó[2], Minnie Sarwal[1].
[1]Surgery, University of California San Francisco, San Francisco, United States; [2]Kidney Transplant Unit, Bellvitge University, Barcelona, Spain.

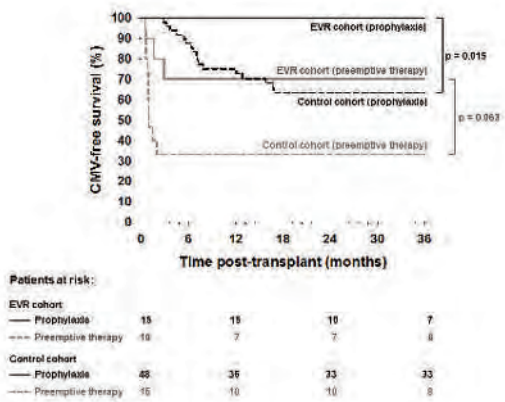
Body: Subclinical allograft rejection (sc-AR) is still a main cause of allograft loss that can only be assessed through invasive surveillance biopsies. We sought to investigate whether the combination of novel non-invasive biomarkers at the molecular and immune functional level could help identifying patients at risk of sc-AR after kidney transplantation.
Methods: We combined the assessment of the donor-specific IFN-γ T-cell ELISPOT with a highly sensitive and specific transcriptional biomarker test in peripheral blood samples predicting kidney solid organ clinical rejection (KSORT) using qPCR, in a group of 75 consecutive kidney transplant patients at the time of 6-month protocol biopsies.
Results: All patients received CNI-based IMS and either rATG or basilimab. 22/75(29%) patients showed histological lesions of sc-AR (18 TCMR, 5 ABMR and 1 mix TCMR/ABMR), 22 showed borderline (BL) lesions and 31 a stable (STA) parenchyma. The KSORT showed a high-risk (HR) and low-risk (LR) scores in 23% and 77% patients, respectively. The T-cell ELISPOT was positive in 41% of patients, whereas negative in 59%. 82% and 70% patients with BL lesions showed a LR KSORT and negative T-cell Elispot, respectively. The KSORT correctly classified as LR 98% STA and as HR 70% sc-AR ($p<0.001$), further discriminating as HR all (100%) sc-ABMR and 62.5% sc-TCMR ($p<0.001$). The d-s T-cell ELISPOT accurately ruled out the presence of sc-TCMR in 72% and predicted its presence in 83.3% ($p<0,001$), whereas it did not discriminate patients with sc-ABMR (p=NS). Transplant recipients with a positive T-cell ELISPOT showed significantly higher tubulitis (at) and interstitial infiltrates (ai) than patients with a negative ELISPOT test, whereas those patients with a positive KSORT showed higher at, ai as well as higher glomerulitis (ag) and peritubular capillaritis (ptc).
Conclusions: Combining a non-invasive molecular and functional cellular immune assay allows an accurate identification of patients developing sc-AR, dissecting the main alloimmune effector mechanism responsible for it.

459.1

Impact of everolimus and low-dose ciclosporin on cytomegalovirus replication and disease in pediatric renal transplantation

Britta Höcker[1], Sebastian Zencke[1], Lars Pape[2], Kai Krupka[1], Lennart Köster[1], Luca Dello Strologo[2], Isabella Guzzo[2], Rezan Topaloglu[2], Birgitta Kranz[2], Jens König[2], Martin Bald[2], Nicholas J.A.Webb[2], Aytul Noyan[2], Hassan Dursun[2], Stephen Marks[2], Zeynep B.Ozcakar [2], Florian Thiel[2], Heiko Billing[2], Martin Pohl[2], Henry Fehrenbach[2], Lutz T.Weber[2], Reinhard Feneberg[2], Paul Schnitzler[2], Thomas Bruckner[2], Thurid Ahlenstiel-Grunow[2], Burkhard Tönshoff[1].
[1]University Children's Hospital, Department of Pediatrics I, Heidelberg, Germany; [2]CERTAIN, Research Community, Germany.

Purpose: Preclinical studies indicate an anti-cytomegalovirus (CMV) activity of the mammalian target of rapamycin inhibitor (mTORi) everolimus (EVR), but data in pediatric renal transplant recipients are lacking.
Methods: In the framework of the Cooperative European Paediatric Renal Transplant Initiative (CERTAIN) Registry, we thus analyzed the impact of EVR-based immunosuppressive therapy on CMV replication and disease in a large cohort (n = 301) of pediatric kidney allograft recipients.
Results: The EVR cohort (n = 59), who also received low-dose ciclosporin, was compared with a control cohort (n = 242), who was administered standard-dose ciclosporin or tacrolimus and an anti-metabolite, mostly mycophenolate mofetil (91.7%). Multivariate analysis revealed an 83% lower risk of CMV replication in the EVR cohort than in the control cohort ($p = 0.005$). In CMV high-risk (D+/R-) patients (n = 88), the EVR-based regimen was associated with a significantly lower rate of CMV disease (0% vs. 14.3%, $p = 0.046$) than the standard regimen. In patients who had received chemoprophylaxis with (val-)ganciclovir (n = 63), the CMV-free survival rates at 1 year and 3 years post-transplant (100%) were significantly ($p = 0.015$) higher in the EVR cohort (n = 15) than in the control cohort (n = 48; 1 year, 75.0%; 3 years, 63.3%) (Fig. 1).



Conclusions: Our data suggest that in patients at high risk of CMV infection the use of EVR and low-dose ciclosporin is associated with a lower incidence of CMV disease compared to a standard-dose calcineurin inhibitor-based regimen.

459.2

Vaccination status and titers before and after pediatric renal transplantation: an analysis of the CERTAIN Registry

Britta Höcker[1], Martin Aguilar[1], Paul Schnitzler[2], Lars Pape[2], Luca Dello Strologo[2], Nicholas J.A.Webb[2], Martin Bald[2], Gurkan Genc[2], Heiko Billing[2], Jens König[2], Markus J.Kemper[2], Stephen Marks[2], Martin Pohl[2], Marianne Wigger[2], Rezan Topaloglu[2], Alexander Fichtner[1], Susi Rieger[1], Kai Krupka[1], Burkhard Tönshoff[1].
[1]University Children's Hospital, Department of Pediatrics I, Heidelberg, Germany; [2]CERTAIN, Research Community, Germany.

Purpose: Prevention of systemic viral and bacterial infections by effective vaccination in kidney allograft recipients is of vital importance, but data on the vaccination status in pediatric patients are scarce.
Methods: In the framework of the Cooperative European Paediatric Renal Transplant Initiative (CERTAIN) Registry, we therefore performed a multicenter, cross-sectional study in 254 patients (mean age 10.0 ± 5.6 years) and analyzed their vaccination status and titers before and after renal transplantation (RTx).
Results: Only 2/3 of patients had a complete country- and era-specific vaccination status for most vaccines prior to RTx. In particular, the vaccination rate against human papillomavirus (HPV) (27.3%), pneumococcal (42.2%) and meningococcal (47.9%) infections was low. As few as 58.1% of patients developed a hepatitis B titer (HBsAb titer) > 100 I.U./L before RTx. 39.6% of patients showed a secondary vaccination titer loss post-transplant, especially against the life-virus vaccines varicella and mumps as well as the inactivated vaccines tetanus, diphtheria, pneumococcus and hepatitis B. Patients with a HBsAb titer between 10 and 100 I.U./L prior to RTx experienced significantly ($p < 0.05$) more often a hepatitis B vaccination titer loss post-transplant than patients with a HBsAb titer > 100 I.U./L prior to RTx. The revaccination rate post-transplant was low and failed to induce protective titers in a considerable amount of patients: only 37.5% developed a sufficient HBsAb titer, and as few as 14.3% of patients showed a protective pertussis titer after revaccination.
Conclusions: The vaccination coverage rate of CKD patients prior to RTx is insufficient, particularly against HPV, pneumococcal and meningococcal infections. Recommended revaccinations post-transplant are performed deficiently. Given the rate of secondary vaccination titer loss after RTx, the recommendations of the American Society of Transplantation to measure vaccination titers against tetanus, hepatitis B and pneumococcus at regular intervals post-transplant should be followed in order to induce timely revaccination and thus avoid the development of vaccine-preventable diseases.

459.3

Pediatric kidney transplant outcomes: A single-center experience according to transplant era

Marta Monteverde[1], Juan C.Lopez[1], Juan P.Ibanez[1], Gerardo Nyman[1], Alexia Diaz Moreno[1], Liliana Bisigniano[2].
[1]Nephrology, Hospital de Pediatria JP Garrahan, Buenos Aires, Argentina; [2]Scientific and Technical Secretary, Incucai, Buenos AIres, Argentina.

Background: Improvements in management of kidney transplantation have led to better outcomes. In Argentina there are no pediatric data comparing transplant outcomes in children over different eras. The purpose of this study was to evaluate patient and graft survival in children with a kidney transplant (KT) from living related (LRD) and deceased donors (DD) in 2 periods and to analyze risk factors of graft loss and causes of death in the whole cohort.
Methods: All pediatric KT performed between 1988 and 2015 were included (n=773); 446 from DD and 327 from LRD. As in 2001 major management practices were generalized (induction therapy, MMF/MPS maintenance therapy, and all rejections confirmed by biopsy), we divided the analysis into two periods: 1988-2000 and 2001-2015.
Results: Causes of ESRD were not different between periods. Age at transplant time was slightly higher in the second era: 11(IQR: 7-14) vs 11.8 (IQR: 8.8-15) years (p=0.048). Time on dialysis before KT increased from 17 (IQR: 9-31) to 28 (IQR: 17-48) months ($p <0.001$). At 1, 3, 5, 7, and 10 years, in DD KT recipients, patient survival was 97%, 93%, 90%, 89%, and 87% in 1988-2000 vs. 100%, 99% , 98%, 98%, and 98% in 2001-2015 ($p <0.001$). Graft survival was 83%, 75%, 68%, 64%, and 52% vs. 95%, 87%, 83%, 76%, and 61%, respectively ($p <0. 001$). In LD KT, patient survival at 1, 3.5, 7, and 10 years was 99%, 99%, 98%, 95%, and 95% in the first and 100% , 96%, 96%, 96%, and 96 %, in the second era ($p = 0.74$); graft survival was 97%, 91%, 85%, 78%, and 67% in the first vs 95%, 88%, 85%, 81%, and 76% in the second cohort ($p = 0.81$). Delayed graft function (DGF) declined from 33% to 18% ($p=<0.001$) in DD, but remained unchanged (12% vs 9%; p=0.5) in LRD recipients. Prevalence of early acute rejection (1st 90 days post KT) diminished both in DD and LRD recipients (68% to 12%; $p=<0.001$, and 65% to 21%, $p=<0.001$, respectively). The first cause of graft loss was chronic rejection (61% and 62%); the second was patient death with a functioning graft (16% vs 8%; p=0.1), and the third was thrombosis (14% vs. 5%; $p = 0.04$). Crude mortality rate dropped from 7.6% to 1.3% ($p<0.001$). The first cause of death was bacterial infection (56% vs 67%; p= 0.63). Predictors of graft loss for DD KT were: DGF (HR: 4.4; 95% CI 1.6-3.3), late acute rejection (HR: 3.7; 95% CI 1.4- 3), FSGS as cause of ESRD (HR: 2.5; 95% CI 1.6-4), and early acute rejection (HR: 2.2, 95% CI 1.1-2.2); and for LRD recipients: DGF (HR: 4.8; 95% CI 2.5-9.2), age at transplant >12 years (HR: 2.7; 95% CI, 2.4-5), and late acute rejection (HR: 2.1; 95%: 1.2-3.8).
Conclusion: DD KT improved patient and graft survival in the second period. Chronic rejection remained the leading cause of graft loss. Mortality rate diminished. DGF was the main predictor of graft loss in DD and LRD KT.

459.4

Perception, diagnosis, and management of BK polyomavirus replication and disease in paediatric kidney transplant recipients in Europe

Lars Pape[1], Burkhard Toenshoff[2], Hans H.Hirsch[3,4,5].
[1]Pediatric Nephrology, Hannover Medical School, Hannover, Germany; [2]Department of Paediatrics I, University Children's Hospital Heidelberg, Heidelberg, Germany; [3]Transplantation & Clinical Virology, Department Biomedicine (Haus Petersplatz), University of Basel, Basel, Switzerland; [4]Infection Diagnostics, Department Biomedicine (Haus Petersplatz), University of Basel, Basel, Switzerland; [5]Infectious Disease & Hospital Epidemiology, University Hospital Basel, Basel, Switzerland.

Introduction: BK polyomavirus (BKPyV)-associated nephropathy remains a challenge to the success of kidney transplantation, but its impact varies in different transplant programs.
Methods: We investigated current practice through a web-based questionnaire made available by the European Society for Paediatric Nephrology (ESPN).
Results: A total of 90 physicians (23% of 391 active members) from 27 countries participated in the study. BKPyV-associated nephropathy is seen in 1-5% of patients annually with treatment success in 30-60%, and graft loss in 10%. Quantitative BKPyV load testing is available to >90% of physicians. Screening is performed in urine alone in 26%, in urine and blood in 37%, and in blood alone in 37%. Most physicians (47%) screen at month 1, 2, 3, 6, 9 and 12 post-transplant. For patients with baseline renal function and plasma BKPyV loads of 10'000 – 1'000'000 copies/mL, 50% report performing renal biopsies prior to intervention. Intervention consists of reducing immunosuppression first with mycophenolate (Myc) in 40%, first with calcineurin inhibitors (CNI) in 29%, or with both in 31%. Changing immunosuppressive drugs is considered mainly for biopsy-proven nephropathy consisting of discontinuation of Myc in 75%, and switching from CNI to mTOR inhibitors (52%). Cidofovir, intravenous immunoglobulin G, leflunomide, and fluoroquinolones are used in less than one third of this group. 66% of participants see a need for new antiviral drugs and new immmunosuppressive strategies, and almost 90% are willing to participate in future observational and interventional trials.
Conclusion: This ESPN survey suggests that prompt translation of a positive screening test into reducing immunosuppression could improve outcomes. Most participants of the survey are willing to participate in future observational and interventional studies on BKPyV.

Pubertal development in pediatric kidney transplant patients receiving mammalian target of rapamycin inhibitors or conventional immunosuppression

Julia Förster[1], Thurid Ahlenstiel-Grunow[1], Antonia Zapf[2], Martin Mynarek[3], Lars Pape[1,3].
[1]Pediatric Nephrology, Hannover Medical School, Hannover, Germany; [2]Department of Medical Statistics, University Medical Center Göttingen, Hannover, Germany; [3]Department of Pediatric Hematology and Oncology, University Medical Center Hamburg-Eppendorf, Hamburg, Germany.

Introduction: Data regarding the onset of puberty in children receiving mammalian target of rapamycin (mTOR) inhibitors are limited.
Methods: Kidney transplant patients aged <14 years were analyzed retrospectively to a maximum age of 18 years, with a minimal observation period of one year. Immunosuppression comprised (i) standard CNI-based regimen or (ii) low-exposure mTOR inhibitor with reduced-exposure CNI, initiated either de novo or in the maintenance phase.
Results: Of 108 children analyzed, 67 received an mTOR inhibitor (56 everolimus, 11 sirolimus) and 41 did not. The age at which girls reached Tanner stage P2 was similar with mTOR inhibitor therapy (median 11.6 years) or without (median 11.1 years) (p=0.262), as was age at stage B2 (median 11.6 versus 11.2 years; p=0.753). In boys, both the age of attaining Tanner stage P2 (median 12.9 versus 13.0 years; p=0.796) and Tanner stage G2 (median 13.1 versus 12.9 years; p=0.344) were also similar with or without an mTOR inhibitor. Age at menarche in girls, and age at spermarche in boys, did not differ between the two groups.
Conclusions: In this retrospective analysis, sexual maturation ages and reproductive hormone levels were comparable in adolescent kidney transplant patients receiving low-exposure mTOR inhibitors and reduced CNI therapy or conventional CNI-based immunosuppression.

Transitional care and adherence of adolescents after KTX in Germany and Austria: A binational observatory census within the TRANSNephro trial

Martin Kreuzer[1], Jenny Prüfe[1], Reinhard Brunkhorst[5], Dirk Bethe[4], Martina Oldhafer[3], Marie-Luise Dierks[2], Lars Pape[1].
[1]Pediatric Nephrology, Hannover Medical School, Hannover, Germany; [2]Department of Epidemiology, Social Medicine and Health System Research, Hannover Medical School, Hannover, Germany; [3]German Society of Transition Medicine, Hanover, Germany; [4]Division of Pediatric Nephrology, Center for Child and Adolescent Medicine, Heidelberg University Hospital, Heidelberg, Germany; [5]KfH Center of Nephrology, Hospitals of the Hannover Region, Hannover, Germany.

Introduction: Transition from child to adult-oriented care is widely regarded a challenging period for young people with kidney transplants and is associated with a high risk of graft failure.
Material and Methods: We analyzed the existing transition structures in Germany and Austria using a questionnaire and retrospective data of 119 patients transferred in 2011-2012.
Results: Most centers (73%) confirmed agreements on the transition procedure. Patients' age at transfer was subject to regulation in 73% (18 years). Median age at transition was 18.3 years (16.5 – 36.7). Median serum creatinine increased from 123 to 132 µmol/l over the 12 month observation period before transfer ($p = 0.002$). 25/119 patients showed increased creatinine ≥20% just before transfer. Biopsy proven rejection was found in 10/119 patients. Three patients lost their graft due to chronic graft nephropathy.
Mean coefficient of variation (CoV) of immunosuppression levels was 0.20 ±0.1. Increased creatinine levels ≥20% just before transfer were less frequently seen in patients with CoV <0.20 ($p = 0.007$).
Conclusions: The majority of pediatric nephrology centers have internal agreements on transitional care. More than half of the patients had CoV of immunosuppression trough levels consistent with good adherence. Though, 20% of the patients showed increase in serum creatinine close to transfer.

Health and wealth in children and adolescents with kidney transplants (K-CAD study)

Madeleine Didsbury[1], Anita Van Zwieten[1], Kerry Chen[1], Meredith Medway[1], Allison Tong[2], Robin Turner[3], Fiona Mackie[4], Steven McTaggart[5], Anna Francis[2,5], Tonya Kara[6], Amanda Walker[7], Sarah White[8], Kirsten Howard[2], Siah Kim[1], Jonathan Craig[1,2], Germaine Wong[1,2,9].
[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [2]Sydney School of Public Health, The University of Sydney, Sydney, Australia; [3]Department of Biostatistics, University of New South Wales, Sydney, Australia; [4]Department of Nephrology, Sydney Children's Hospital at Randwick, Sydney, Australia; [5]Child & Adolescent Renal Service, Lady Cilento Children's Hospital, Brisbane, Australia; [6]Department of Nephrology, Starship Children's Hospital, Auckland, New Zealand; [7]Department of Renal Medicine, The Royal Children's Hospital, Melbourne, Australia; [8]Sydney Medical School, The University of Sydney, Sydney, Australia; [9]Centre for Transplant and Renal Research, Westmead Hospital, Sydney, Australia.

Background: Poverty and social inequality are major barriers for achieving optimal health outcomes in children, but their impact on outcomes in children after kidney transplantation remains unclear. The K-CAD study is anAustralian multicentre longitudinal cohort study that aims to describe the prevalence of economic hardship among caregivers and to determine the relationship between socioeconomic status of caregivers and self-rated health of children with chronic kidney disease (CKD).
Method: Two hundred and ninety-three children aged 6-18 years with CKD [stage 1-2 (n=69), stage 3-5 (n=77), dialysis (n=35), transplant (n=112)] were recruited from four tertiary children's hospitals across Australia. Comparisons by quintile of socioeconomic status for nominal self-rated health outcomes among children with CKD were analysed using adjusted multinomial logistic regression.
Results: The mean ages of the caregivers and children were 43.5 years (SD: 8.0) and 12.5 (SD:3.9), respectively. More than 50% of all households earned less than $1250AUD per week. Only 20% (n=60) of caregivers engaged in fulltime employment and 30% (n=89) had completed tertiary education. Across the cohort, carers who reported higher levels of financial difficulty were twice as likely to report that their child's health was poor than those with lower levels of financial difficulty (OR 2.01, [95% CI 1.2-3.3], $p<0.01$). Compared to children with pre end-stage disease, parents of children with a kidney transplant were more than twice as likely to report that their income had decreased since the diagnosis of their child's disease (OR 2.4, [95% CI 1.4-4.3]), and parents of children on dialysis were nearly five times as likely (OR 4.8, [95% CI 2.1-10.9], $p<0.05$). Socioeconomic status did not have a significant effect on access to pre-emptive transplantation or graft outcomes.
Conclusion: Socioeconomic status of caregivers appears to have a profound impact on the self-rated health in children with CKD. Families of children with end stage renal disease experience more financial hardship compared to those with less severe disease. Longitudinal follow-up will help delineate the cause of socioeconomic disadvantage in these children and the long-term effects on disease progression and wellbeing outcomes.

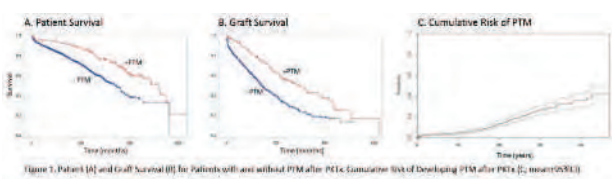
Incidence of post-transplant malignancy (PTM) after pediatric kidney transplantation (PKTx)

Oscar Serrano[1], Ananta Bangdiwala[2], David Vock[3], William D.Payne[1], Ty B.Dunn[1], Srinath Chinnakotla[1], Erik B.Finger[1], Raja Kandaswamy[1], Timothy L.Pruett[1], Arthur J.Matas[1], Blanche Chavers[4].
[1]Surgery, University of Minnesota, Minneapolis, MN, United States; [2]Biostatistics and Bioinformatics Core, University of Minnesota, Minneapolis, MN, United States; [3]Biostatistics, University of Minnesota, Minneapolis, MN, United States; [4]Pediatrics, University of Minnesota, Minneapolis, MN, United States.

Purpose: Post-transplant immunosuppression is associated with an increase in cancer rates. To date, the long-term incidence of PTM among PKTx recipients has not been well-characterized.
Methodology: Between 1963 and 2015, 881 pediatric (age: 0-17 years old) recipients received 1055 KTx at our institution. The incidence and type of malignancy in this cohort was analyzed. Patient outcomes were compared and the relative risk of developing PTM after PKTx was determined.
Results: After a median follow-up of 33 years, 202 PTM occurred in 136 (15.4%) patients at a median age of 29 years old. The 3 most common malignancies were cutaneous malignancies (55.0%), post-transplant lymphoproliferative disease (PTLD; 23.3%) and non-skin carcinomas (16.8%). On multivariate analysis, factors associated with increased risk of developing PTM included: increasing age at KTx (aHR, 2.69 [1.59, 4.54]), receiving an allograft from a living unrelated donor (aHR, 2.74 [1.13, 6.64]), and induction therapy with thymoglobulin (aHR, 2.09 [1.11, 3.96]). Having a rejection episode was found to be associated with decreased risk of developing PTM (aHR, 0.51 [0.29, 0.91]). Maintenance immunosuppression, rejection treatment, or graft status were not found to be associated with development of PTM. Unadjusted analysis shows excellent patient and graft survival (Fig. 1A, B), but patients had to survive long enough to develop PTM. Median time to develop a PTM after PKTx was 18 years (Fig. 1C). Of PTM patients who died during the study time period, 30/47 (63.8%) died of malignancy. The most common cause of death was PTLD (50%). Time-dependent analysis of PTM patients demonstrated a significant risk of death (aHR, 26.0 [8.0, 85.2]) and death-censored graft failure (aHR, 1.8 [1.1, 3.0]).
Conclusion: Increasing age at transplant, receipt of a graft from a living unrelated donor, and thymoglobulin induction increases the risk of developing PTM among PKTx recipients, and this has a significant adverse effect on patient and graft survival long-term.



459.9

Incidence of cardiovascular disease after pediatric kidney transplantation

Oscar Serrano[1], Ananta Bangdiwala[2], David Vock[3], William D.Payne[1], Ty B.Dunn[1], Srinath Chinnakotla[1], Erik B.Finger[1], Raja Kandaswamy[1], Timothy L.Pruett[1], Arthur J.Matas[1], Blanche Chavers[4].
[1]Surgery, University of Minnesota, Minneapolis, United States; [2]Biostatistics and Bioinformatics Core, University of Minnesota, Minneapolis, United States; [3]Biostatistics, University of Minnesota, Minneapolis, United States; [4]Pediatrics, University of Minnesota, Minneapolis, United States.

Purpose: Kidney transplant (KTx) recipients have increased risk of cardiovascular disease (CVD), related to time on dialysis and post-KTx immunosuppression. To date, the incidence of post-KTx cardiovascular events (CVE) among pediatric KTx recipients (PKTx) has not been well-characterized.
Methodology: Between 1963 and 2015, 881 pediatric (age: 0-17 years old) recipients received 1055 KTx at our institution. The incidence and type of CVE (angina, arrhythmia, stroke/cerebrovascular accident, cardiomyopathy, congestive heart failure, coronary artery disease, myocardial infarction, peripheral vascular disease, thrombotic disease, valve dysfunction) was assessed. Patient outcomes were compared and the relative risk of developing CVE after PKTx was determined.
Results: After a median follow-up of 16 years, 340 CVE occurred in 164 (18.6%) patients at a median age of 18 y.o. Thrombotic/embolic events and arrhythmias accounted for 20.0% and 14.7% of CVE, respectively. On multivariate analysis, factors associated with increased risk of developing CVE included: pre-KTx CVD (aHR, 2.34 [95% CI 1.55-3.54]), graft failure (aHR, 3.63 [95% CI 2.61-5.03]), having an acute rejection episode (aHR, 2.19 [95% CI 1.56-3.08]), induction therapy with OKT3 (aHR, 2.54 [95% CI 1.01-6.41]), ATG (aHR, 2.31 [95% CI 1.42-3.75]) or thymoglobulin (aHR, 2.54 [95% CI 1.6-4.02]), maintenance immunosuppression with azathioprine/prednisone (aHR, 1.85 [95% CI 1.15-2.97]) or mycophenolate/calcineurin-inhibitor/prednisone (aHR, 7.02 [95% CI 2.95-16.7]). Overall, patient survival was excellent in patients who developed CVE (Fig. 1A; $p<0.001$); however, patients needed to survive long enough to develop disease. Graft survival was similar among patients ($p=0.26$; Fig. 1B). The median time to developing a CVE after PKTx was 10 years (Fig. 1C). Of patients who developed CVE and died, 53/81 (65.4%) died of CVE causes. Time-dependent analysis of CVE patients demonstrated a significant risk of death (aHR, 2.5 [95% CI 1.6-4.0]).
Conclusion: Pre-KTx CVD, graft failure, acute rejection, induction with OKT3, ATG or thymoglobulin, and maintenance immunosuppression with azathioprine/prednisone or mycophenolate/calcineurin-inhibitor /prednisone are independent risk factors for post-KTx CVE in PKTx recipients. Post-transplant CVD increases the risk of death after PKTx.

470.1

The role of HLA class II antibodies in chronic kidney rejection

Gabriel Cantanhede[1], Jeremy Palmer[1], Keith Giles[2], Vaughan Carter[2], John Kirby[1], Simi Ali[1].
[1]Institute of Cellular Medicine, University of Newcastle, Newcastle upon Tyne, United Kingdom; [2]National Health Service Blood Transfusion, NHSBT, Newcastle upon Tyne, United Kingdom.

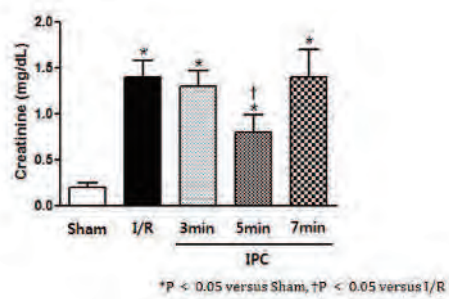
Background: Antibody-mediated rejection is one of the major causes of chronic rejection. This is mediated by endothelial cell activation, a process of endothelium microvascular inflammation and leukocyte recruitment. Despite evidence pointing to the relevance of HLA class II antibody in graft rejection, the role of antibody-endothelium interaction in the absence of complement is not fully understood. This project seeks to identify signalling cascades activated by HLA class II antibodies and mechanisms mediating endothelial cell – leukocyte interaction.
Methodology: Stably-transfected Ea.hy926 class II transactivator and HMEC-1 cells were stimulated with HB145, a pan-HLA class II mouse monoclonal antibody. Cell signalling pathways were examined using a R&D Human phosphokinase array, Western Blot and RT-qPCR. The expression of ICAM-1 and VCAM-1 was determined using flow cytometry. Wound healing assays were performed using µ-slide cell culture inserts. Eahy.926 CIITA and HMEC-1 cells were genotyped for HLA class I and II epitope expression using PCR-SSP. HB145 was characterised for class I and class II by Luminex. Antibody from multiparous women and sensitised transplant kidney patients have been used to verify cell signalling cascades and functional expression of adhesion markers contributing to leukocyte trafficking via statically via flow cytometry and dynamically via a microfluidics platform manufactured by Cellix (Dublin, Ireland).
Results: Interpreted HLA Types were Ea.hy926 CIITA DR11(5), 13(6); DQ6(1),7(3) and HMEC-1 DR12(5), 18(3); DQ4, 5(1). HB 145 was found a comprehensive pan-class II antibody. Eahy.926 cells stimulated with HB145 showed time-dependent phosphorylation of p-ERK, p-AKT, p-mTOR, and p-AMPK α1,α2. Phosphorylation of p-mTOR was abrogated by Rapamycin at 20nM. Stimulated Ea.hy 926 CIITA upregulated the expression of mRNA encoding Cyclin D1 ($p<0.001$) after 24h of treatment, while levels of c-myc remained unchanged. In HMEC-1 cells, HB145 induced a 3-fold expression of ICAM-1 after 72h of treatment ($p<0.001$). Stimulation of HMEC-1 cells using both HLA class I and HLA class II monoclonal antibodies (after subsaturation with IFN-gamma) led to increased adhesion of monocytes through a microfluidics platform. In Eahy.926 CIITA cells, HB145 treatment alone also increased the overall wound closure rate, reaching faster wound closure (11h vs. 14h; $p<0.005$) when compared to a HLA-class I monoclonal antibody (W6/32). Sensitised tranplanted patient samples produced similar phosphorylation cascades seen with monoclonal antibody and ICAM-1 upregulation.
Conclusions: Exposure of endothelial cells to HLA class II antibody induces an activation of signalling cascades characteristic of endothelial cell activation. This activation is further responsible for upregulation of adhesion molecules, which facilitate the interaction of donor endothelium and recipient leukocytes. Strategies to block endothelium-leukocyte interaction might reduce the incidence of allograft rejection and improve allograft survival.

470.2

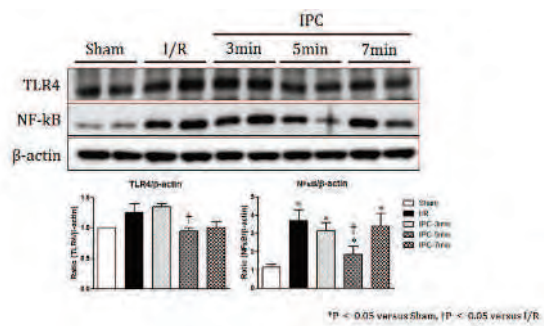
The proper ischemic preconditioning attenuates against renal ischemia-reperfusion injury by inhibiting toll-like receptor 4/NF-kB signaling pathway in mice

Jeongkye Hwang[1], Hyunsu Choi[2], Ilyong Shin[1], Kyungjai Ko[4], Kangwoong Jun[4], Mi-Hyeong Kim[4], Sangdong Kim[5], Suncheol Park[3], Jiil Kim[4], Insung Moon[4].
[1]Surgery, Daejeon St.Mary's hospital, Daejeon, Korea; [2]Clinical Research Institute, Daejeon St.Mary's hospital, Daejeon, Korea; [3]Surgery, Uijeongbu St.Mary's hospital, Uijeongbu, Korea; [4]Surgery, Seoul St. Mary's Hospital, Seoul, Korea; [5]Surgery, Incheon St.Mary's Hospital, Incheon, Korea.

Purpose: Ischemic preconditioning (IPC) is a potent renoprotective strategy which underlying mechanisms are not completely understood. In this study, we analyzed the hypothesis that proper IPC downregulates the expression of Toll-like receptor 4 (TLR-4) resulting in attenuation of renal ischemia-reperfusion (I/R) injury.
Methods: Male C57BL/6 mice were randomized into four groups according to IPC times; control (non-IPC), 3 min (group I), 5 min (group II), 7 min (group III). After right nephrectomy, mice were subjected to IPC and then 10 min reperfusion before 30 min ischemia. We assessed serum creatinine, microscopically morphology, and mRNA expression of tumor necrosis factor-alpha (TNF-a), IKK-beta, IL-1b and MCP-1. Renal expression of TLR-4 and nuclear factor kappa-B (NF-kB) was determined by western blotting and immunohistochemistry.
Results: The expression of intra-renal TLR4 and NF-kB protein were increased by renal I/R injury, and significantly decreased by IPC. ($P = 0.031$, 0.012, respectively). Among the four groups, there was significant difference in serum creatinine levels ($P = 0.042$).



Serum creatinine levels were 1.4±0.18 (non-IPC), 1.3±0.17 (group I), 0.8 ±0.19 (group II), 1.4 ±0.30 (group III). In 5min IPC group (group II), tubule-interstitial abnormality was clearly slighter compared with the other groups ($P < 0.001$). IKK-b, IL-1b and MCP-1 transcription levels were significantly less compared with the non-IPC group ($P<0.05$).



Conclusion: These data demonstrated that proper IPC (5min/10min) could attenuate renal I/R injury by inhibition of TLR-4/NF-kB pathway.

470.3

Relationship between B cell-rich tertiary lymphoid organs and systemic as well as local humoral alloresponses in a murine kidney allograft model

Anna Nowocin, Lucy Meader, Kathryn Brown, Raul Elgueta, Wilson Wong.
DTIMB, King's College London, London, United Kingdom.

Introduction: Tertiary lymphoid organs (TLO) are formed at sites of chronic inflammation such as an allograft, and are thought to contribute to the immune response. The analysis of their involvement in promoting or regulating the alloresponses has resulted in contradicting conclusions. We have characterised the structure and function of TLO in solid organ transplantation to elucidate their contribution in the alloresponses in a mouse model of kidney transplantation
Materials and Methods: Fully allogeneic DBA/2 (H-2d) kidney grafts were transplanted into C57BL/6 (H-2b) recipients. B cells infiltrating TLO in allografts were analysed histologically. The presence of antibody secreting cells on the isotopic differentiation of the alloantibodies was evaluated.
Results: DBA/2 allografts survive in C57BL/6 recipients with varying degree of dysfunction. We show that TLO can be associated with a beneficial rather than a destructive response in a kidney allotransplantation model. B cell subsets within tertiary lymphoid organs in mouse kidney allografts consist of naive, plasma and memory B cells which are mostly grouped within or in close proximity of TLO (Figure 1). Staining for intracellular IgG showed that some of these B cells within tertiary lymphoid organs are capable of producing antibodies. Although allospecific antibodies are found in the serum of recipient mice, and are deposited in the transplanted kidneys, graft function was not affected in this model. However more specific IgG isotope profiling reviled that the levels of IgG1 and IgG2b, but not total IgG or IgG2c and IgG3 in sera could be used to predict graft faith (Figure 2). This suggesting that additional protective mechanisms are at work to prevent donor specific antibodies from damaging the graft.
Discussion: We tried to establish whether TLO presence and/or graft function are affected by alloantibody presence in circulation or in the graft, and how can be this linked with local infiltration by B cells and antibody producing cells. The results presented here are reflective of the ability of TLO to provide an environment for either a stimulatory or a regulatory response, in the same way as secondary lymphoid tissues.
Conclusions: Our data indicates that tertiary lymphoid organs are capable of supporting the B cell response and contribute to the humoral arm of the alloresponses. The presence of cellular infiltrates or high levels of alloantibodies was not a prerequisite of kidney rejection.

470.4

Kidney transplant recipients after solid organ transplantation other than kidney show low alloreactivity but an increased risk of infectious complications

Thomas Schachtner[1,2], Maik Stein[2], Petra Reinke[1,2].
[1]Nephrology and Internal Intensive Care, Charité University Medicine Berlin, Berlin, Germany; [2]Berlin-Brandenburg Center for Regenerative Therapies, Charité University Medicine Berlin, Berlin, Germany.

Introduction: The number of kidney transplant recipients (KTRs) after solid organ transplantation (SOT) other than kidney is increasing to approximately 3-5% of all kidney transplantations. Knowledge on patient and allograft outcomes, infectious complications, and immunological characteristics, in KTRs after SOT other than kidney, however, remain scarce.
Material and Methods: Here, we studied 40 KTRs from 2004 to 2013, who underwent a previous SOT other than kidney. 15 of 40 KTRs (37%) underwent a previous liver transplantation and 25 of 40 KTRs (63%) underwent a previous heart or lung transplantation. 720 single KTRs of a first kidney allograft and 119 retransplant KTRs were used for comparison. Samples were collected before transplantation and at +1, +2, +3 months posttransplantation. Alloreactive T-cells and CMV-specific T-cells were measured using an interferon-γ Elispot assay.
Results and Discussion: KTRs after SOT other than kidney show comparable patient survival, allograft survival, and allograft function compared with first KTRs. In contrast, KTRs after SOT other thank kidney show a tendency for superior patient and allograft survival, and superior allograft function compared with retransplant KTRs ($p<0.05$). Interestingly, KTRs after SOT other than kidney show less preformed panel reactive antibodies, less preformed alloreactive T-cells, and less acute cellular rejection compared with retransplant KTRs ($p<0.05$). KTRs after SOT other than kidney, however, show a significantly higher incidence of EBV viremia and development of PTLD compared with first and retransplant KTRs ($p<0.05$). KTRs after SOT other than kidney show a significantly higher incidence of septic complications and death from sepsis compared with first and retransplant KTRs ($p<0.05$). A tendency of impaired CMV-specific immunity was associated with more CMV-replication compared to retransplant KTRs.
Discussion: Our results suggest patient and allograft outcomes in KTRs after SOT other than kidney comparable to KTRs of a first kidney allograft. The observed low alloreactivity may be attributed to the effects of maintenance immunosuppression. Caution should be taken in KTRs after SOT other than kidney regarding overimmunosuppression with development of EBV viremia and septic complications.

470.5

Aging effect on immunity implying to minimize immunosuppression in elder transplant recipients in a murine model

Wei-Chen Lee, Kun-Ming Chan, Yu-Chao Wang, Tsung-Han Wu, Chih-Hsien Cheng, Chen-Fang Lee, Ting-Jung Wu, Hong-Shiue Chou.
Liver and Transplantation Surgery, Chang-Gung Memorial Hospital, Taoyuan, Taiwan.

Background: Aged people to have solid organ transplantation are increasing. Clinically, aged recipients have a higher incidence of complications and lower rejection rate than young recipients. However, the difference of immunity between aged and young recipients is not really clear. The understanding of aging effects on immunity will be helpful for post-transplant care in transplant recipients.
Methods: C3H mice were employed as donor. Old (12-month-old) and young (10-week-old) C57BL/10J mice were employed as recipients. The phenotypic cells in old and young were examined by flow cytometry. The allogeneic proliferation capacity and cytotoxicity were performed to examine the aging effect on immunological reactions.
Results: The spleen cells from old and young mice were stained with CD11b and Gr-1 and analyzed by flow cytometry. The result showed that the population of bone marrow-derived suppressor cells was higher in old than in young mice. The proliferation capacity of old T-cells was lower than that of young T-cells in mixed lymphocyte reaction (0.350±0.003 O.D. versus 0.430±0.017 O.D. at responders/stimulatory cells = 100/1). T-cells derived from old mice also had a lower Ag-specific cytotoxic ability than T-cells derived from young mice (21.2±3.0% versus 39.3±4.8% at target cell/effector cells = 1/100, p=0.003). When T-cells were activated for 3 days, a higher frequency of regulatory cells was induced in T-cells derived from old mice than young mice (7.87±3.42% versus 5.04±2.71%, p=0.023). Allogeneic skin transplantation was performed and the result showed that the skin transplanted to young mice was rejected earlier.
Conclusion: The immunity was altered along aging process. The aged mice had a higher population of immunosuppressive cells including bone marrow-derived suppressor cells and regulatory cells. These aging effects on immunity implied that immunosuppressive agents could be reduced for aged recipients to achieve survival.

470.6

CD3+CD8+GranzymeB+ cytotoxic T lymphocytes play role in chronic antibody mediated transplant rejection

Narayan Prasad[1], Brijesh Yadav[1], Vikas Agarwal [2], Vinita Agarwal [3], R. K. Sharma[1].
[1]Nephrology and Renal Transplantation, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [2]Clinical Immunology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India; [3]Pathology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India.

Introduction: Chronic antibody associated transplant rejection (CABMR) accounts for 20-63% graft loss in late transplant period, often associated with C4d deposition in peritubular capillaries, circulating donor specific antibody, duplication of glomerular capillary wall, proteinuria, and hypertension. CABMR is also associated with glomerular and interstitial inflammation. Besides antibody mediated complement activation and injury to the graft, the role of infiltrating cytotoxic T cell and simultaneous changes in circulating Cytotoxic T cell profiles has not studied in same cohorts in CABMR.
Aim: We undertook this study the changes icytotoxic T cell in circulating blood and Intragraft tissue of patient and their association with CABMR.
Methods: From our cohort of renal allograft recipients, total 42 (CABMR-32, and stable functioning graft SGF-10) patients were included. SGF was defined as stable graft function for 6 months without proteinuria and <10% cortical surface area with IF/TA on biopsy; and CABMR was defined as per Banff's classification 2013. We have analyzed peripheral blood cytotoxic T cell frequency by flow cytometry, Soluble and biointact Granzyme B (GzmB) level in serum and PBMCs culture supernatant with ELISA; and tissue Granzyme-B mRNA transcript, in renal biopsy specimen by Taqman real time PCR and protein expression by Immunohistochemistry, in both groups of patients. Non parametric continuous variables were analyzed with Mann Whitney U test.Fold change was calculated by 2-^^Ct methods.
Results: The mean age of patients in CABMR and SGF group was 40.90±12.68 and 37.93±12.78 years; post-transplant time at biopsy was 70.18±34.48,and 49.70±22.71 months; S.creatinine was 2.40±0.80,and 1.23±0.18 mg/dl; and daily urine protein 2.94±1.54,and 0.13±0.10 g respectively.
Peripheral blood CD3+CD8+ T cell frequencyin CABMR and SGF was 27.55±6.53% and 19.89±4.37% (p=0.001), respectively. The peripheral cytotoxic T cell (CD3+CD8+GzmB+) was significantly low in CABMR group (15.38±3.29%), as compared to SGF (27.96±4.86%; p<0.001). Soluble GzmB level in serum was significantly high in CABMR group (177.82±48.66) as compared to SGF(100.82±22.41; P<0.001).However, Biointact GzmB level was significantly low in CABMR group (82.69±19.88) as compared to SGF (109.41±33.27; p<0.003). The Intragraft mRNA transcript expression of Granzyme-B in CABMR was (3.59±1.45) fold higher as compared to SGF (1.01±0.04; P<0.001). Number of GzmB+cell/mm^2, in CABMR was high (8.03±3.76) as compared to SGF patients (1.75±2.45; p<0.001).
Discussion: Granzyme B is Serine/Threonine proteases that activates MMPs, Procaspase, IL-1β and cleaves cytoskeleton, nuclear lamin protein and generates reactive oxygen species formation. This leads to allograft injury and induces apoptosis in endothelium/podocytes cell of microcappilary and ultimately leading to proteinuria. Higher intragraft granzyme suggest CABMR is associated with Granzyme mediated injury. Low frequency of cytotoxic T cell and high Granzyme serum level in CABMR suggest release of Granzyme B in serum. Simultaneous high intragraft expression suggest sequestration of cytotoxic cells into the graft from circulation.Therapy against cytotoxic T cell may be benficial in cases of CABMR.
Conclusion: CD3+CD8+GzmB+ Cytotoxic T cell is asociated with chronic antibody mediated rejection.

Body mass index (BMI) is associated with microalbuminuria in the late renal transplant period

Boris Zingerman[1,2], Ruth Rahamimov[1,2], Arie Erman[1,2], Avry Chagnac[1,2], Benaya Rozen-Zvi[1,2].
[1]Nephrology and Hypertension, Rabin Medical Center, Petach-Tikva, Israel; [2]Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel.

Introduction: Microalbuminuria is an established risk factor for cardiovascular morbidity and mortality in the general population. In renal transplant recipients it also predicts graft loss. Obesity is an independent predictor of chronic kidney disease in the general population, but its effect on microalbuminuria in renal transplant recipients has not yet been studied. The aim of the present investigation was to evaluate the relationship between obesity and microalbuminuria in the renal transplant population.
Materials and Methods: This cross-sectional prospective study was performed on adult renal graft recipients with a daily urinary albumin excretion rate of up to 300 mg. Measurements were performed at least 6 months after renal transplantation on accurately carried out 24-hour urine collections. Patients were divided into two groups: the early period - 6 months to 3 years after transplantation and the long term period - more than 3 years after transplantation. A multivariate regression analysis was performed in order to identify predictors of microalbuminuria (albumin excretion rate of 30 to 300 mg/day).
Results and Discussion: Two hundred and seven patients (66.7% males, 38.2% diabetics, mean age 53.7±12.5 years) were studied. There were 111 patients in the early group with median time from transplantation of 1.1 years (range 0.6-2.9) and 97 patients in the long term group with median time of 7.7 years (range 3-25). BMI was 27.3±5.1, waist circumference was 97.5±16.6 cm and albumin excretion rate was 22.9 (3-295) mg/24 hr.
For the early group there was no association between BMI and the risk of albuminuria by univariate analysis (Hazard Ratio (HR) 1.001 per kg/cm2, 95% Confidence Interval (CI) 0.94-1.09, p=0.81). In contrast, in the long term group the risk of albuminuria was associated with increased BMI by univariate (HR 1.18 per kg/cm2, 95% CI 1.07-1.31, p=0.001) and multivariate analysis (HR 1.25 per kg/cm2, 95% CI 1.09-1.44, p=0.001). In a similar manner, waist circumference was not associated with albuminuria in the early group, but was significantly associated with this outcome in the long term group (HR 1.04 per cm, 95% CI 1.01-1.07, p=0.018 and HR 1.06 per cm, 95% CI 1.02-1.11, p=0.005, in univariate and multivariate analysis, respectively).
BMI and waist circumference are independent predictors of microalbuminuria in the late post-transplant period. These variables are not associated with microalbuminuria in the early post-transplant period. Considering the established causal relationship between obesity and albuminuria in the general population, the findings of the present study suggest that a 3-year lag time must elapse for an increased adiposity to affect albumin excretion rate in the transplant population.
Conclusion: Adiposity is an independent predictor of microalbuminuria in the late- but not early-period after renal transplantation.

Posttransplant hyperuricemia as a cardiovascular risk factor: Correlation between cardiovascular risk factors

Siren Sezer[1], Emre Tutal[1], Zeynep Bal[1], Mehtap Erkmen[1], Gokhan Moray[2], Turan Colak[1], Mehmet Haberal[2].
[1]Department of Nephrology, Baskent University Faculty of Medicine, Ankara, Turkey; [2]Department of General Surgery, Baskent University Faculty of Medicine, Ankara, Turkey.

Introduction: Hyperuricemia is common after renal transplantation (RT) and a strong evidence supports its inverse prognostic role in graft function[1]. Patients with chronic kidney disease (CKD) are under high risk of cardiovascular disease (CVD)[2]. Chronic inflammation, disturbed calcium-phosphorus-parathyroid hormone axis, increased fibroblast growth factor-23 (FGF-23), increased advanced glycation end-products (AGE) and decreased Klotho gene activity are some of the possible factors that will play a role in progression of kidney disease and cardiovascular disease in renal disease population[3]. In this study we aimed to analyze if there is a relationship between hyperuricemia, AGE, FGF-23 and Klotho activity in a group of RT recipients.
Materials and Methods: A total of 100 patients (28 female, 39.2 ± 11.2 years aged) who underwent RT at least 12 months ago were included in this observational cross-sectional study. Demographic characteristics of patients and mean of creatinine, calcium, phosphorus, parathyroid hormone, CRP and uric acid (UA) levels of the last 3 months were collected from patient charts. A plasma sample was studied for Klotho activity, FGF-23 and AGE levels in each subject. Patients were grouped according to UA levels as hyperuricemic (≥ 6 mg/dL, n: 50) and control (n:50) groups for statistical analysis.
Results and Discussion: Hyperuricemic patients had higher serum CRP [5.7 (7) vs 4.5 (4), p:0.009], AGE [1.6 (3.5) vs 0.6 (0.9), p:0.0001] and FGF-23 [71.6 (187) vs 43 (36), p: 0.008] levels while they also had lower Klotho [0.5(0.9) vs 1.1 (4.7), p0.0001]activity. Uric acid levels were positively correlated with serum CRP (r:0.237, p:0.018), FGF-23 (r:0.352, p:0.0001) and AGE (r: 0.481, p:0.0001) levels and negatively correlated with Klotho activity (r: -0.364, p:0.0001). Hyperuricemic patients also had lower creatinine clearance (53.8 ± 23.1 vs 80.6 ± 23.7 mL/min). A linear regression analysis revealed that AGE and FGF-23 levels were significant determinants of UA levels (p: 0.0001, 0.012 respectively). Hyperuricemia is closely related with decreased Klotho activity, increased FGF-23, AGE levels and inflammation.
Conclusion: Prognostic influence of hyperuricemia may depend on strong association with the cardiovascular risk factor in renal transplant recipients.

Definite (dBKPVN) and presumptive (pBKPVN) polyomavirus associated nephropathies cannot be distinguished clinically but viral clearance in pBKPVN depends on renal function at the time of the biopsy.

CinthiaB. Drachenberg, John C.Papadimitriou, Muhammad Chaudhry, Richard Ugarte, Beje Thomas, Manju Mavanur, Nadiesda Costa, Charles Cangro, Abdolreza Haririan.
Pathology and Medicine, University of Maryland School of Medicine, Baltimore, MD, United States.

Introduction: Persistent, increasing BK viremia is considered a marker of renal parenchymal disease (BK polyomavirus associated nephropathy, BKPVN), however, histological evaluation of the kidney in these patients may or may not reveal the infection. The term presumptive BKPVN (pBKPVN) was coined to classify patients with persistent BK viremia (typically with concurrent BK viruria) but a biopsy without viral inclusions and negative for SV40 staining. Early intervention in patients with BK viremia is considered ideal, in order to prevent irreversible organ damage, however, the exact impact of clinical intervention in pBKPVN versus BKPVN is not known.
Materials and Methods: We retrospectively evaluated biopsy and clinical findings in 73 consecutive patients with sustained (>3 weeks) BK viremia (viral copies/ml) who underwent protocol or for cause renal transplant biopsies. The biopsies were classified as dBKPVN or pBKPVN based on the presence or absence of SV40 staining infected cells, respectively. The patients were 56 males/17 females (M:F 3.2/1) with a mean age of 55.6 (31-87). The patients racial composition was 35 AA, 25 Caucasian, 5 Hispanic and 2 Asian/Pacific.
Results: Overall, 24.6% (n=18) of the biopsies in this cohort were classified as pBKPVN based on the presence of sustained BK viremia but negative SV40 biopsy staining. The pBKPVN represented 44.4% (8 of 18) and 27% (10 of 37) of the protocol (surveillance) and for cause biopsies, respectively. There were no significant differences between pBKPVN and dBKPVN in the protocol and for cause biopsy groups with respect to serum creatinine at the time of the biopsy, level of BK viremia and demographics.

Biopsies with normal-baseline creatinine
26 "protocol" Bx

	dBKPVN	pBKPVN	
Number of bx: 26	18	8	
Serum Cr at Bx	1.37 mg/dl (±.25)	1.04 mg/dl (±.24)	(NS)
Viremia	Mean 784,000 Median 39,000 Range 3,400-12,000,000	Mean 259,000 Median 18,500 Range 5,500-1,900,000	(NS)
Time of biopsy (days post-tx)	Mean 152 (median 120)	Mean 215 (median 139)	(NS)
SV40%	1-85%	0% (per definition)	
Follow up post Tx	1220 days (±502)	1142 days (±395)	(NS)
Last creatinine Graft loss*	2.14 mg/dl (±1.31) 1 of 18: mixed ACMR and AMR	1.42 mg/dl (±.48) 0 of 8	(NS)
Viral clearance	69.23%	100%	p=.0308

Biopsies with increasing creatinine
47 for cause bx

	dBKPVN	pBKPVN	
Number of bx: 47	37	10	
Serum Cr at Bx	2.45 mg/dl (±1.1)	2.37 mg/dl (±.85)	(NS)
Viremia	Mean 71,000 Median 50,000 (±2,000 500) Range 1600-7,500,000	Mean 48,580 Median 46,000 (±71,900) Range 2500-220,000	(NS)
Time of biopsy (days post-tx)	Mean 344 (median 171)(±381)	Mean 407 (median 123) (±627)	(NS)
SV40%	1-75%	0% (per definition)	
Follow up post Tx	1217.7 (±738)	839 days (±509.2)	(NS)
Last creatinine Graft loss*	3.61 mg/dl (±2.67) 7 of 37 (18.9%)	2.66 mg/dl (±1.27) 0 of 10	(NS) (NS)
Viral clearance	62.16%	50%	(NS)

After a minimum of 36 weeks of follow-up, viral clearance occurred in 100% of the patients with pBKPVN and normal renal function at the time of the biopsy (protocol biopsy). In contrast only 50% of the patients with pBKPVN and increased creatinine achieved viral clearance in the same time period. There was no difference in viral clearance between dBKPVN in protocol and for cause biopsies (69.23% and 62.16% respectively).
Conclusions: Definite and pBKPVN apparently cannot be distinguished clinically, these two pathological categories appear to represent true sampling variations in a quantitative spectrum rather than a biologically different process. On the other hand, pBKPVN had better outcome (viral clearance) when the renal function was intact at the time of the biopsy. These findings support the current recommendations for early diagnosis (e.g. bu the usage of pBKPVN diagnosis) and prompt decrease of the immunosuppression before the renal function is altered.

471.4

The preventative effect of mTOR inhibition by anti-A/B antibody ligation and mTOR-inhibitor on anti-HLA-DR antibody mediated complement dependent cytotoxicity

Kenta Iwasaki[1], Yuk Miwa[1], Kazuharu Uchida[1], Takaaki Kobayashi[2].
[1]Kidney Disease and Transplant Immunology, Aichi Medical University School of Medicine, Nagakute, Japan; [2]Renal Transplant Surgery, Aichi Medical University School of Medicine, Nagakute, Japan.

Background: Although de novo Donor-specific antibody (DSA) against HLA class II have been well recognized to cause antibody mediated rejection (CAMR), the mechanistic insight of HLA-class II DR expression on endothelial cell remain unclear.. The condition of no injury even in the presence of anti-donor antibody has been referred to as "accommodation", which would be one of the key factors for successful long-term graft survival. The aim of this study was to analyze the beneficial effect of anti-A/B antibody ligation on endothelial cells against HLA-DR antibody-mediated, complement-dependent cytotoxicity (CDC).
Method: Blood group A/B-expressing endothelial cells EA.hy926 or Human Umbilical Vein Endothelia Cells (HUVEC) were incubated with IFNg in the presence or absence of anti-A/B antibody or mTOR inhibitor (mTOR-i) for 48 hours. The effects on signaling pathway, HLA expression, complement regulatory factors, and CDC were investigated.
Results: Pre-incubation with anti-A/B antibody had resistance to HLA-DR antibody-mediated CDC against IFNg-treated cells in a concentration-dependent manner. This finding was ascribed to decreased expression of HLA-DR by post-translational regulation and increased expression of CD55/59, which was related to ERK and mTOR pathway inhibition. mTOR-i also inhibited HLA-DR expression by itself. Furthermore, the combination of mTOR-i and anti-A/B ligation had an additive effect in preventing HLA-DR antibody-mediated CDC.
Conclusion: Anti-A/B antibody might play a preventive role in CAMR through the inhibition ERK and mTOR signaling pathway. Inhibition of mTOR signaling pathways by anti-A/B antibody or drugs including direct mTOR inhibitor may partially contribute to the development of a novel treatment in the maintenance period after transplantation.

471.5

Outcome of renal transplantation in obese recipients

Mahir Kirnap, Ebru H.Ayvazoglu Soy, Aydincan Akdur, Gokhan Moray, Mehmet Haberal.
Transplantation Center, Baskent University, Ankara, Turkey.

Background: In literature there are conflicting results regarding to effect of obesity on kidney transplantation outcome. The aim of our study is to summarize our obese kidney recipients outcomes and investigate the association between continuous and categoric values of BMI and graft survival as an independent risk factor in renal transplantation.
Materials and Methods: Between October 1985 and December 2015 we performed 2248 kidney transplants at our centers. We excluded patients with insufficient data. We retrospectively reviewed 1125 kidney transplant recipients to evaluate graft and patient survivals between nonobese (BMI <30) and obese (BMI ≥30) patients at the time of transplantation, considering BMI as a categoric variable.
Results: We followed 1125 kidney transplant recipients for 10.6 ± 4.2 years. Among these 1125 patients, 987 patients were nonobese and 138 patients were obese. When we compared obese and non obese patients there was no significant difference in graft survival at the first year of transplantation. However, at the third year of transplantation there was a significant difference in graft survivals between obese and non obese recipients; 23.2% of obese recipients and 5.3% of nonobese recipients lost their grafts (p=0.003). First year's (8.1% vs 2.2%; p=0.024) and third year's (16.9% vs 4.3%; p=0.035) mortality rates were statistically higher in obese patients. Overall graft loss was significantly higher among obese compared with nonobese recipients.
Conclusions: Here in this study we confirmed that BMI higher than 30 kg/m² is an independent risk factor for graft survival and patient mortality. Careful patient selection and weight loss before transplantation may be useful to reduce early posttransplantation complication and improve long term outcomes of kidney transplantation.

471.6

Decreased number of plasma cells in peripheral circulation is associated with acute rejection in renal transplantation

Mukut Minz[1], Ravi Dhital[1], Ranjana Minz[2], Ashish Sharma[1], Ritambhara Nada[3], Sarbpreet Singh[1], Deepesh Kenwer[1].
[1]Renal Transplant Surgery, Post Graduate Institution of Medical Education and Research, Chandigarh, India; [2]Immunopathology, Post Graduate Institution of Medical Education and Research, Chandigarh, India; [3]Histopathology, Post Graduate Institution of Medical Education and Research, Chandigarh, India.

Background: Plasma cells are antibody producing cells and are the major cells that regulate humoral immunity. After their differentiation, plasma cells primarily reside in bone marrow and are a major source of persistent donor specific allo- antibody production in sensitized patients. Therefore we aim to estimate the percentage of plasma cells in the peripheral blood at the time of acute rejection.
Methodology: Percentage of Plasma cells in peripheral blood was quantified by flowcytometry using monoclonal antibodies against CD20, CD27, CD138 and CD38. Phenotypes with CD27-CD138+CD38+ gated over CD20- lymphocyte population were considered plasma cells. Percentage of plasma cells were compared among 38 cases of acute renal allograft rejection (Rejection group), 40 cases of stable graft function (Non Rejection group) at corresponding time and 40 cases of healthy controls. Rejection group was further classified as acute cellular (ACR, n= 21), acute antibody mediated (ABMR, n= 8) and mixture of both (Mixed, n= 9). Percentage of plasma cells was compared among rejection types.
Results: No significant difference in percentage of plasma cells was noticed between patients with end stage renal disease and healthy controls. Post transplantation, a significant decrease in the percentage of plasma cells was noticed at the time of rejection ($P<0.0001$) whereas, no significant change was noticed in non rejection group at the corresponding time points. When the rejection group was further classified, the decrease of plasma cells during rejection was equally significant in all the types of rejection ($P<0.0001$).
Conclusion: Decrease of plasma cells from peripheral circulation is associated with acute rejections and indicates their possible localization in rejecting grafts. The phenomenon is equally prominent in cellular rejection. The finding suggests the importance of elimination of plasma cells in the treatmen of acute cellular rejection.

472.1

Towards a standardized informed consent procedure for live donor nephrectomy: What do surgeons tell potential donors?

Kirsten Kortram, Jan N.M.Ijzermans, Frank J.M.F.Dor.
Surgery, Erasmus MC University Medical Center, Rotterdam, Netherlands.

Background: A recent systematic review demonstrated that there is no consensus on how the informed consent procedure in live donor nephrectomy should be arranged and practices vary. The aim of this survey study was to evaluate the surgical informed consent procedure for live donor nephrectomy, with special regards to disclosed complications.
Methods: A web-based survey was sent to all surgeons in the Netherlands who were believed to be, or had been in the past, involved in live kidney donation (n=50). Surgeons were asked if, and how often they mentioned 23 items regarding short- and long-term complications. In addition, questions were included regarding the informed consent practices in each transplant center. Center- and surgeon characteristics (e.g. center volume, surgeons' gender, specialization, experience) were compared to assess whether information disclosure was related to any of these features.
Results: The response rate was 98% (N=49), and responses were obtained from all eight kidney transplant centers. Of these 49 respondents, 32 were still involved in living kidney donor education. Surgeons had the following subspecializations: transplant surgery (50%), vascular surgery (31%), abdominal surgery (13%), and urology (6%). Informed consent procedures vary between centers, ranging from assumed to signed consent. Some respondents from the same center report different procedures. Bleeding was the only complication every surgeon mentioned. Risk of death was always mentioned by 16 surgeons (50%), sometimes by 12 (37.5%), four surgeons (12.5%) never disclosed this disastrous complication. Reported mortality rates ranged from 0.003% to 0.1%. Mentioning frequencies for all other complications varied per individual surgeon, but also per center.
High volume surgeons reported more complications than low volume surgeons. The risk of postoperative pain was more often disclosed by consultant surgeons than fellows, and the risk of death was more often disclosed by surgeons with a differentiation in transplant surgery.
Conclusion: Important complications are not always disclosed during the surgical informed consent process for live donor nephrectomy. Informed consent procedures vary. To optimally prepare living kidney donors for the procedure, a standardized informed consent procedure for live donor nephrectomy is highly recommended.

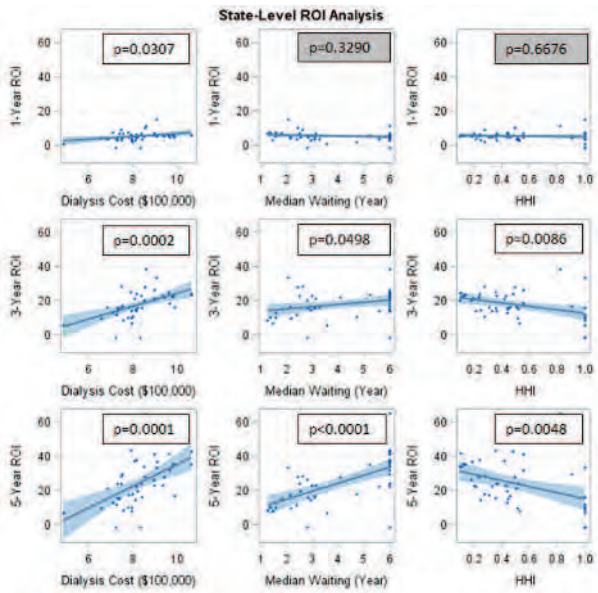
Analysis of dialysis cost and median waiting time on return on investment (ROI) of the US National Living Donor Assistance Center (NLDAC) program

Robert M. Merion[1,2], Jiawei Xing[2], Barry Hong[3], Akinlolu O. Ojo[1], Patricia H. Warren[4], Kimberly A. Gifford[4], Amit K. Mathur[5,6].
[1]University of Michigan, Ann Arbor, MI, United States; [2]Arbor Research Collaborative for Health, Ann Arbor, MI, United States; [3]Washington University School of Medicine, St. Louis, MO, United States; [4]American Society of Transplant Surgeons, Arlington, VA, United States; [5]Mayo Clinic Arizona, Phoenix, AZ, United States; [6]Robert D. and Patricia E. Kern Center for the Science of Healthcare Delivery, Mayo Clinic, Rochester, MN, United States.

Introduction: The US National Living Donor Assistance Center (NLDAC) program is a means-tested federally funded program that has provided reimbursement of travel and other out-of-pocket expenses to living kidney donors since 2008. Compared with deceased donor transplant, living donor kidney transplant results in earlier transition from dialysis to transplant. However, there is marked geographic variation in maintenance dialysis and transplant costs in the US. Therefore, we analyzed the association between NLDAC program return on investment (ROI) and state-based predictors including dialysis cost, waiting time, and transplant program competition.
Methods: ROI was calculated using NLDAC program costs from 2012-2015, USRDS estimates of state-specific dialysis and transplant costs, and SRTR-based calculations of state-level median waiting time. Transplant program competition was calculated using Hirschman-Herfindahl Index (HHI), where lower HHI indicates more competition. Univariable and multivariable linear regression models were fitted to test associations of predictors with 1-, 3-, and 5-year NLDAC ROI.
Results: In univariate analyses, higher state-specific annual dialysis cost was significantly associated with 1-year ROI, and the effect increased monotonically at 3 and 5 years (Figure). Longer median waiting time showed similar associations, and were significant at 3 and 5 years. More state-level transplant program competition (lower HHI) was associated with significantly higher ROI at 3 and 5 years. Transplant cost was strongly correlated with dialysis cost at the state level (r=0.77; p<0.0001).



In multivariable linear regression models, state-specific dialysis cost was strongly associated with a progressive increase in ROI at 1, 3, and 5 years (Table). Median waiting time was a significant independent predictor of ROI only at 5 years. HHI was not significant in any multivariable ROI model, suggesting that program competition may be accounted for by its relationships to dialysis cost and waiting time.

ROI Model	Parameter	Estimate	95% Confidence Interval	p-value
1-year	Dialysis Cost (per $10,000)	0.82	0.08 - 1.56	0.0307
3-year	Dialysis Cost (per $10,000)	3.76	1.91 - 5.61	0.0002
5-year	Dialysis Cost (per $10,000)	4.40	1.72 - 7.07	0.0019
	Median Waiting Time (per year)	3.77	2.11 - 5.43	<.0001

Conclusions: Dialysis cost is a strong driver of ROI for the NLDAC program for living kidney donors. Longer waiting time for deceased donor transplant is also independently associated with long-term NLDAC ROI. These findings suggest that enhanced marketing of NLDAC donor expense reimbursement to kidney programs in states with higher dialysis cost and longer waiting time may further enhance the effectiveness of this program aimed at removing financial disincentives to live organ donation.

The increasing number of unspecified living kidney donors

Willij Zuidema[1], Jacqueline Wetering van de[1], Emma K.Massey[1], Sohal Ismail[3], Jan N.M.IJzermans[2], Michiel G.H.Betjes[1], Willem Weimar[1].
[1]Internal Medicine, Nephrology and Transplantation, Erasmus MC, Rotterdam, Netherlands; [2]General Surgery, Erasmus MC, Rotterdam, Netherlands; [3]Psychology and Psychiatry, Erasmus MC, Rotterdam, Netherlands.

Background: An emerging strategy to bridge the gap between supply and demand for kidneys is the use of unspecified living kidney donors. Unspecified donation characterizes donation to an anonymous and unspecified recipient without any emotional link. There is no material benefit for the donor. Over the years the general public became more aware of this type of donation through reports in the media. We wondered whether this affected the actual number of unspecified donations.
Methods: From 2000-2015, we prospectively collected data on individuals who approached our center (adherent population 2.3 million) with the intention to donate a kidney in an unspecified way.
Results: In total 317 candidate donors contacted the coordinator in our center for information. They received a DVD and written information about the procedures and consequences of living unspecified donation. Two hundred and eleven (211) donor candidates embarked on the screening procedure which included a medical and psychological evaluation. One hundred and twenty eight of them (128/211, 62%) have donated. There were slightly more female than male (67 vs 61) and their age was 57 (median), range 21-89 year.
Unspecified donors donated to 72 recipients of incompatible couples in domino paired procedures, and to 56 patients on the waitlist, while 87 bridge donors (donors of the incompatible couples) donated either to recipients of incompatible couples (15) or to waitlist recipients (72). The 128 unspecified donations resulted in a total of 215 kidney transplants.
The number of unspecified donations increased over the years: 2000-2004: 5, 2006-2010: 52, 2011-2015:71, resulting in 6, 97, and 112 kidney transplants respectively. In 2015 22/114 (19.1%) of the living kidney transplants were donated by unspecified donors.
Conclusion: The number of unspecified living kidney donors is increasing over the years. Both patients on the deceased donor waiting list and those participating in a kidney exchange program stand to benefit from unspecified donation. Given that other research has shown no differences in physical or mental health outcomes between these donors and other living donors, this type of living donation should be encouraged.

472.4

Chinese adult perception towards organ donation in Hong Kong

Wah Chun LI[1], John Albarran[1], Issy Bray[1], Chi Shing LI[2].
[1]Faculty of Health & Life Sciences, University of the West of England, Bristol, United Kingdom; [2]School of Public Health, University of Hong Kong, Hong Kong, Hong Kong.

Introduction: Organ transplantation is a treatment of choice for most end-stage organ failure patients. However, organ transplant rates in Asia remain the lowest around the world. According to the International Registry on Organ Donation and Transplantation (2015), the organ donation rate in Hong Kong was 5.4 deceased donors per million of the population (pmp) in 2014, which is a far lower than Western countries like Spain of 36 donors pmp. The number waiting for organ transplantation has increased from 1,628 in 2007 to 2,113 in 2014 (Hong Kong Department of Health, 2015). The reasons for low donation rates remain a major challenge for healthcare providers, and a burden for those on waiting lists. Having a better understanding of organ donor's decision making processes and related behaviours in Asian populations is important for developing effective strategies to promote organ donation among the public.
Aim: A qualitative descriptive study was designed with the aim of investigating the current values, beliefs and experiences of Adult Hong Kong Chinese people around organ donation.
Methods: Two semi-structured focus group interviews were carried out in December 2015 with members of the public. A total of 15 participants who are registered or not registered as organ donors, were included. Participants are aged 18 or above without cognitive impairments, who have ordinarily resided in Hong Kong for a continuous period of not less than seven years and with an ability to speak fluent Cantonese. Translation and backward translation together with thematic analysis was used to analyse interview data.
Results: Both registered and not registered groups demonstrated an understanding that organ donation could help to save lives. However, culture and traditional beliefs hamper a commitment towards organ donation. In addition, participants dare not to talk or think of organ donation in front of elderly, as this would be disapproved. Previous unpleasant experience on the last journey of a relative, inadequate understanding of brain death, worry about deceased person will suffer from pain during organ removal [IB1] and disfigurement of the deceased body were the factors affecting their willingness to donate their own or family members' organs after death. Four registered donors misinterpreted that a missing or lost donor card meant that individuals would no longer be eligible to donate. Lack of follow-up after donor registration had a negative impact on willingness to donate in the future. However, public campaigns with catchy slogans or regular media promotion were believed to be helpful in reaching more potential donors.
Conclusion: It is apparent from the study that the public of Hong Kong are well aware of the benefits of organ donation. Despite various public events in promoting organ donation (e.g. forums, sports events, media and education in schools), the donation rate remains low. A major step forward is registered donor follow-up, and strategies to increase the coverage of organ donation in the media are important in meeting the ever-increasing need for donor organs.

Kidney transplantation from donors with rhabdomyolysis and acute renal failure: a report of 16 cases

Xiaopeng Yuan, Chuanbao Chen, Changxi Wang, Jian Zhou.
Organ Transplant Center, First Affiliated Hospital of Sun Yat-sen University, Guangzhou, People's Republic of China.

Objectives: To explore the clinical effect of kidney transplantation from donors with terminal acute renal failure (ARF) and rhabdomyolysis.
Methods: Kidney transplantation from donors with ARF and rhabdomyolysis from January 2012 to December 2015 was retrospectively reviewed. ARF was defined by RIFLE criteria. Rhabdomyolysis was defined by creatinine kinase (CK) level higher than five times normal (> 1000U/L in conjunction with high serum myoblobin.
Results: Eight donors suffered from rhabdomyolysis and ARF with peak CK 10623 ± 3692U/L, peak serum myoblobin 20618 ± 7959μg/L and peak serum creatinine 483 ± 176μmol/L. Three donors received plasmapheresis therapy (1～3 sessions), 2 donors received continuous renal replacement therapy and 1 donor received extra-corporeal membrane oxygenation treatment. Kidneys from these donors were transplanted into 16 recipients with 4 cases (25.0%) of delayed graft function, 4 cases (25.0%) of slow graft function and 8 cases of normal graft function. With a follow-up of 6 - 46 months, both patient and kidney graft survival were 100%. Mean 6 and 12-month glomerular filtration rate were 65.4 ± 13.5 and 71.2 ± 14.3 mL/(min•1.73m2) respectively.
Conclusions: Kidneys from donors with terminal ARF caused by rhabdomyolysis have excellent short-term outcomes. Screening for rhabdomyolysis should be recommended in deceased donors with acute renal injury.

Increased consented-not recovered (CNR) cases as a consequence of aggressive donor pursuit: Impact and implications

Jeffrey P. Orlowski[1], Chad C. Muse[1], Janice F. Whaley[1], Jan Foutch[1], Ronald A. Squires[1,2].
[1]LifeShare Transplant Donor Services of Oklahoma, Oklahoma City, OK, United States; [2]Department of Surgery, University of Oklahoma Health Science Center, Oklahoma City, OK, United States.

Introduction: One U.S. organ procurement organization (OPO) achieved significant growth in the number of deceased donors for the years 2014 and 2015 as compared to historical performance. One key strategy in achieving this growth was "aggressive pursuit" of any donor with a potentially transplantable organ. The OPO noted that as donors increased, so too did "consented-not recovered" (CNR) cases, or cases authorized and worked up for donation in which organs ultimately were not recovered for transplant.
Methods: A retrospective review of recovered and CNR cases was conducted. The 24 month cohort of 2014/2015 was compared to the prior 24 month cohort of 2012/2013. Donors, organs transplanted, donor types (DBD, DCD), CNR type and frequency data, and hours worked on CNR cases were compared.
Results and Discussion: In 2012/2013, 183 deceased donors were recovered (DBD and DCD combined); in 2014/2015, 315 deceased donors were recovered (+72.1%). Comparing the same periods, organs transplanted increased from 612 to 924 (+51.0%) and CNR increased from 41 to 92 (+124.4%). CNR in intended DBD cases increased from 25 to 52 (+108.0%) and in intended DCD cases from 16 to 40 (+150.0%). Total CNR case length (from authorization to case shut-down) increased from 633.5 hours in 2012/2013 (15.5 hours per case) to 1495.9 (16.3 hours per case) in 2014/2015 (+136.2%).
Conclusions: Aggressive pursuit of DBD cases, which may be older or have significant co-morbidities, combined with aggressive pursuit of DCD cases determined to have any likelihood of arrest has allowed our OPO to dramatically increase deceased donors recovered and organs transplanted. However, this aggressive pursuit has increased CNR at an even more dramatic rate when compared to growth in donors (124.4% vs. 72.1%). While we have accepted this as a consequence necessary to achieve a 51% increase in organs transplanted (lives saved), the primary implication is a 136.2% increase in case time spent on CNR (i.e., non-productive cases). The total financial cost of the extra manpower, testing, and ICU time is difficult to measure but is no doubt significant and it should be understood by OPOs and Transplant Centers alike that aggressive pursuit of deceased donors will result in increased cost per transplantable organ. Prospectively, the OPO will be seeking to quantify and categorize the costs associated with CNR separate from recovered donors.

Pediatric renal transplantation in the scandiatransplant region 1997-2012

Lars Wennberg[1], Anna Bjerre[3], Marie Larsson[1], Juuso Talnio[2], Helle C.Thiessson[4], Hannu Jalanko[2], Søren Schwartz Sørensen[5], Timo Jahnukainen[2].
[1]Department of Transplantation Surgery, Karolinska University Hospital, Stockholm, Sweden; [2]Department of Pediatric Nephrology and Transplantation, Childress Hospital, Helsinki, Finland; [3]Department of Pediatrics, Oslo University Hospital, Oslo, Norway; [4]Department of Nephrology, Odense University Hospital, Odense, Denmark; [5]Department of Nephrology, Copenhagen University Hospital, Copenhagen, Denmark.

Introduction: The Nordic Pediatric Renal Transplantation Study Group (NPRTSG) has registered data on all pediatric renal transplants (RTx) performed in the Scandiatransplant region (Denmark, Finland, Norway and Sweden) since 1994. Data from 430 RTx performed 1982-1996 was published 1998[1].
Methods: NPRTSG include all patients <16 years and is updated annually. We have studied factors affecting patient- and graft survival in 602 RTx performed 1997-2012. We also performed a comparison to the 1982-1996 cohort
Results and Discussion: The number of transplants increased by 30% and the number of recipients <2 years was doubled. Patients with glomerular disease decreased from 25% to 12%. The proportion of LDs increased from 54% to 60%, but differed between countries. The use of TAC and MMF increased from practically 0% to 50% and 40% respectively. Graft survival at 1 and 3 years was improved significantly ($p<0.001$) since 1997, especially among the youngest recipients with deceased donors.
For RTx performed 1997-2012, graft survival was significantly better for young recipients (<2 years) and for patients transplanted 2005-2012. Patients with ≤1 HLA A, B and DR mismatch had significantly better graft survival. There was a tendency towards better graft survival with living donors. Cold ischemia time, type of CNI or induction therapy did not affect graft survival. Acute rejection occurred in 149 patients (26%) but the incidence was reduced with time from 44.4% to 5.6%. Induction therapy did not reduce the incidence of acute rejection.
Conclusion: Between 1997 and 2012, 602 pediatric RTx was performed in the Scandiatransplant region. When compared with 1982-1996, results was significantly improved.

Results of the first kidney transplant in pediatric patients in Argentina: Period 1998-2014

Liliana Bisigniano[1], Viviana Tagliafichi[1], Daniela Hansen Krogh[2], Marta Monteverde[4], Maria del Carmen Bacque[3].
[1]Scientific and Technical Direction, INCUCAI, Buenos Aires, Argentina; [2]Informatic Direction, INCUCAI, Buenos Aires, Argentina; [3]Presidence, INCUCAI, Buenos Aires, Argentina; [4]Pediatric Nephrology, Hospital de Pediatraia J. P. Garrahan, Buenos Aires, Argentina.

Objective: To describe both patient and graft survival after kidney transplant, using living and cadaveric donor, in patients under the age of 18 in Argentina.
Material and Methods: patients under the age of 18 at the time of transplant (TX) between January 1, 1998, and December 31, 2014.The results were reported as a percentage of categorical variables and the median of numerical variables To estimate survival the Kaplan-Meir curve was used.Variables included in the Cox model were age and gender of the donor, cause of death of the donor (CVA, head trauma, and other), cold ischemia time (CIT) (< or > 12hours), years on waiting list (< or > 0.55) and years on dialysis (< or > 2)at the time of transplant , etiology on listing, and donor-recipient compatibility.
Results: 1255 patients were assessed in 48 centers, 932 (74%) received a kidney from a cadaveric donor (CD) and 233 (26%) received a kidney from a related living donor (LRD).
Median age of the recipient was 13.0 years (CI 95% 12.6-13.4); 55 % of the recipients were males. Median time in years on waiting list and on dialisys at the time of transplant was 0.5 (CI95% 0.4-0.6) and 2.0 (CI95% 1.9-2.19) respectivily. Both patient and graft survival after transplant with a cadaveric donor was 98% and 92%; at 3 years, 96%, and 83%; at 5 years 94% and 78%, respectively. The median time in years on waiting list ad dialisys at the time of transplant with LRD was 0.14 (CI95% 0.10-0.19) and 0.33 (CI95% 0.21-0.47 respectivily. Patient and post-transplant graft survival with LRD respectively was at 1 year 98% and 96%, at 3 years 97%, and 92%, at 5 years 95% and 88%. In recipients over 12 using CD, age was associated with post transplant mortality, and was statistically significant with a HR 2.21 (1.18 and 4.15). Graft survival as associated with age over 12, (HR 1.47; CI 1.13 and 1.91), glomerulonephritis, (HR 1.36; 1.02 and 1.83) and years on dialysis to TX with CD (HR 1.34; CI 1.03 and 1.75), adjusted with patient variables.
Conclusions: in recipients over 12 using CD, age was a risk factor in terms of post transplant graft survival. In the case of CD, glomerulonephritis as an etiology and time on dialysis before transplant were risk factors for post transplant graft survival.

Enbloc kidney transplant in pediatric recipients - The Miami experience

Vincent J.M. Chia, George Burke, Gaetano Ciancio, Linda J. Chen.
Miami Transplant Institute, University of Miami/ Jackson Memorial Hospital, Miami, United States.

Introduction: Enbloc renal transplantation (EBKT) is not commonly performed in pediatric recipients due to its potential complications. There is very limited published literature on this form of transplantation.
Methods: A retrospective review of all pediatric patients who received EBKT was performed.
Results: Between 2004-2014, 25 patients had EBKT, including 7 patients who had liver-kidney transplants. The recipient median age was 4.6 (range,0.9- 17.0) years and weight was 17.9 (range, 5.6-70.0) kg. The median donor age was 22 (range,2-108) months and weight 12.0 (range,5.8-21.1) kg. There are 7 patients who were preemptively transplanted. During the perioperative period, 4 patients required surgical intervention for complications;1 patient had a succesful thrombectomy and repair of urine leak, 1 patient required allograft repositioning/ureteric reimplantation, 1 patient had allograft ischemia,1 patient had kidney rupture. The last 2 patients had graft loss eventually. There was 1 intraoperative mortality from a liver-kidney patient. Patient and graft survival at 1 year is 96% and 88% respectively. The median serum creatine at 1 year, 3yr and 5yr was 0.42mg/dL, 0.51mg/dL and 0.62mg/dL respectively.
Conclusion: This paper represents the largest series of EBKT in pediatric recipients. Our center experience shows that EBKT is an acceptable form of transplantation in pediatric recipients.

When the vena cava inferior is missing: kidney transplantation in children with venous drainage to the portal vein

Udo Vester[1], Anja Büscher[1], Jürgen Treckmann[2], Peter Hoyer[1], Andreas Paul[2].
[1]Pediatric Nephrology, University Hospital, Essen, Germany; [2]Transplant Surgery, University Hospital, Essen, Germany.

Introduction: Kidney transplantation requires patent vascular access with the recipients circulation. Vascular malformations or thrombotic complications are major challenges in transplant surgery. We report the outcome of kidney transplantation in two boys after complete thrombosis of the vena cava inferior (VCI) who were transplanted using the portal circulation.
Case 1: A boy with congenital nephrotic syndrome and extensive thrombosis of the caval and iliacal veins received a pre-emptive kidney transplant (DD) at the age at of 5 4/12 years. Venous anastomosis was achieved with the portal vein. Post-operative recovery was uneventful with stable graft function. After follow-up of 5 years, eGFR is 58 ml/min/1.73m2. No signs of portal hypertension or splenomegaly have been observed since transplant.
Case 2: A boy suffered from septicemia with renal failure and caval and bilateral renal vein thrombosis at the age of 3 weeks. Peritoneal dialysis was performed until kidney transplant (DD) at the age of 2 9/12 years using the portal vein. Within the first 24 h after transplantation, portal vein thrombosis due to portal distortion requires surgical revision with complete recovery. After follow-up of 2 years, eGFR is 73 ml/min/1.73m2. On ultrasound, no evidence of portal hypertension or splenomegaly was seen.
Conclusion: In children with complete thrombosis of the VCI, successful renal transplantation can be achieved using the portal vein of the recipient. Despite increased portal blood flow, no signs of portal hypertension were observed.

Nationwide conversion to generic tacrolimus in paediatric kidney transplant recipients

Derisha Naicker, Tonya Kara, William Wong, Chanel Prestidge.
Paediatric Nephrology, Starship Children's Hospital, Auckland, New Zealand.

Introduction: PHARMAC, the New Zealand government agency which regulates access to and funding of pharmaceuticals, awarded sole supply of tacrolimus to Tacrolimus Sandoz® in March 2014. This necessitated conversion in all renal transplant recipients from the previously used brand Tacrolimus Prograf® to Tacrolimus Sandoz®. Bioequivalence has been demonstrated in adult subjects but clinical experience and safety data for generic tacrolimus in solid organ transplantation is limited, and particularly so for paediatric transplant recipients[1],[2]. The aim of this study was to evaluate the safety of conversion from Tacrolimus Prograf® to the generic preparation Tacrolimus Sandoz® in paediatric renal transplant patients. The primary outcome measurement was change in mean tacrolimus concentration after generic conversion. Additionally changes in renal function pre- and post- conversion, the need for dose adjustments and episodes of biopsy proven rejection in the 12months following the change were evaluated.
Methods: We conducted a retrospective cohort study in 37 paediatric renal transplant recipients in New Zealand who had been switched from Tacrolimus Prograf® to Tacrolimus Sandoz® over a 3 month period in 2014. We analysed the mean pre- and post-conversion tacrolimus trough concentrations and eGFR using the updated Schwartz equation. The 3 pre-conversion tacrolimus trough concentrations were recorded over no more than the prior 3 month period. The 3 post-conversion tacrolimus trough concentrations were measured on Day 3, Day 10 post conversion and the next subsequent level.
Results: Thirty-seven patients (41% females, age 3-19 years) who were a median of 3 years post transplantation were included. The mean trough tacrolimus concentration pre-conversion was 5.02µg/L and post-conversion 5.05µg/L. The median creatinine was 83µmol/L with an eGFR of 65.5ml/min/1.73^2 pre-conversion compared to the median creatinine of 79µmol/L with an eGFR of 69ml/min/1.73^2 post-conversion. There was no difference between the number of drug dose changes per patient for the 12months pre- and post- conversion. Three patients had biopsy proven acute rejection within the 12months post-conversion compared to 1 patient within the 12month period pre-conversion.
Conclusion: This study finds that paediatric renal transplant patients can be safely converted from Tacrolimus Prograf® to Sandoz® with no difference in the tacrolimus trough concentration, immediate allograft function or an increased requirement for dose alterations. Of some concern was the increased number of biopsy proven acute rejection episodes in the 12 month period post-conversion, however non-adherence contributed in at least one of these episodes. This difference was clinically and statistically not significant.

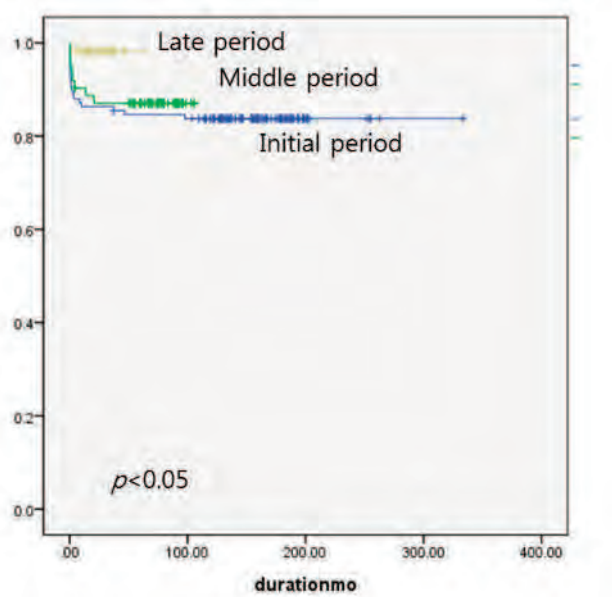
Recent advancements in the pediatric liver transplantation: A single-center study of 235 patients over 27 years

Nam-Joon Yi, Kyung Chul Yoon, Suk Kyun Hong, Hyo-Sin Kim, Hyeyoung Kim, Kwang-Woong Lee, Kyung-Suk Suh.
Surgery, Seoul National University College of Medicine, Seoul, Korea.

Background: Pediatric liver transplantation (PLT) has been the key therapy for end stage liver disease and the outcome has been excellent. However, still surgical complication associated with small recipient is the main cause of graft loss. In the present study, we assessed recent advances in outcome of PLTs through our experience.
Methods: A total of 235 PLTs performed between Mar 1988 and July 2015 were analyzed. Three chronological periods were investigated: the initial period (1988-2007, n=117), the mid-term period in which our PLT management protocol was settled down (2008-2011, n=62), and the period in which surgical procedures were refined for small children (2012-2015, n=56).
Results: The grafts' (84% vs. 82% vs. 98%) and patients' (84% vs. 87% vs. 98%) survival have been improved ($p<0.05$), whereas the number of biliary atresia (31% vs. 45% vs. 50%) deceased and the proportion of deceased donor (24% vs. 36% vs. 52%) and split PLT (7%vs. 16% vs. 46%) increased ($p<0.05$). The number of re-LT (3% vs. 9% vs. 2%) has been changed. ABO incompatible PLT has introduced on the last period (9%).
Conclusion: The quality of the PLT has recently been standardized through a large volume of experience, and the operation has been proven to improve the survival outcome. However, a constant evaluation of our experience is critical for further progress.



474.1

Immunosuppression at first hospital discharge after transplantation may not accurately predict risk of cancer in solid organ transplant recipients

Claire Vajdic[1], Angela C. Webster[2], Andrew E. Grulich[3], Nicola S. Meagher[4], Geoffrey W. McCaughan[5], Anne M. Keogh[6], Renhua Na[4], Maarit ALaaksonen[1].
[1]Centre for Big Data Research in Health, UNSW Australia, Sydney, Australia; [2]School of Public Health, University of Sydney, Sydney, Australia; [3]Kirby Institute, UNSW Australia, Sydney, Australia; [4]Prince of Wales Clinical School, UNSW Australia, Sydney, Australia; [5]The Centenary Research Institute, University of Sydney, Sydney, Australia; [6]Victor Chang Cardiac Research Institute, St Vincent's Hospital Sydney, Sydney, Australia.

Introduction: Organ transplant recipients can experience marked changes in the prescribed type and dose of immunosuppressive agents over time. For rare post-transplantation outcomes like cancer, population-based cohorts may be the only source of evidence of associations with specific immunosuppressive drugs. Longitudinal immunosuppression data can be very challenging to collect at the population level. As a consequence, most risk factor analyses of major health outcomes are based on immunosuppression at first hospital discharge after transplantation ("discharge"), and assume exposure is unvarying after that.
Materials and Methods: We conducted a population-based cohort study of all adult Australian liver, heart and lung transplant recipients 1984-2006 (n=4141). We abstracted risk factor data including immunosuppression at discharge and regular intervals thereafter from hospital medical records. We ascertained incident melanoma (n=48), lip cancer (n=58), and late (>1 year after transplant) non-Hodgkin lymphoma (NHL, n=61) and deaths by probabilistic record linkage between transplant registries and the Australian Cancer Database and National Death Index. We estimated adjusted hazard ratios (HR) using the Fine and Gray proportional subdistribution hazards model, accounting for death as a competing risk. We compared findings from two modeling approaches, (i) time-dependent immunosuppressive agents and (ii) immunosuppressive agents at discharge.
Results: The median time from transplantation to cancer diagnosis was 6.9, 6.1 and 3.6 years for lip cancer, late NHL and melanoma respectively. In fully adjusted models using time-dependent immunosuppressive agents, higher mean daily dose of azathioprine increased the risk of lip cancer (HR 2.28, 95%CI 1.18-4.38) and late NHL (HR 1.78, 95%CI 1.12-2.84) but not melanoma (HR 0.55, 95%CI 0.29-1.04). In fully adjusted models using immunosuppressive agents at discharge, higher mean daily dose of azathioprine was not associated with risk of lip cancer (HR 1.33, 95%CI 0.87-2.04), late NHL (HR 1.23, 95%CI 0.92-1.81) or melanoma (HR 0.71, 95%CI 0.44-1.13). No other immunosuppressive agents were significantly associated with risk of any of the cancers using either modeling approach.
Discussion: Assessments of cancer risk that rely solely on discharge immunosuppression data can differ from those that capture changes over time in the dose and type of immunosuppression.
Conclusion: With over two-decades of follow-up and detailed longitudinal data on individual immunosuppressive agents, this study provides the first evidence that observational risk factor analyses using discharge immunosuppression data may generate spurious findings due to misclassified drug exposure. Our findings have implications for clinical guidelines that draw from such evidence.

474.2

Longitudinal immunosuppression data reduces exposure misclassification and improves outcome prediction among solid organ transplant recipients

Maarit Laaksonen[1], Angela C.Webster[2], Andrew E.Grulich[3], Nicola S. Meagher[4], Geoffrey W. McCaughan[5], Anne M. Keogh[6], Renhua Na[4], Claire M.Vajdic[1].
[1]Centre for Big Data Research in Health, University of New South Wales, Sydney, Australia; [2]Sydney School of Public Health, University of Sydney, Sydney, Australia; [3]Kirby Institute, University of New South Wales, Sydney, Australia; [4]Prince of Wales Clinical School, University of New South Wales, Sydney, Australia; [5]Centenary Institute of Cancer Medicine & Cell Biology, University of Sydney, Sydney, Australia; [6]Victor Chang Cardiac Research Institute, St Vincent's Hospital Sydney, Sydney, Australia.

Introduction: Most observational studies on the effect of immunosuppressive agents on clinical outcomes among solid organ transplant recipients have relied on discharge immunosuppression data, which assumes the immunosuppressive regimen remains unchanged throughout follow-up. We studied the changes in immunosuppressive regimens of Australian liver, heart and lung transplant recipients over time and compared survival outcomes for individual agents and common drug combinations.
Material and Methods: We performed a cohort study in Australia using population-based liver and cardiothoracic transplant registries (1997–2006; n=2330). We recorded immunosuppressive agents (cyclosporine, tacrolimus, azathioprine, and mycophenolate) at first hospital discharge after transplantation and at 1 and 5 years, and classified transplant recipients according to the individual agents and combinations they were prescribed at discharge and whether they remained on those regimens during the follow-up period. We identified deaths from all causes by record linkage with the National Death Index. We estimated the risk of death from exposure to individual immunosuppressive agents and compared the risks between different dual therapies, as defined by discharge immunosuppression data (discharge analysis) versus longitudinal immunosuppression data (longitudinal analysis), using hazard ratios (HR) from Cox proportional hazards models adjusted for age, sex, organ type, and year of transplantation.
Results: During the 10-year follow-up, the immunosuppressive regimens of 660 (28%) transplant recipients were altered, most often involving removal of azathioprine, and 463 (20%) recipients died. Of the individual drugs, receipt of mycophenolate or tacrolimus was associated with a significant reduction in risk of death in longitudinal analysis (HR (95% CI): 0.69 (0.52, 0.93) and 0.75 (0.57, 0.98), respectively) whereas in discharge analysis the results for these agents were only suggestive of reduced risk (0.77 (0.58, 1.01) and 0.80 (0.61, 1.03), respectively). Recipients on mycophenolate and tacrolimus dual therapy had a lower risk of death compared to those on azathioprine and cyclosporine dual therapy in longitudinal (0.55 (0.33, 0.92)) but not in discharge (0.67 (0.42, 1.08)) analysis whereas the other dual therapies did not differ in their risk.
Discussion: As expected, we observed notable changes in the immunosuppressive regimen during follow-up, especially among those who started on azathioprine. Innovatively, accounting for those changes in longitudinal analysis revealed significant differences between drug regimens which were not identified by the discharge analysis.
Conclusion: Use of longitudinal immunosuppression data will help avoid exposure misclassification and improve prediction and comparison of outcomes related to immunosuppressive therapy, which may affect choice of immunosuppressive regimens, and conclusions about the pathogenicity of different agents.

National transplantation pregnancy registry (NTPR): 25 years of data collection

Michael J. Moritz[1,2], Lisa Coscia[2], Dawn P.Armenti[2], Serban Constantinescu[2,3].
[1]Surgery, Lehigh Valley Health Network, Allentown, PA, United States; [2]National Transplantation Pregnancy Registry (NTPR), Gift of Life Institute, Philadelphia, PA, United States; [3]Medicine, Temple University, Philadelphia, PA, United States.

The year 2016 marks 25 years of continuous data collection by the National Transplantation Pregnancy Registry (NTPR). Since 1991, the NTPR has studied pregnancies of transplant recipients in North America. The NTPR is the largest study of its kind. Data are collected via telephone interviews and review of medical records. The NTPR follows participants and their children indefinitely. To date, 1465 female solid organ transplant recipients, including over 1000 kidney recipients, participate in the NTPR (Table). The majority of children are reported healthy and developing well. At least 125 grandchildren now comprise a second generation providing the ability to study theoretical concerns about potential far-reaching effects of in utero exposure to immunosuppressive medications. NTPR analyses have contributed to clinical recommendations regarding advisability and timing of pregnancy, medications, comorbid conditions and other aspects of post-transplant motherhood. The NTPR also serves as a resource for recipients who are making family planning decisions. Pregnancy considerations vary depending on the organ transplanted, but the most significant factors for successful outcomes for mother and child are stable prepregnancy graft function, avoidance of mycophenolic acid during the 1st trimester, and close follow-up during pregnancy and postpartum. To provide the most complete information to the transplant community, NTPR will expand in 2016 to include recipients treated or transplanted beyond North America.

NTPR: Pregnancy Outcomes in Female Transplant Recipients

	Recipients	Pregnancies	Additional Multiple Birth Outcomes	Total Outcomes	Estimated Conception Date Range	Pregnancies in Progress	Fetal Losses*	Live Offspring

*miscarriages, terminations due to fetal anomalies, stillbirths, neonatal deaths, and child deaths due to congenital issues

Conclusions: The NTPR is a reliable resource for the worldwide transplant community. For many recipients, pregnancy after organ transplantation is possible with the majority of the pregnancies resulting in a healthy live birth. Healthcare providers who counsel transplant recipients about parenthood and transplant recipients themselves are encouraged to contact the NTPR.

The NTPR is supported by grants from Astellas Pharma, US Inc., Bristol-Myers Squibb Co. and Pfizer Inc.

Prospective randomized controlled study evaluating the relationship between electronic adherence data and tacrolimus concentration data

Lisa Potter[1], Brenna Kane[1], Mark Lockwood[1], Adam Bodzin[1], Diane Covington[2], Kimberly Mayer[2], J. Michael Millis[1].
[1]Transplant Surgery, University of Chicago, Chicago, IL, United States; [2]Innovative Clinical Research, Pheonix, AZ, United States.

Purpose: The SIMpill® Medication Adherence System (MAS) is being evaluated in transplant recipients in a prospective 3-year study. The MAS captures patient medication adherence data in real-time. This report describes preliminary results combining adherence data and tacrolimus levels.
Methods: 89 solid organ transplant recipients were randomized to 1 of 4 groups: 2 intervention groups (I1 and I2) and 2 control groups (C1 and C2). Subjects in I1 or I2 received a MAS, a medication-dispensing device that communicates timing of openings or doses taken to a secure server. If a dose is missed, a text reminder message is sent to the subject (I1). In addition to patient reminders, providers were notified if consecutive doses were missed over a 72 hour period (I2), enabling intervention. C1 received a MAS but feedback was not provided to the patient or provider. C2 did not receive a MAS device. The MAS utilizes patient dose timing data with a one-compartment pharmacokinetic (PK) model to project individual tacrolimus drug level plots. The individual tacrolimus blood levels are plotted on drug curves based on the adherence data.
Results: PK modeling utilizing MAS data combined with tacrolimus levels resulted in 4 adherence profiles: A) patients with consistent dose timing with a blood draw time close to patient's planned dose time, B) patients with irregular day to day dose timing with a blood draw time close to patient's planned dose time, C) patients with consistent dose timing with a blood draw after the dose time resulting in a low trough level, and D) patients who do not withhold their dose before the blood draw resulting in the perception of a high trough level [figure 2].
Conclusions: Utilizing a MAS system may improve the interpretation of actual serum tacrolimus levels. Preliminary results indicate that the MAS may provide useful PK projections of tacrolimus serum levels. Irregular dose administration results in variable and/or inaccurate tacrolimus trough levels.

Automatic ischemia time calculation in the intra-operative nursing record

Carmen Sierra, Marie Telfort.
Transplant Living Donor, Jackson Memorial Hospital/Miami Transplant Institute, Miami, United States.

Introduction: Reducing ischemia time calculation during transplant surgey leads to better outcomes for graft survival. Inaccurate calculation in ischemia time may lead to erroneous quality reporting. One source of inaccurate data is manual ischemia time calculation.By implementing an automatic ischemia time calculation segment in the electronic intra-operative nursing record,perioperative nurses can reduce wrong ischemia time from being calculated by way of data entry or inaccurate mathematical computation. Utilizing technology to facilitate mathematical computation with minimal errors in data entry and calculation leads to better reporting of ischemia time calculation and improved quality measures.
Purpose: The goal of this study is to reduce the amount of mathematical errors made by the circulating nurse in calculation ischemia time. By reducing the errors in manual arithmetic, accurate quality data becomes available to make necessary quality improvements.
Methodology: Daily autdits of the ischemia time calculated and entered in the intra-operative nursing record over the course of twenty-three months was performed. A total of 307 chart audits prior to implementation were performed and 388 chart audits after implementation.
Results: There were 40.4% errors or 59.6% accuracy with manual calculation. This implementation demonstrated a 99.5% accuracy in ischemic time calculation with the implementation of automatic ischemia time calculation segment in the eletronic nursing medical record. Manual ischemia times increase probability of errors.
Conclusion: Improving quality data reporting through the application of technology has proved to be instrumental in providing accurate data. There is a significant correlation in the manual entry of ischemia times and errors versus a significant decrease in errors when ischemia time calculation is automatically calculated by the eletronic intra-operative nursing record. Having accurate quality data will provide quality improvement measures when technology is appropriately applied.

Impacts of ureteric stent removal timing on post renal transplant major urological complication. A single centre experience

Syed Raza[1], Abbas Ghazanfar[2], Ibrahim Alahmadi[1], Hani Alahdal[1], Jens Brockmann[1], Dieter Broring[1], Amira Abassi[1], Hassan Aleid[1].
[1]Department of Kidney and Pancreas Transplantation, King Faisal Specialist Hospital & Research Center, Riyadh, Saudi Arabia; [2]Department of transplant Surgery , St Georges Healthcare NHS Trust, London, United Kingdom.

Background: Renal transplant (RTx) has high allograft success rate but is also associated with some potential complications. Urinary leak, ureteric stenosis and stricture are few such major urological complications (MUC) that can result from transplant ureteroneocystostomy. To prevent such complications different techniques of ureteroneocystostomy are used some with Double J ureterovesical stents (JJ-stent) and some without. The timing of postoperative removal of these stents varies considerably between 7 days to six weeks. In King Faisal Specialist Hospital (KFSH) this is a common practice to remove urinary catheter with JJ-stents on 41h postoperative day. In this present study we describe our experience with JJ-stent removal on 4'h post opt day following Adult RTx.
Material and Methods: In this retrospective study we analyzed outcome of patients for MUC between Jan 2004 and Dec 2013. In our renal database all the information are prospectively logged including all the demographics, outcome and complications. We divided the patient into two cohorts; cohort A where JJ-stent was removed in 4 days and cohort B where the stent was left longer then 4 days. We compared risk incidence of MUC between the two cohorts. We used SPSS 21 for statistical analysis and a P value of <0.05 was considered statistically significant.
Results: A total of 39 (3.06%) MUC including 8 ureteric leaks and 31 ureteric stenosis were recorded among 1271 Adult RTx. Majority of patients had their stents removed within 4 postoperative days (cohort A n=1052) compared with more than 4 days (Cohort B n=219). There was no significant MUC risk recorded between two cohorts [RR 1.1406; 95% CL 0.8591 to 1.8966; P=0.7638]. General demographics and complications are in Table 1. There was no significant survival or hazard function difference between the two groups [P=0.4051].
Conclusion: Removal of JJ-stent at 4'h postoperative day is a safe option with not increased risk of MUC

Prospective treatment and novel biomarkers of BK polyomavirus associated nephropathy

Minal Borkar[1], Vikas Srivastava[2], Ryan Cunnington[1], Tejeswin Sharma[1], Lee Anne Tibbles[1].
[1]Faculty of Medicine, University of Calagry, Calgary, AB, Canada; [2]CSIR-Indian Institute of Toxicology Research, Lucknow, India.

Background: BK polyomavirus assoiciated nephropathy (BKVAN) is documented as an important cause of graft failure in renal posttransplant. To date, the mechanisms involved in the progression of fibrosis associated with BKV nephropathy are poorly understood and an effective treatment against BKV is unavailable.
Objective: To determine the key epigenetic mechanism BKV uses to induce fibrosis and necroptosis, and to assess DNA methyl transferase 1 (DNMT1) as a potential therapeutic target.
Methodology: Human Proximal Tubular Epithelial Cells (HPTCs) and CCD1105 cell lines were infected with BKV. A low drug dose (5um) of RG108 (DNMT1 inhibitor) was used to treat BKV infected cells and RNA/DNA was isolated. Methylation Specific PCR (MSP) and Bisulfite Sequencing (BS) assays were performed to assess the hypermethylation of promoter of genes and expression study was carried out using real-time PCR. Further, Western blotting and Flow cytometry were executed to confirm necroptosis.
Results: BKV infection results into significant downregulation of epithelial cell markers E-cadherin (CDH1) and collagen IV (COLIVA1) gene expression, whereas, fibrotic marker collagen I mRNA level was increased suggesting that BKV infection causes cells to undergo epithelial to mesenchymal transition (EMT). MSP confirmed silencing of those genes through DNA methylation mechanism by demonstrating hypermethylation of promoters of CDH1 and COLIVA1 genes. RG108 treatment had shown altered COLIVA expression and decrease in methylation of promoter, as demethylating agent verified that BKV may uses epigenetic mechanism (DNA methylation) for inducing EMT and eventually fibrosis.
The expression based study at both mRNA and protein level confirmed increase in Receptor-interacting serine/threonine-protein kinase 3 (RIPK3), phospho-Mixed Lineage Kinase Like pseudokinase (pMLKL) and High Mobility Group Protein B1 (HMGB1). The treatment with RG108 potentially reduced the expression of these necroptotic genes, demonstrating that BKV may induce necroptosis epigenetically in renal tubular cells.
BS, MSP and real-time results had shown that BKV also hypermethylates the RB1 gene promoter to silence it and instigate host cell division for its own replication however, followed by RG108 treatment results had demonstrated significant decrease in BKV DNA (p-value<0.037).
Conclusion: This study confirms that BKV epigenetically induces EMT and necroptosis for pathogenesis hence, hypermethylated genes could act as potential biomarkers for early diagnosis. RG108 inhibits DNMT1, prevents these epigenetic events and blocks BKV replication, therefore, may act as potential drug for treating BKVAN however, further studies targetting DNA methylation to lessen BKV induced fibrosis are warranted.

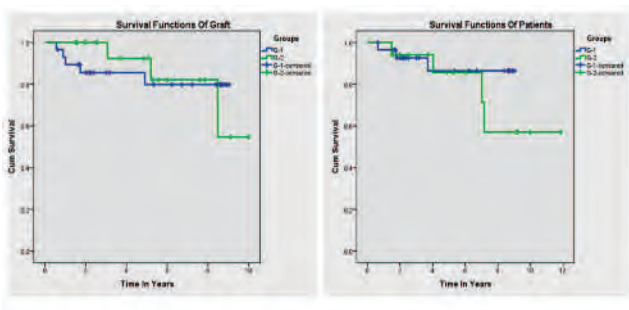
BK Virus nephropathy in renal transplantation- A Pathologist's perspective

Kamlesh Suthar, Aruna V.Vanikar, Rashmi D.Patel, Kamal V.Kanodia, Lovelesh A.Nigam.
Department of Pathology, Lab. Medicine, Transfusion Services and Immunohematology, Institute of Kidney Diseases & Research Centre and Institute of Transplantation Sciences (ITS), Ahmedabad, India.

Introduction: BK Polyoma virus nephropathy (BKVN) occurs in 1-10% of allografts leading to 30-50% graft loss in renal transplant (RT) recipients. We present our experience of BKVN in RT.
Material and Methods: We analysed BKviral load in urine/blood and correlated with renal graft pathology. Totally 2932 biopsies performed between 2006 and 2015 were evaluated and divided in 2 groups on basis of timeline of BKVN. Group-1 included BKVN ≤ 1 year RT and group-2 included BKVN > 1 year RT. Formalin fixed allograft biopsies were processed, stained by standard techniques and evaluated following modified Banff-'13 guidelines[1]. Urine was screened for decoy cells. Blood and urine samples were simultaneously tested for BKV-DNA by polymerase chain reaction (PCR) in a subset of patients. There were 29 recipients (25 males) in group-1 and 17 (14 males) in group-2. Mean patient age (years) was 38.05 in group-1 and 33 in group-2, with mean HLA match of 2 in each. Mean donor age (years) was 48 in group-1 and 46 in group-2. One patient in group-1 and 3 in group-2 had persistent BKVN. All patients received antiviral therapy with modified immunosuppression.
Results and Discussion: BKVN incidence was 1.6% (39 males, 7 females), 1% at mean 0.31 years post-RT in group-1 and 0.6% at 3.3 years post-RT in group-2. Decoy cells were observed in 13.8% of group-1 and 11.8% of group-2. In group-1, BKV-DNA was observed in 16.7% blood and 33.3% urine and in group-2, 33.3% blood and 66.7% urine samples. Histopathology stage-A was observed in 48.3% of group-1 and 41.2% of group-2, stage-B in 44.8% of group-1 and 47.1% of group-2, stage-C in 6.9% of group-1 and 11.8% of group-2. Associated rejection was observed in 20.7% of group-1 and 17.7% biopsies of group-2. Mean SCr (mg/dL) at 1, 5, 7 and 9 years post-RT was 2.06, 1.79, 1.82 and 2.34 in group-1 and 1.41, 2.12, 3.05 and 4.87 in group-2 respectively. Patient loss was 10.3% in group-1 and 23.5% in group-2 mainly due to septicemia. There was 13.8% graft loss in group-1 and 23.5% loss in group-2. Kaplan Meier analysis revealed better outcome in group-1.



Our study had lower incidence of BKVN compared to others[2]. Our observations are similar to 15%, 25-75% and >80% risk of graft loss with patterns A, B and C respectively reported in literature[3]. Measurement of BKV load in urine/plasma helps in identifying patients at risk of developing BKVN and for monitoring response to therapy[4]. All RT recipients should be screened for BKV with quantitative plasma PCR for timely patient management[5].
Conclusion: BKVN leading to deterioration in RT outcome was observed in 1.6% biopsies in our 10 year study. BKVN before 1 year post-RT had better outcome compared to BKVN >1 year. Higher

histopathological stage had worst prognosis. Thus biopsy was crucial for patient management.

The impact of recurrent glomerulonephritis after kidney transplantation in the era of contemporary maintenance immunosuppression

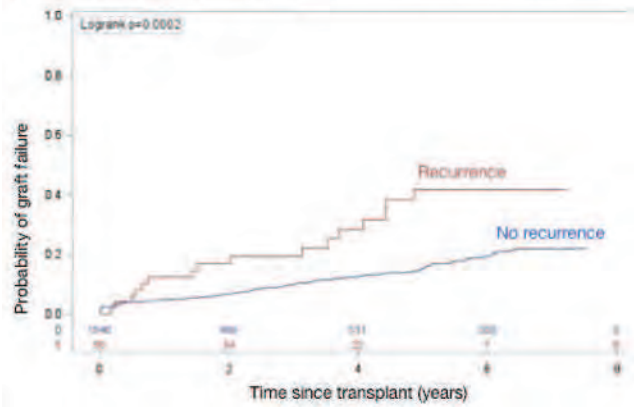
Penelope Allen[1,7], Steven J.Chadban[3,6], Jonathan C.Craig[1], Wai H.Lim[2], Richard D.Allen[3,6], Germaine Wong[1,3,4,5].

[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [2]Department of Renal Medicine, Sir Charles Gairdner Hospital, Perth, Australia; [3]Renal Medicine and Transplantation, Royal Prince Alfred Hospital, Sydney, Australia; [4]Centre for Transplant and Renal Research, Westmead Hospital, Westmead, Australia; [5]Sydney School of Public Health, The University of Sydney, Sydney, Australia; [6]Sydney Medical School, The University of Sydney, Sydney, Australia; [7]The Australian National University, Canberra, Australia.

Background: Glomerulonephritis (GN) is a common indication for kidney transplantation, with recipients at variable risk of recurrence and graft loss. However, the impact of recurrence on graft outcomes in the context of contemporary immunosuppression is relatively uncertain. We aimed to determine the prevalence and estimate the excess risk of graft loss in recipients with recurrent GN.

Methods: Data was obtained from the Australia and New Zealand Dialysis and Transplant Association (ANZDATA) registry. All primary living and deceased-donor kidney transplant recipients between 2006 and 2013 whose end stage kidney disease (ESKD) was attributed to GN were included in the analyses. The association between the risk of overall and death-censored graft loss was calculated using adjusted Cox proportional regression models.

Figure 1. Cumulative incidence of overall graft loss in recipients with and without recurrent glomerulonephritis.



Results: Among the 3,739 kidney transplant recipients followed for a total of 11,057 person-years, GN was the primary cause of end-stage renal disease in 1,590 (42.5%) recipients. The most common types were IgA (n=585, 36.8%), focal segmental glomerulosclerosis (FSGS) (n=308, 19.4%) and lupus nephropathy (n=80, 50%). A total of 50 (3.1%) recipients experienced disease recurrence, with the median time to disease recurrence of 0.7 (interquartile range (IQR): 2.25) years. Of those that recurred, FSGS was the most rapidly recurring GN (0.1 years from time of transplantation, IQR: 0.52 years), followed by mesangioproliferative GN (1.09 years, IQR: 0.53) and IgA nephropathy (1.26 years, IQR: 2.34). The incidence of overall graft failure for those whose GN disease recurred was 12.7% compared to 4.09% in those without disease recurrence (p value <0.001). Adjusted hazard ratios (HRs) for overall graft loss and death-censored graft loss were 3.18 [(95%CI: 1.89 – 5.4)] and 4.52 [(95%CI: 2.55 – 8.05)], respectively. (Figure 1). Of those who experienced disease recurrence, recurrent GN was the leading cause of graft loss (70%), followed by chronic allograft nephropathy (22%) and acute rejection (2%).

Discussion: Whilst there is a small overall risk of recurrent GN in the transplanted kidney (3.1% at a median follow up time of 3 years post transplant), disease recurrence continues to have significant impact on graft survival in the contemporary era.
The Australia and New Zealand Dialysis and Transplant Registry (ANZDATA)

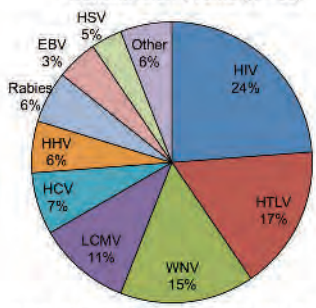
Trojan kidneys: Unexpected donor-derived viral transmission in kidney transplant recipients – a systematic review

Rashmi Shingde[1], Vaishnavi Calisa[1], Jonathan C.Craig[1,2], Allison Tong[1,2], Germaine Wong[1,2,3].
[1]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia; [2]Sydney School of Public Health, The University of Sydney, Sydney, Australia; [3]Centre for Transplant and Renal Research, Westmead Hospital, Sydney, Australia.

Introduction: Unexpected donor-derived viral transmission may occur through kidney transplantation due to a false-negative donor test or a lack of pre-donation donor testing. Although rare, it is associated with significant morbidity and mortality. We aimed to evaluate the outcomes of donor-derived unexpected viral infections in kidney transplants.
Methods: We searched MEDLINE, Embase and the Cochrane Central Register of Controlled Trials (CENTRAL) to December 2015. Studies that provided evidence of 'proven' or 'probable' unexpected donor-derived viral transmission events were included. Recipient survival estimates were calculated using the Kaplan-Meier method.
Results and Discussion: We identified 49 studies eligible for inclusion and all were case reports or case series. In total, there were 57 renal transplant donors and 85 recipients. Of the donors, 43 (75.4%) were deceased and 31 (54.4%) were female. The average donor age was 36.7 years (SD=13.2). Of the recipients, 48 (56.5%) were male and the mean age at time of transplant was 42.3 years (SD=12.8). The recipients varied by the region of origin: North America (n=41), Europe (n=31), Asia (n=5), Australia & NZ (n=5) and South America (n=3).
Human Immunodeficiency Virus (HIV) was the most common (23.5%) unexpected donor-derived viral infection in kidney transplants, followed by Human T-cell Lymphotropic Virus (HTLV) (16.5%) and West Nile Virus (WNV) (15.3%) (See Figure 1). Time from transplantation to symptomatic disease onset ranged from 0.7 months (SD=0.2) for WNV to 5 months amongst Hepatitis C (HCV) recipients (SD=3). HIV had a median time to disease onset at 1.7 months (IQR=12.6), compared to 2.7 months for HTLV (IQR=23.5).

Figure 1. Frequency of Unexpected Donor-derived Viral Transmission Events (n = 85)



HIV = Human Immunodeficiency Virus, HTLV = Human T-cell Lymphotropic Virus, WNV = West Nile Virus, LCMV = Lymphocytic Choriomeningitis Virus, HCV = Hepatitis C Virus, HHV = Human Herpesvirus, HSV = Herpes Simplex virus, EBV = Epstein - Barr Virus, Other = B19, Arenavirus, CVB3

All five rabies-infected recipients died from rabies-related complications. Prior to death, all 3 rabies-infected donors had altered mental status with fever. Patients with WNV experienced the worst prognosis, with more than 66.7% recipients dying within 12 months, followed by 7.1% of HIV-infected recipients dead in a 12-month period (See Figure 2). The median survival times for recipients with WNV and HIV were 0.88 months (IQR=1.49) and 23.5 months (IQR=25) respectively.
Treatment data was available for 54 out of the 85 recipients. Approximately one third of the patients received antiviral therapy (28.2%) and had immunosuppression withdrawn (29.4%).
Conclusion: The most frequently reported unexpected donor-derived viral infections in kidney transplants were HIV, HTLV and WNV.

Neuroinvasive viruses were associated with the worst recipient prognoses. These data suggest that donors with unexplained death and/or neurological symptoms should be deferred. By understanding the prognoses of such unexpected donor viral transmission events, the safety of organ recipients can be maintained whilst expanding the pool of potential donors.

Figure 2. Recipient Survival Estimates
With 95% Confidence Limits

Sequential biopsy findings of Polyomavirus associated nephropathy

Handan Özdemir[1], Nurhan Özdemir[2], Aysen Terzi[1], Sebnem Ayva[1], Eda Yılmaz Akçay[1], Hande Arslan[3], Gökce Özdemir[1], Mehmet Haberal[4].
[1]Pathology, Baskent University, Ankara, Turkey; [2]Nephrology, Baskent University, Ankara, Turkey; [3]Infectious Disease, Baskent University, Ankara, Turkey; [4]Transplant Surgery, Baskent University, Ankara, Turkey.

Introduction: The sequential biopsy findings of Polyomavirus nephropathy (PVN) has not been investigated in detail before. The aim of this study is two folds; first to find out the difference of histopathological findings in sequential biopsies of patients with PVN, second to investigate the impact of histopathological findings on graft survival.
Material and Method: Total 70 of 580 patients (12%) had sustained BKV viremia. Only 53 patients whom had at least 2 sequential biopsies (BXs) after initial biopsy with PVN were included to study. All sequential BXs (n:184) of 53 patients (M/F: 43/10) with a mean age of 35,5±16,2 years were re-evaluated. Both initial diagnostic biopsy and the sequential 2nd BXs of all patients were scored according to Banff criteria. The mean interval between initial BX and the 2nd BX was 3,1±1,4 months. HLA-DR expression of tubules was noted both in initial 1st and 2nd BXs. Development of interstitial fibrosis (IF) was investigated throughout in all sequential biopsies. Clinical data and viral loads of each patient were retrieved from patients' records.
Results: The mean interval between the diagnosis of PVN and transplant was 12,5±17 months. Most patients received tacrolimus (75,5%). At the same time with PVN, CMV viremia was found in 23 patients. SV-40 was positive in 26 patients (49,1%) in 1st BX and it was positive in 32 patients (60,4%) in 2nd BX. Glomerular SV40 was positive in 7 cases. BXs containing both cortex and medulla had higher rate of SV-40 staining ($p<0.001$). Statistically significant differences was found between 1st and 2nd BXs in regards of stage of PVN and PVL ($p<0.001$ for both). The stage of 1st BXs was increased to higher stage in 25 cases in the 2nd BXs. Also PVL was increased to higher degree in 16 cases in the 2nd BXs. The tubulitis score and interstitial inflammation significantly increases in the 2nd BXs compared to 1st BXs. The rate of acute humoral and cellular rejection at the same time with PVN was 24,5%. Thrombotic microangiopathy was found in 9 cases (17%). When we compared 1st and 2nd BXs in regards of tubular HLA-DR expression, we noted that expression was increased from 28,3% to 47,2% with increasing degree of interstitial inflammation ($p<0.001$). The development of IF in sequential BXs was found in 28 cases (52,8%) in a mean time of 5,5±3,4 months. Patients whom had glomerular SV40, CMV viremia, higher degrees of inflammation and PVL showed higher risk of IF. The risk of graft loss was found to be increased with increasing PVN stage and PVL ($p<0.01$). Thrombotic microangiopathy, IF, glomerular SV-40 have also shown a negative influence on graft lost.
Conclusion: The rate of negative SV40 can be reached to 50,9% especially in the early BXs and there was a significant differences between two sequential BXs. Therefore it is important to follow-up these patients with sequential BXs in order to diagnose early, to schedule their therapy and to evaluate the prognostic parameters. We also showed that histological findings were correlated well with graft outcome and PVN is morphologically indistinguishable from interstitial rejection.

550.6

Polyomavirus (PV) replication and smoking are independent risk factors for bladder cancer after renal transplantation

John C. Papadimitriou, Sandy Liu, Borislav Alexiev, Cinthia B. Drachenberg.
Pathology, University of Maryland School of Medicine, Baltimore, MD, United States.

Solid organ transplant recipients are at increased risk for polyomavirus nephropathy (PVAN), particularly BK, as well as for developing malignancies, primarily due to immunosuppression. The cancer risk that is associated with PV replication and the concurrent effect of other carcinogenic factors has not been assessed. The aim of this study was to investigate the incidence of PV replication in kidney transplant recipients and assess its correlation with the development of specific malignant neoplasms, alone or in association with smoking.
A retrospective case-control study was conducted for PV replication in all kidney biopsies and urine cytologies received between 1998 and 2014 from kidney transplant recipients. PV replication positive patients (n=943) were defined as having a kidney biopsy with PVAN or any urine cytology with "decoy" (PV infected) cells. PV negative patients (n=943) were defined as never having evidence of PV replication. Incidence of any malignancy (excluding non-melanoma skin tumors) was determined in these 1,886 patients and correlated with demographic data and smoking.
The overall cumulative incidence of PVAN in out total population (3612 patients)t was 8.1% and the cumulative incidence of any decoy cell shedding was 25.2%. There was a 8% incidence of malignant tumors after a mean post-transplant follow-up of 7.9 years.
There was a total of 149 solid organ and hematologic cancers among the 1,886 transplant patients (7.9% incidence); one patient had synchronous urothelial and prostate cancers. In the PV positive group, there were a total of 85 non-skin malignancies/carcinomas: 11 bladder, 14 kidney, 10 prostate, 8 lung, 8 colon, 5 breast, 3 anus, 3 cervix, 3 metastatic carcinomas of unknown primary, 2 stomach, 2 head and neck, 2 liver, 1 thyroid, 1 ovary, 1 pancreas, and 1 esophagus carcinomas, and 8 leukemias/lymphomas.
In the PV negative group, there was a total of 64 non-skin malignancies/carcinomas: 2 bladder, 13 kidney, 8 prostate, 11 lung, 6 colon, 4 breast, 3 endometrial, 2 pancreas, 2 esophagus, 1 metastatic carcinomas of unknown primary, 1 head and neck, 1 cervix, 1 vagina, and 1 thyroid carcinomas, and 8 leukemias/lymphomas.
Only bladder carcinoma, among all cancer subtypes, was significantly associated with PV replication. PV replication and smoking were both independent risk factors. By multivariate analysis, PV replication and smoking incrased the risk of bladder cancer by 11.73 fold (p=0.0013) and 5.62 fold (p=0.0053), respectively.
Conclusions These findings suggest that kidney transplant recipients with PV replication and smoking history are at particular risk to develop bladder carcinomas, and further support the need for long term cancer surveillance in these patients.

550.7

BK virus-associated nephropathy in Scotland: evidence of better transplant survival but variation in incidence, management and outcome between renal units

Michaela Petrie[1], Colin Geddes[2], David Walbaum[3], Nicola Joss[6], Andrew Henderson[4], Annette Alfonzo[5], Lorna Henderson[1].
[1]Renal and Transplant Unit, Edinburgh Royal Infirmary, Edinburgh, United Kingdom; [2]Renal and Transplant Unit, Queen Elizabeth University Hospital, Glasgow, United Kingdom; [3]Renal Unit, Aberdeen Royal Infirmary, Aberdeen, United Kingdom; [4]Renal Unit, Ninewells Hospital, Dundee, United Kingdom; [5]Renal Unit, Victoria Hospital, Kirkaldy, United Kingdom; [6]Renal Unit, Raigmore Hospital, Inverness, United Kingdom.

Introduction: BK virus associated nephropathy (BKVAN) is a significant cause of renal transplant graft loss. The benefit of screening and optimum management once diagnosis is confirmed remains unclear. The study aim was to assess the incidence, management and outcome of BKVAN in a national cohort, looking for variation and potential improvement in practice.
Methods: All kidney or simultaneous kidney/pancreas recipients transplanted in Scotland between 1/1/2009 and 31/12/2013 (n=1044) were identified. Scotland has two transplanting units but six renal units providing follow-up, all of whom contributed complete data. Details of biopsy-proven BKVAN cases diagnosed up to 21/12/15 were collected. All patients had a minimum two years post-transplant follow-up.
Results and Discussion: Of 1044 patients transplanted, 49 (4.7%) developed BKVAN at median time from transplant of 398 days (inter-quartile range (IQR) 122-587, range 30-1839 days). The incidence varied by unit from 1.4% (the only unit screening for BK viraemia) to 8.5% (p=0.09) and between patients transplanted in the West of Scotland (3.4%) versus East of Scotland (6.3%) (p=0.06). There were no differences between units in immunosuppression regimen or patient characteristics. All BKVAN cases had immunosuppression reduced and 27/49 (55%) patients were prescribed "anti-viral" medicines with no observable benefit versus immunosuppression reduction alone. Six patients (12%) suffered transplant loss secondary to BKVAN (no transplants lost to rejection) with median time to failure of 322 days (IQR 197-377, range 20-1612 days). The remainder had stable transplant function with median loss of 1 ml/min in eGFR (IQR -6 - +4.5, range -31 - +26 ml/min) by two years since diagnosis (figure 1).

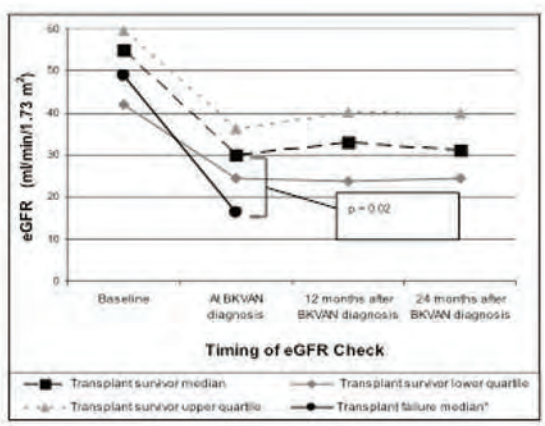

Figure 1. Change in eGFR at BKVAN diagnosis until 2 years follow-up (* only 1 patient in the graft failure group had graft survival beyond 11 months)

The BKVAN-associated transplant failure rate varies by unit from 0 - 25% (p=0.07). The median BK viral level at diagnosis was 171,325

copies/ml (IQR 135,000-1,120,663) for transplant failure cases compared to 100,000 copies/ml (IQR 33,643-599,338) for those with ongoing transplant survival (p=0.006). Greater degree of fibrosis and atrophy on biopsy (PyVAN-C)[1] was associated with greater risk of transplant failure (p=0.01) but patients with lesser fibrosis/atrophy (PyVAN-A and B) had better graft survival than previously published outcome data[1].

Conclusion: BKVAN affects almost 1 in 20 patients in this national cohort, but the difference in incidence and outcome between units warrants further assessment, particularly of BK viraemia screening practice and potential differences in immunosuppression burden. Routine prescription of "anti-viral" drugs did not appear to offer benefit over immunosuppression reduction alone in this observational study. In the absence of severe tubular atrophy or fibrosis on biopsy, BKVAN outcome was better than previously described[1].

High numbers of intragraft blood dendritic cell antigen-1 (BDCA-1)-positive myeloid dendritic cells during BK polyomavirus–associated nephropathy

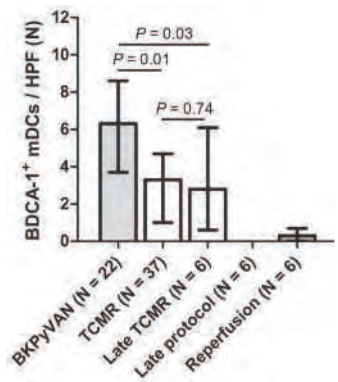
[1]Academic Medical Center, Amsterdam, Netherlands; [2]Emma Children's Hospital, Academic Medical Center, Amsterdam, Netherlands; [3]Radboud University Nijmegen Medical Center, Nijmegen, Netherlands.

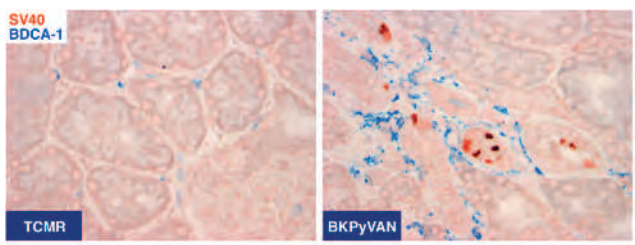
Introduction: Although both polyomavirus infection and T cell–mediated rejection (TCMR) are characterized by tubulointerstitial inflammation in the renal allograft, these conditions are treated with opposing therapeutic regimens. The aim of our study was to gain more insight into the differences between antiviral and alloimmune responses.

Materials and Methods: We performed a case-control study, in which we immunophenotyped the inflammatory infiltrates in renal biopsy specimens with BK polyomavirus-associated nephropathy (BKPyVAN) and specimens with TCMR (T cells, B cells, plasma cells, type II and total macrophages and mature, plasmacytoid and DC-SIGN$^+$ and BDCA-1$^+$ myeloid dendritic cells).

Results and Discussion: Compared with TCMR, BKPyVAN was diagnosed later after transplantation; therefore, BKPyVAN specimens showed more signs of chronic damage than TCMR specimens showed. However, TCMR and BKPyVAN specimens had comparable levels of tubulointerstitial inflammation. Adjustment for confounders in various multivariable models revealed more blood dendritic cell antigen-1$^+$ (BDCA-1$^+$) myeloid dendritic cells (mDCs) present during BKPyVAN (adjusted odds ratio, 2.31; 95% confidence interval, 1.03 to 5.16; P=0.04) than during TCMR.



Double immunostaining for SV40 and BDCA-1 showed that, during BKPyVAN, BDCA-1$^+$ mDCs were localized in proximity to the polyomavirus–infected tubular epithelial cells.



We ensured that time of biopsy after transplantation was not a confounding factor by including additional specimens with late TCMR

and protocol biopsy specimens matched for biopsy time. These additional specimens showed amounts of BDCA-1$^+$ mDCs comparable with those in the early TCMR specimens.
Conclusion: These results suggest that BDCA-1$^+$ mDCs, known to be involved in the antiviral immune response during various viral infections, have a pivotal role during BKPyVAN infection in the renal allograft.

Outcome after Eculizumab therapy to prevent recurrence of atypical hemolytic uremic syndrome: experience in twelve renal transplant recipients

Charlene Levi[1], Marion Rabant[1,2], Veronique Fremeaux-Bacchi[2,3], Anne Scemla[1], Julien Zuber[1,2], Christophe Legendre[1,2], Rebecca Sberro-Soussan[1].
[1]Department of Renal Transplantation, Necker Hospital, Paris, France; [2]Universite Paris Descartes, Sorbonne Paris Cité, Paris, France; [3]Department of Immunology, Georges Pompidou European Hospital, Paris, France.

Atypical hemolytic uremic syndrome (aHUS) is a rare disease with a high recurrence rate after kidney transplantation. aHUS is associated with histological lesions of thrombotic microangiopathy that mainly leads to graft loss. The successful use of Eculizumab (Ecu) to prevent or to treat post-transplantation aHUS recurrence has been scarcely reported. In this study, we describe 12 patients who received a renal transplantation for aHUS and who were treated by Ecu for renal transplantation.
Twelve renal transplants recipients with aHUS on their native kidney received Ecu at our center between 2010 and 2015. Ten patients received prophylactic Ecu at day 0. Two were treated at time of recurrence (day 6 and 25). We reviewed clinical, genetic testing and histological data, and posttransplant course. Median follow-up was 24,6 (4,5 – 68,2) months.
Five patients had at least one previous transplantation that failed secondary to recurrent aHUS. A genetic mutation was identified in eleven patients (H factor (4) ; I factor (3), CFH-CFHR1 hybrid gene (1) ; C3 (1), CFHR1 deletion and anti-H-factor antibody (2)). No patient experienced biological thrombotic microangiopathy (TMA) recurrence under treatment. We found transient histological lesions in the 2 patients with later Ecu introduction. One patient lost his graft of recurrence after discontinuation of eculizumab for an infectious complication. Three antibody mediated rejections (AMR) occurred during treatment including one associated with histologic TMA lesions. One patient, with aHUs on his native kidneys experienced a C3 glomerulonephritis.
These data confirm that Ecu is highly effective to prevent post-transplantation aHUS recurrence, with a good renal function. However, Ecu doesn’t prevent AMR. The best treatment duration remains to be defined.

Influence of pancreas import and cold ischemia on outcomes following pancreas transplantation

Robert Stratta[1], Jeffrey Rogers[1], Alan Farney[1], Giuseppe Orlando[1], Hany El-Hennawy[1], Muhammad Khan[1], Amber Reeves-Daniel[2], Amudha Palanisamy[2], William Doares[3], Scott Kaczmorski[3].
[1]Surgery, Wake Forest, Winston-Salem, NC, United States; [2]Internal Medicine, Wake Forest, Winston-Salem, NC, United States; [3]Pharmacy, Wake Forest, Winston-Salem, NC, United States.

Introduction: New changes in pancreas transplant (PT) allocation in the US may improve organ sharing but increase cold ischemia time (CIT).
Methods: We performed a single center, retrospective study of 202 consecutive PTs in 192 patients and analyzed outcomes according to donor site of origin and CIT. Nearly all pancreata were preserved with UW solution and PT was performed with portal-enteric drainage. All patients received either rATG or alemtuzumab induction with tacrolimus, MMF, and tapered steroids.
Results: From 11/01 to 3/13, we performed 162 simultaneous kidney-PTs (SKPT) and 40 solitary PTs; 160 were local and 42 were import organs. Solitary PT recipients were more likely to receive an import organ (47% solitary vs 14% SKPT, p<0.001). 37 PTs were performed with pancreas CITs ≥20 hours (mean CIT 21.8 hours) whereas the remaining 165 PTs had CITs <20 hours (mean CIT 14.9 hours, p<0.001). There were no other differences between the study groups except that import organs came from younger donors (mean import donor age 23 vs local 27 yrs, p=0.04) with longer pancreas CITs (mean import 17.3 vs local 15.6 hrs, p=0.02). With a mean follow-up of 7 years, actual patient survival (78.4% ≥20 vs 85.8% <20, p=0.31), kidney (51.5% ≥20 vs 78.3% <20, p=0.004) and pancreas graft (PG, 45.9% ≥20 vs 64.2% <20, p=0.04) survival rates were inferior in PTs with prolonged CITs. Death-censored kidney and PG survival rates were 63% ≥20 vs 86.3% <20 and 51.5% ≥20 vs 75% <20 (both p=0.01), respectively. The early (3 month) relaparotomy rate was 56.8% ≥20 vs 32.7% <20 (p=0.008) including an early PT thrombosis rate of 13.5% ≥20 vs 6.7% <20 (RR=2.0, p=0.18). One- and 5-year actuarial kidney graft (import 95%/83% vs local 97%/80%), PG (import 83%/58% vs local 87%/72%), and patient survival (import 98%/89% vs local 97%/92%, all p=NS) rates were comparable between recipients of import and local organs. PG survival was significantly worse in SKPT recipients from import donors (1- and 5-year PG survival for imports 78%/45% vs local 87%/73%, p=0.013) and was related to longer CIT. Technical and non-technical causes of PG failure were similar with import and local donors.
Conclusions: Prolonged pancreas CIT is associated with inferior graft survival rates. We observed that PG survival was inferior in SKPT recipients from import donors despite similar causes of PG loss with import and local organs. Strategies to decrease CIT should be deployed for improving utilization and outcomes.

551.2

Why are pancreas transplants declining in the united states in the past decade?

Robert Stratta[1], Angelika Gruessner[2], Jon Odorico[3], Jonathan Fridell[4], Rainer Gruessner[2].
[1]Surgery, Wake Forest, Winston-Salem, NC, United States; [2]Surgery, SUNY Upstate, Syracuse, NY, United States; [3]Surgery, University of Wisconsin, Madison, WI, United States; [4]Surgery, Indiana University, Indianapolis, IN, United States.

In the past decade, the annual number of pancreas transplants (PTxs) in the US has steadily declined coincident with increasing numbers of PTxs performed outside of the US.
Methods: We retrospectively reviewed data from the International Pancreas Transplant Registry (IPTR) to identify and track trends pursuant to the scope of PTx in the US.
Results: As of 12/14, >48,000 PTxs were reported to the IPTR including >29,000 from the US. The total annual number of US PTxs steadily increased until 2004 (peaking at 1484) but has since declined substantially in the past decade with only 954 PTxs performed in 2014, which is the lowest total since 1994. Since 2004, the overall number of simultaneous pancreas-kidney (SPK) transplants declined by 10% whereas decreases in PTx after kidney (PAK) and PTxs alone (PTA) were 55% and 34%, respectively. Coincident with the 35% decrease in overall PTx activity in the US, fewer patients are being added to the waiting list, waiting times have increased, and wait list mortality for SPK transplant candidates is 10%. Paradoxically, these changes occurred in the setting of improvements in graft and patient survival outcomes and transplanting higher risk patients. PTx is now associated with an extremely low mortality rate, ranging from 3-4% at 1 year to <6% at 3 years in all 3 PTx categories. At 3 years, graft survival (insulin-free) rates are 83% for SPK, 76% for PAK, and 65% for PTA recipients. The number of active US PTx centers has decreased from 132 to 114; 11 centers currently perform ≥20 PTxs per year and nearly half perform <5 PTxs annually. Only 50% of centers perform PAK and 25% PTAs. 14 centers in North America are currently certified for PTx fellowship training (minimum of 20 PTxs/year required). This national trend in diminishing numbers of PTxs is disturbing and related to a number of factors including lack of a primary referral source and acceptance by the diabetes care community, changing donor and recipient demographics, and increasing risk aversion because of regulatory scrutiny.
Conclusions: Given that the incidence of end stage renal disease secondary to diabetes remains high, a national initiative is needed to "re-invigorate" SPK and PAK transplants as preferred options for appropriately selected uremic patients taking insulin irrespective of C-peptide levels or "type" of diabetes. Moreover, many patients may benefit from PTA because all categories of PTx are not only life-enhancing but life-extending procedures.

Introduction: Simultaneous Pancreas Kidney transplantation (SPK) or Pancreas Transplantation after Kidney (PAK) are the only curative treatment options for patients with type 1 diabetes and impaired renal function. Severe diabetic complications such as nephropathy, retinopathy, neuropathy and angiopathy can be avoided by pancreas transplantation. According to the existing allocation system in the Eurotransplant area only organs from donors age <50 years and BMI <30 could be allocated for transplantation. While the waitlists are increasing, there is a decrease of organs meeting the currently accepted criteria.
Materials and Methods: The aim of this study was to extend the organ pool by using organs with extended donor criteria either from donors age 50 to 60 or with a BMI 30 to 34. For the study a new allocation system was implemented. All patients on the waitlist for primary SPK or PAK were evaluated. The study was conducted as a prospective, multicentre, single-blinded, non-randomized, two-arm trial. The primary endpoint was insulin-free pancreas allograft survival rate after 3 months. Rejection episodes, kidney function and quality of life were secondary endpoints. A patient who agreed to participate in the trial and received an extended pancreas allograft (EDC) was included as study group patient. A patient who received a normal criteria organ was followed-up as a control-group patient. Patients remained blinded during the study period and received standard immunosuppressive treatment. Follow-up was 1 year.
Results: A total of 79 patients were included in 12 German centres from July 2011 to April 2015. 18 received an EDC organ and 61 a standard criteria organ. Recipient demographics were similar in both groups.

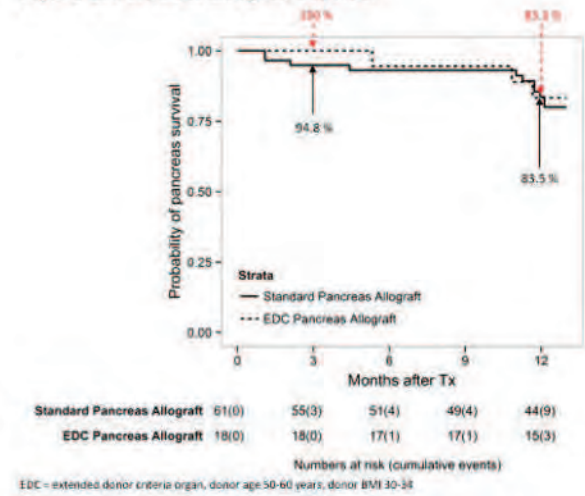
Table 1: Patient (recipient) demographics

	Standard group	EDC group	p-value
Number of patients (male / female in %)	61 (67.2 / 32.8)	18 (66.7 / 33.3)	0.965
Age [years ± SD]	43.7 ± 9	47.7 ± 8	0.085
Body weight [kg ± SD]	73.5 ± 12	76.9 ± 15	0.316
Time of diabetes [years ± SD]	**28.3 ± 9**	**32.3 ± 9**	0.103
Daily dose of insulin [IU ± SD]	33 ± 19	33 ± 21	0.940
Medical History [no. of patients in %]			
Nephropathy	100	94.4	0.228
Retinopathy	77.0	77.8	1.000
Neuropathy	55.7	66.7	0.409
Coronary heart disease	24.6	27.8	0.785
Peripheral arterial disease	18.0	11.8	0.540
Chronical dialysis [no. of patients in %]	90.2	88.9	0.875
Time on dialysis [years ± SD]	**2.8 ± 2**	**3.2 ± 3**	0.555
Type of dialysis [haemodialysis / CAPD in %]	83.6 / 16.4	81.2 / 18.7	0.823
Waiting time for transplantation [month ± SD]	**20.5 ± 16**	**18.7 ± 13**	0.895

EDC = extended donor criteria organ, donor age 50-60 years, donor BMI 30-34

Mean donor age was 51.4 ± 5 years in the EDC group vs. 31.7 ± 12 in the control group. Insulin-free graft survival was 83.3% for EDC organs vs. 77.6% for standard organs (p=0,75) after 3 months. Pancreas allograft survival was 100% in the EDC group after 3 months (p=0.03) and 83.3% after 1 year vs. 94.8% and 83.5% in the standard group.

Figure 1: Pancreas allograft survival



EDC = extended donor criteria organ, donor age 50-60 years, donor BMI 30-34

Kidney allograft survival was 94.4% in both groups after 1 year. Rejection episodes or quality of life did not differ between groups.
Conclusions: The EXPAND study shows for the first time in a prospective trial that extended pancreas criteria organs can be used with similar outcome. Therefore, the organ shortage can be reduced, as well as waiting times, by allocating carefully selected EDC organs without additional risk. This study substantiates the full implementation of EDC organs in the Eurotransplant area allocation system.
We would like to thank the responsible staff within Eurotransplant and the DSO for contribution to establishment of the rescue allocation system. We would also like to thank the supportive personnel at each site for contribution. Partial funding was provided by a research grant from Novartis and Astellas

551.4

Preservation of human pancreas with hypothermic machine perfusion

Diego Cantarovich[2], Karine Renaudin[1], Julien Branchereau[2].
[1]Pathology, Nantes University Hospital, Nantes, France; [2]ITUN, Institut de Transplantation, Urologie et Nephrologie, Nantes University Hospital, Nantes, France.

Pancreas transplantation is one of the best treatment options for insulin-dependent diabetes. The pancreas is high vulnerable to ischemic damage and ischemic-reperfusion injury. Graft thrombosis is the consequence of this process and accounts for the majority of graft losses. Cold storage is the mainstay preservation method applied for pancreas preservation.
Hypothermic machine perfusion (HMP) has proved its value in preserving kidney transplants. Whether HMP could prevent ischemic reperfusion damage in human pancreas transplants and therefore decrese graft failure is not known. The first pancreas pulsatile perfusion was done in canine pancreas autografts in the eighties; this was a high pressure perfusion and induced severe edema. Today, there is no clinical study designed to investigate the impact of HMP on human pancreas allografts.
In our pre-clinical study, 7 human pancreas from deceased heart beating donors rejected for clinical transplantation because of advanced age and/or other comorbidities, were used and perfused with the Wave (Waters Medical Systems) perfusion machine. Pancreas were prepared identically as for human transplantation of vascularized organs. The splenic artery and superior mesenteric artery were anastomosed to an iliac artery division. We therefore perfused all pancreas with a pressure of 25 mmHg. Tissue biopsies were collected at baseline and after 6, 12 and 24 hours of HMP.
Histology did not demonstrate edema after 6, 12 and 24 hours of HMP. We conclude that human pancreas preservation with a pulsatile machine perfusion is feasible and does not induce edema after 24 hours or perfusion under low pressure.

551.5

A proposal for new donor criteria for pancreas transplantation based on postoperative insulin secretion

Taihei Ito[1], Takashi Kenmochi[1], Minoru Oshima[1], Naohiro Aida[1], Atsushi Suzuki[2], Mamoru Kusaka[3], Hitomi Sasaki[3], Midori Hasegawa[4], Hisahiro Matsubara[5], Kiyotaka Hoshinaga[3].
[1]Department of Organ Transplant Surgery, Fujita Health University, School of Medicine, Aichi, Japan; [2]Division of Endocrinology and Metabolism, Fujita Health University, School of Medicine, Aichi, Japan; [3]Department of Urology, Fujita Health University, School of Medicine, Aichi, Japan; [4]Department of Nephrology, Fujita Health University, School of Medicine, Aichi, Japan; [5]Department of Frontier Surgery, Chiba University, Graduate School of Medicine, Chiba, Japan.

Background: Under a revision to the law in 2010, the number of pancreas transplantations from brain dead donors has been increasing in Japan. Although about 70% of donors have been defined as marginal according to Kapur's criteria, there has been no significant difference between marginal donors and non-marginal donors in terms of pancreatic graft survival in Japan. Moreover, the major criteria for brain dead donors of pancreas transplantation in Europe and the United States do not refer to HbA1c which must be measured in our country. Therefore, we establish here a new donor criteria for pancreas transplantation in Japan.
Methods: 36 recipients who received pancreas transplantation in our facility and who underwent a Glucagon tolerance test 1 month after transplantation were analyzed. These recipients were divided into the two groups according to the levels of ΔCPR (CPR6min-CPR0min, ng/ml) of a Glucagon tolerance test which was used to be an index of insulin secretion; Well function group (WF, ΔCPR ≧1.0, n=31) and Poor function group (PF, ΔCPR ＜1.0, n=4). Donor's background including age, cause of death, presence of cardiopulmonary arrest episode, BMI, HbA1c, TIT, days of ICU stay, dose of catecholamine and s-Cre level on admission and preoperatively, were compared between the two groups.
Results: 13 out of 32 (40.6%) of the donors in the WF died of cerebrovascular accidents (CVA), while all 4 donors (100%) in the PF died of cerebrovascular accidents with significant difference ($P<0.05$). There was a significant difference in terms of preoperative s-Cre level between the WF (0.82±0.62mg/dl) and the PF (2.78±3.03) ($P<0.01$). ΔCPR was significantly lower when donor age was over 50 (2.02±1.36) compared to when donor age was under 49 (3.06±1.40) ($P<0.05$). ΔCPR was also significantly lower when donor's HbA1c was over 5.6% (1.37±0.86) compared to when donor's HbA1c was under 5.5% (3.03±1.38) ($P<0.01$).
According to these results, we are proposing new donor criteria for pancreas transplantation in our country: 1. Donor's age≧50, 2. HbA1c≧5.6%, 3. Brain death of CVA, 4. Preoperative s-Cre≧1.5mg/dl.⊿CPR was 0.91±0.22 in the donors with 3 or 4 factors, 2.15±0.76 with 2 factors, 3.34±1.52 with single factor and 3.35±1.40 without any factor. When donors had multiple marginal factors, ?CPR was significant lower than with only one factor or without any factors. Two recipients out of 4 (50%) transplanted with the pancreas from the donors with 3 factors showed the low levels of⊿CPR(<1.0) The recipient transplanted with the pancreas from the donor with 4 factors 1/1 (100%) failed to achieve an insulin independency despite of positive setum CPR.
Conclusion: These results suggest that our new donor criteria for pancreas transplantation should be reasonable in terms of postoperative insulin secretion of pancreatic graft. Using these criteria, named Fujita Univ. criteria, we have to be careful for the indication for pancreas transplantation in terms of postoperative insulin secretion when the donor has more than 3 factors.

Total pancreatectomy with islet autotransplantation improves quality of life allowing for the resolution of the intractable pain with good glucose control in properly selected patients with chronic pancreatitis

Julia Solomina[1], Sabrina Matosz[1], Andres Gelrud[2], Karolina Golab[1], Celeste Thomas[2], Zehra Tekin[1], Louis H.Philipson[2], Lindsay Schenck[1], W. James Chon[2], Justyna Golebiewska[3], Sabarinathan Ramachandran[1], Martin Tibudan[1], Maciej Sledzinski[4], Jeffrey B.Matthews[1], Piotr Witkowski[1].
[1]Surgery, University of Chicago, Chicago, United States; [2]Medicine, University of Chicago, Chicago, United States; [3]Nephrology, Transplantology and Internal Medicine, Medical University of Gdańsk, Gdańsk, Poland; [4]General Surgery, Endocrinology and Transplantology, Medical University of Gdańsk, Gdańsk, Poland.

Background: There is a group of patients with chronic pancreatitis (CP) who develop malnutrition, constant pain with narcotics dependency, and extremely poor quality of life[1]. We evaluated the outcomes of total pancreatectomy with islet autotransplantation (TPIAT) in our recent cohort of such patients.
Material and Method: Total pancreatectomy with islet autotransplantation was offered to patients with intractable pain who exhausted all medical and surgical intervention. Most of the patients 7 of 13 (54%) were diagnosed with a genetic mutation (SPINK1, PRSS1, CFTR) driving chronic inflammation and progression of symptoms.
Results: Thirteen patients suffered from CP for 9.5 years (3-39). Over that time, they had multiple endoscopic or surgical procedures- 4 (2-15), with an average of 4 (1-6) episodes of acute pancreatitis per year. They experienced severe chronic pain- 9.5 (5-10) in Visual Analogue Score (VAS), which led to chronic narcotic medication use in 12 (92%) patients for 7.5 (1-110) months prior to surgery in mount of 52 (5-240) morphine equivalent doses (MED). However, narcotics allowed only for partial relief of pain to VAS of 4.5 (2-5). Three patients (23%) require central line for pain control or parental nutrition. Most patients, 9 (70%) required pancreatic enzyme supplementation and one of them insulin support. Patients received on average 211,000 (76,600-379,000) islet equivalents (IEQ) infused into their portal vein. Wound infection was recorded in 3 (23%) patients and 8 (61%) patients developed incisional hernia requiring repair.
On day 75 follow up, 6 of 13 (46%) patients were insulin free with A1c<6.5. Remaining individuals presented also good glucose control with insulin (1-18 U/day, or 0.07-0.17U/kg of body mass), and median A1c 6 (5.9-7.3). At the same time, 5 patients were able to completely wean off narcotics. Remaining individuals required lower dose- 37.5 (10-130) MED. Abdominal pain due to an incisional hernia was recorded in 4 out of 8. All patients denied diarrhea or steatorrhea after adjusted pancreatic enzyme supplementation. At 1-year evaluation, 4 of 7 (57%) patients remained insulin free with A1c 6.25 (5.6-6.5) and the rest had continuously good glucose control with A1c of 7.3 (6.3-7.5). Patient BMI declined from median 28 (20-39) prior to procedure to 24.4 (range 18.6-33.7) on day 75, and 22.7 (range 19.9 -28.4) on 1-year follow-up.
All patients expressed overall improvement in pain control and quality of life. Prior the procedure, physical health (dimension A) based on SF36 questionnaire was compromised to 24.6% (17-46.3), which improved to 33.1% (19.5-56.2) on day 75 and 44.3% on 1 year. Mental health (dimension B) was 44.3 % (17.5-60.8) and improved to 51.2% (32.7-65.8) on day 75 and 1 year to 52.8% (31.2-56.8).
Conclusion: TPIAT provides improved quality of life with pain resolution and good glucose control in selected patients suffering from chronic pancreatitis and intractable pain.

Validation of a new North American islet donor score for donor pancreas selection and successful islet isolation

Sabrina Matosz[1], Julia Solomina[1], Ling-jia Wang[4], Tatsuya Kin[5], Zehra Tekin[1], Karolina Golab[1], Maciej Sledzinski[2], Justyna Golebiewska[3], Omid Savari[1], Piotr Witkowski[1].
[1]Surgery, University of Chicago, Chicago, United States; [2]General Surgery, Endocrinology and Transplantation, Medical University of Gdansk, Gdansk, Poland; [3]Nephrology, Transplantology and Internal Medicine, Medical University of Gdansk, Gdansk, Poland; [4]Surgery, Cell Isolation Program, University of Illinois at Chicago, Chicago, United States; [5]Clinical Islet Transplant Program, University of Alberta and Alberta Health Services Edmonton, Edmonton, Canada.

Background: The selection of the optimal pancreas donor is one of the key factors determining the ultimate outcome of the human islet isolation. We developed and validated a new pancreas scoring system based on data from the multiple islet centers.
Method: We designed and conducted a retrospective multicenter analysis of data from eleven islet isolation centers in North America. The data set from 1,056 deceased donors was used for development of scoring system to predict islet isolation success (defined as post-purification islet yield >400,000 islet equivalents). Then we created donor-scoring systems (points from 0 to 100) consisting main donor variables influencing outcome. We plotted receiver operating characteristic (ROC) curve for each scoring system. We calculated area under the curve (AUC) (also referred as c-index) to assess the ability of scoring system to predict successful islet isolation. Finally, we identified a scoring system having the highest AUC and named it North American Islet Donor Score (NAIDS).

Table 1. North American Islet Donor Score

BSA	X<1.54	1.54≤X<1.82	1.82≤X<2	2≤X<2.18	2.18≤X
	0	5	10	20	25
Vasopressor		more than 2	double	single	none
		0	3	10	15
BMI	X<20.1	20.1≤X<28.1	28.1≤X<32.5	32.5≤X<52.0	52.0≤X
	0	2	7	10	0
Unfavorable factors	Age (y) > 20 : +75 C/T (h) ≤ 2 : +17 Body weight (kg) < 55 HbA1c (%) > 6.5	ALT (U/L) > 1070 AST (U/L) > 580 BUN (mg/dL) > 80 Amylase (U/L) > 1600		At least one	None
				0	35
Favorable factors	Body weight (kg) > 120 Own team procurement 130<Na (mEq/L)<160 Peak glucose (mg/dl) <478	None	One	Two	More than 2
		0	2	7	15

Next, we tested the validity of NAIDS on the validation cohorts in the University of Alberta, Edmonton and University of Chicago.
Results: Donor body surface area, body mass index and use of vasopressors were recognized as main donor variables included into the NAIDS. There were also two supplemental composite factors-favorable (based on serum Na and glucose, also body weight as well as own organ procuring team), and unfavorable (based on age, cold ischemia time, body weight, serum A1c, liver enzymes, BUN and amylase).
The c-index in the development cohort was as high as 0.70 [95% confidence interval 0.70 - 0.76] indicating high correlation of the score with the outcome of islet isolation. The success rate increased proportionally as NAID score increased, from 6.8% success in NAIDS < 50 points to 53.7% success in NAID score ≥ 80 points. Similar characteristics of NAID score were observed in the validation cohorts from Edmonton N=179 and University of Chicago N=70 (c-index 0.73 [95% confidence interval 0.637 - 0.788] and 0.66 [95% confidence interval 0.526-0.793] p>0.05, respectively. New NAIDS had better ability to predict the outcome of islet isolation also at University of Chicago than the previously used scoring system[1], for which c-index was 0.589 [95% confidence 0.448- 0.749].
Conclusion: Newly developed pancreas donor scoring system (NAIDS) allows for good correlation of the score with the outcome of the islet isolation; the higher score, the higher islet isolation success rate. NAID score might be a useful tool for donor pancreas selection in

the clinical and research practice allowing adjusting donor selection strategy to the center logistic and financial resources.

551.8

Is superior mesenteric artery so indispensable for pancreas transplant?

Alexey Pinchuk, Ilya Dmitriev, Yuri Anisimov, Nonna Shmarina, Roman Storozhev, Aslan Balkarov.
Kidney and Pancreas Transplantation, Sklifosovsky Clinical and Research Institute for Emergency Medicine, Moscow, Russian Federation.

Introduction: The critical deficiency of donor organs as a result of both strict criteria for potential donor selection and anatomic features of pancreas graft (PG) blood supply limits the widespread application of pancreas transplantation (PT). During the multiorgan grafts removal we have quite often to sacrifice the superior mesenteric artery (SMA) in favor of additional hepatic artery. In such cases the implied critical PG ischemia significantly limits its implementation. The evaluation of isolated splenic artery supply (ISAS) sufficiency of the PG had defined the purpose of this study.

Materials and Methods: From January 2008 to June 2015, 47 patients had undergone PT. The gender distribution was: 23 women (48.9%) and 24 men (51.1%). The age of the patients ranged from 25 to 51 years and averaged 35.7 ±6.36 years. 18 (38.3%) patients underwent simultaneous pancreas-kidney transplantation (SPKT) with intra-abdominal localization of PG and the formation of the duodenojejunal anastomosis (DJA), 28 (59.6%) - retroperitoneal SPKT with the formation of interduodenal anastomosis (IDA), 1 (2.1%) – pancreas after kidney (PAK) transplantation with intra-abdominal PG localization and DJA formation. In 45 cases (95.7%) we performed Y-graft arterial reconstruction, in 7 cases (15,6 %) of which the total thrombosis of the SMA developed in the early postoperative period. In 2 cases (4,3%) we performed ISAS PT as a result of the SMA cutting off during organs' explantation

Results: In 9 patients with ISAS of PG we didn't observe any ischemic pancreatic head and/or graft's duodenum necrosis. Furthermore, there were no significant differences in the PG function: □-amylase – 139 vs 146 U/l (p=0,8), pancreatic amylase – 131 vs 124 U/l (p=0.8), lipase – 152 vs 127 U/l (p=0,7), HbA1c 4.8 vs 5.4 % (p=0,27), intact insulin – 24 vs 21 mcIU/ml (p=0,84), C-peptide 5.8 vs 3.4 ng/ml (p=0,052). In addition, statistically-significant differences in glucose metabolism based on the survey results using temperature gradient measuring device and in grafts' blood supply according to CT-perfusion haven't been detected.

Conclusion: PT using grafts with ISAS is reasonable due to well-developed arterial collaterals between splenic and superior mesenteric arteries systems. The viability of the surgical technique with ISAS will allow to expand the criteria for pancreas explantation and increase the number of transplantations.

551.9

Total pancreatectomy with autologous islet transplantation for chronic pancreatitis: considerations for early operation

Joshua Jolissaint[1], Linda W.Langman[1], Claire L.DeBolt[1], Allison N.Martin[1], Andrew Y.Wang[2], Daniel S.Strand[2], Victor M.Zaydfudim[1], Reid Adams[1], KennethL. Brayman[1].
[1]Department of Surgery, The University of Virginia Health System, Charlottesville, VA, United States; [2]Division of Gastroenterology and Hepatology, The University of Virginia Health System, Charlottesville, VA, United States.

Introduction: Chronic pancreatitis (CP) places an immense burden on healthcare systems and can become a debilitating condition for those afflicted. Pain is multifactorial and often refractory to medical and endoscopic treatment. Total pancreatectomy (TP) is an attractive therapy for patients with severe CP and autologous islet transplantation has been employed to counteract the consequent "brittle diabetes," with the loss of glucagon-dependent counter-regulation. Factors leading to insulin-independence after TPIAT and optimal timing for operative intervention both are poorly understood.
Materials and Methods: Institutional Review Board approval was obtained for this single-institution, retrospective and prospective cohort case series utilizing data from the electronic medical record and a telephone-based questionnaire. Islets were isolated at a Current Good Manufacturing (cGMP) islet isolation facility using the standard Ricordi method. Pancreas transport solution and final islet preparation were cultured and release criteria prior to transplantation include a negative endotoxin release assay and gram stain of the final islet preparation. Islets were loaded into transplant bags, heparinized, and infused via portal venotomy.
Results and Discussion: 29 patients have undergone TPIAT at this institution. Mean age was 41 years, median duration of CP was 4.3 years, and mean islet equivalent (IEQ) was 189,793. 27 patients who received TPIAT were >6 months post-transplant and included in data analysis. 19/27 were successfully contacted. 7/27 (26%) are insulin-independent an average of 3.53 years post-transplantation and 5/7 are female. Pain rating based on verbal analog scale was reduced from an average of 9 to 4.6 (p<.001) and 11/19 are narcotic-free. Insulin-independent patients had higher C-peptide levels at their most recent follow up (p<0.05) and trended toward longer continuity of follow up, and shorter duration of CP, however their IEQ and IEQ/kg were comparable (Table 1). 6 patients grew bacterial contaminants in the final islet preparation. These patients had a longer duration of CP and lower islet yield compared to both the cohort and those who became insulin-independent, and currently require insulin therapy (Table 2).

Table 1.

Variable	Insulin-Independent (n=7)	Insulin-Dependent (n=12)
Patients with diabetes prior to transplant+, n (%)	3 (43%)	6 (50%)
C-peptide at time of discharge (ng/mL)	1.1	1.0
C-peptide at most recent follow-up (ng/mL)	4.0*	1.2*
Mean follow-up time (range)	2.3 years	0.82 years
Median duration of CP (years)	3.2	4.0
IEQ	202,286	198,583
IEQ/kg body weight	2,958	2,711
BMI	1.8	1.9

+Diabetes was defined as: HbA1c ≥ 6.5%, elevated glucose tolerance test, or use of pharmacological hypoglycemic agents
*p < 0.05

Conclusions: At 27%, our rate of insulin-independence is comparable to other series[1]-[3]. Patients who achieved insulin-independence did not have significantly higher islet yields compared to those who require insulin. Additionally, patients with bacterial contamination in the final islet preparation have a longer duration of CP with a lower islet yield, likely indicative of multiple interventions over several years with resultant bacterial colonization, pancreatic inflammation, and reduced islet cell mass. This study suggests that patients with severe CP might benefit from early TPIAT, potentially reducing bacterial colonization, maximize islet yield, and improve graft success rates.

Table 2.

Variable	Non-contaminated (n=21)	Insulin Independent (n=7)	Bacterial Growth (n=6)
Median duration of CP (range)	3.875 (0.2-42.4 years)	3.2 years (0.2-42.4 years)	6.3 years (2.5-16 years)
IEQ	208,143*	202,286*	120,000*+
IEQ/kg body weight	3,024*	2,958*	1,534*+

*p<0.05
+p=.068

552.1

A new era for organ donation and transplantation in China

Haibo Wang[1,2].
[1]China Organ Transplant Development Foundation, Shenzhen, People's Republic of China; [2]China Organ Transplant Development Foundation, Beijing, People's Republic of China.

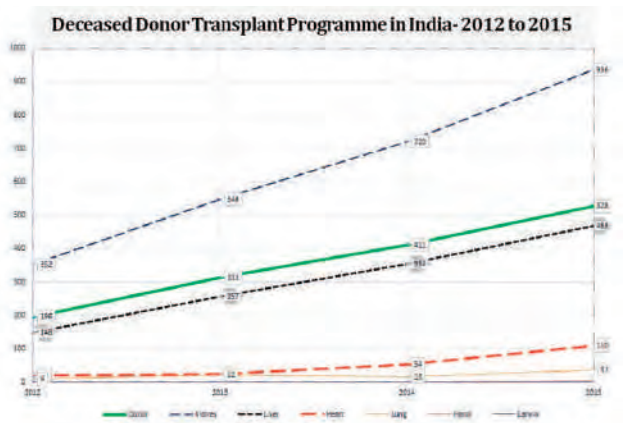
Introduction: In Dec 2014, Dr. Jiefu Huang, the director of the National Organ Donation and Transplantation Committee of China declared the total cessation of the use of death penalty prisoners' organ for transplantation in China, effective on January 1st, 2015. Therefore, the community based organ donation has become the only legitimate source of deceased organ transplantation in China since then. This action marks 2015 as the starting year of a new era for organ donation and transplantation in China. The article aims at providing an overview on the national statistics of the organ donation and transplantation of China in 2015.
Method: China Organ Transplant Response System (COTRS) is the mandatory national organ allocation system, under the authority of National Heath and Family Planning Commission (NHFPC). All of the 131 organ procurement organizations (OPOs) and 169 licensed transplant hospitals were mandated to use COTRS for organ allocation to ensure the fairness and transparency in the process, as well as the traceability of all donated organs requested by the Regulation on Human Organ Transplantation. The data of COTRS was used to generate the statistics of the deceased donors, the characteristics of transplant candidates (liver/kidney) on waitlist, organ allocation and the post-transplant outcomes of China in 2105.
Results: During the year of 2015, 12 154 kidney transplant candidates and 4,076 liver transplant candidates were registered on the waiting list of COTRS, whereas 113 for kidney and 250 for liver died respectively while waiting for transplant. The number of patients remaining on kidney wait list is 22 995 by the end of 2015 and 2,243 for liver. In 2015, there were 2766 deceased organ donation in China, a significant increase of 62.5% compared to the number of community based deceased organ donation in 2014 (1702 cases). Among them, 48.6% were donors of China Category III (Donation after brain death followed by cardiac death). Brain trauma is the most frequent-seen (48.3%) cause of death. The median age of donors is 37.5 years. There were 30.79% of the procured livers and 5.14% of the procured kidneys were shared at national level through COTRS in 2015. The discard rates were 15.2% for liver and 6.5% for kidney. The post-liver transplant survival at 3 months, 6 months and one year were 90.17%,87.62% and 81.85% respectively, which is significantly lower than those of living donor liver transplantation.
Conclusion: China has completely transformed into the community based deceased organ donation and transplantation upon the total cessation on the use of death penalty prisoners' organ for transplantation in 2015. The detailed data of the 2766 altruistic donors was captured and analyzed by COTRS, which signified China's organ transplantation has stepped into a new era in 2015.

552.2

Progress in deceased organ donor transplantation in India

Sunil Shroff[1], Sumana Navin[1], Sujatha Niranjan[1], Pallavi Kumar[1], Lalitha Raghuram[1].
[1]Trustee, MOHAN Foundation, Chennai, India; [2]Kidney Disease, Urology & Transplantation , Madras Medical Mission Hospital, Chennai, India.

Introduction: Organizing a deceased donation programme (DDP) in a developing country like India that has huge regional variations is an administrative and logistic challenge. The first 15 years of the programme saw a slow growth and acceptance but the last five years has seen very encouaging progress.
Material and Methods: Of the 35 Indian States and Union Territories five have been more proactive and helped in the growth of the programme. The central government has recntly rolled out a national programme, and has conducted many consnsus workshops, however it is still in inception and is likely to take a few years to take shape and make an impact. Of all the states the state of Tamil Nadu moved forward and has had an organ sharing network since the year 2000. The state govt. has facilitated in the implementation of the DDP and has implemented procedures to streamline the programme. Similar initiatives were taken by states of Andhra Pradesh, Kerala, Karntaka and Maharastra. MOHAN Foundation an NGO played a key role in four states for establishing the DDP that included Tamil Nadu, Kerala, Rajasthan and Andhra Pradesh. The foundation has actively been undertaking training of transplant coordinators and have trained over 1000 coordinators in the last 6 years.
Results: Since 2012 the number of deceased donors have grown steadily and the donation rate has increased 0.16 in 2012 to 0.5 in 2015 (Fig.1).



In 2012 there were 196 multi organ donors in 2012 and in 2015 there were 528 donors (Fig.2).

Deceased Organ Donation in India - 2015

State	No. of Donors	Kidney	Liver	Heart	Lung	Pancreas	Intestine	Hand	Larynx	Total Organs
Tamil Nadu	155	290	149	51	28	0	1	0	0	519
Kerala	76	132	61	14	2	1	1	4	1	216
Maharashtra	60	106	51	5	0	0	0	0	0	222
Telangana	88	160	92	16	5	0	0	0	0	263
Andhra Pradesh	9	16	7	3	2	0	0	0	0	30
Karnataka	60	91	55	11	0	1	0	0	0	158
Gujarat	3	6	3	0	0	0	0	0	0	9
Madhya Pradesh	3	6	2	1	0	0	0	0	0	9
Uttar Pradesh	4	8	0	0	0	0	0	0	0	8
Delhi-NCR	14	28	14	0	0	0	0	0	0	48
Puducherry	9	16	2	1	0	0	0	0	0	30
Chandigarh	36	69	25	1	0	2	0	0	0	97
Rajasthan	7	14	7	1	0	0	0	0	0	22
Total	528	936	468	110	37	4	2	4	1	1562

Note:
* The statistics projected in the above table is only provisional.
* The statistics for Gujarat, Andhra Pradesh and Delhi-NCR do not reflect all the deceased donations done in the region

The state of Tamil Nadu with the rate of 2.2 per million population (pmp), has almost 4 times the national average of donations. Other states like Kerala, Andhra Pradesh, Karnataka and Maharastra have also seen a rise in donation rate. The trained coordinators have been involved in almnost 50% of the donations happening in the country.
Discussion: The current progress in deceased donation programme in India over the last 5 years has opened a new avenue to overcome organ shortage. The DDP in the State of Tamil Nadu is a role model for the rest of the country. The joint venture of the State Government, transplant hospitals and the Non-Governmental Organizations (NGO) has led to the success of the state's DDP. This Programme has now been adopted by few other states and MOHAN Foundation has partnered with these states in establishing 'Organ Sharing' networks (www.knos.org.in and www.rnos.org)' and helped put procedures in place for its implementation. The placement of trained transplant coordinators has contributed immensely in capacity building and has resulted in increase in the donation rate in the country.
Conclusion: Progres of DDP in India over the last five years has taken care of some of the shortage of organs. All this has been possible due to parternership of the govt. with hospitals and NGO's like MOHAN Foundation. The rate of donation in the last 4 years had increased threefold and this is an encouraging sign for the region.

552.3

The African American journey in organ donation and the methodologies that resulted in movement from the bottom to the top

Clive Callender[1], Naoru Koizumi[2], Patrice Miles[3], J. Keith Melancon[3].
[1]College of Medicine, Howard University, Washington, DC, United States; [2]George Mason University, Arlington, VA, United States; [3]Transplant Institute, George Washington University Hospital, Washington, DC, United States.

Introduction: The shortage of donors is the number one problem in transplantation. In 1982, minorities were more than 50% of the national transplant waiting list, but represented only 15% of the donor population. Previously minorities, especially Blacks, were thought not likely to donate.
Materials and Methods: The methodology was based upon the local grass roots efforts of the D.C. Organ Donor Program (1982-1988) and the Dow Take Initiative Program (1986-1992) focusing on increasing donation rates among African Americans (A.A.) via a mass media campaign. Between 1982 and 1988 in the District of Columbia, A.A. donor card signings increased from 20/month to 750/month and Black donations doubled. A review of the compendium of data including face to face grass roots presentations combined with a nationwide Black donor media campaign was conducted. Gallup Polls in 1985 and 1990 indicated a tripling of Blacks awareness of transplantation and the number of Blacks signing donor cards. Based on these applied successful methodologies, in 1991, a national program was established targeting African American, Hispanic, Asian, and other ethnic groups. A review of the United Network for Organ Sharing (UNOS) database between 1990 and 2010 was accomplished.
Results and Discussion: Total ethnic minority organ donors per million (O.D.M.) increased from 8-10 in 1982 to 35 O.D.M (African American and Latino/Hispanic) in 2002. National minority donor percentages increased from 15% to 28.5% of donors in 2002 (minorities comprised 25% of the USA population in 2000). In 1995, organ donors per million were represented as Whites (34.2), Black (33.1), Hispanic (31.5), Asian (17.9). In 2010, Black organ donors per million totaled 35.36 versus Whites (27.07), Hispanic (25.59) and Asian (14.70). Blacks now represent 17% of the donor population (deceased and living), while representing 13% of the total U.S. population. Based on the data from UNOS, Blacks rank as the number one ethnic group in reference to organ donors per million. Blacks now represent 17% of the donor population (deceased and living), while representing 13% of the total U.S. population.
Conclusion: Based upon the data retrieved from the UNOS in 2010, Blacks were ranked above Whites and other ethnic minority populations as the number one ethnic group of organ donors per million within the U.S. This indicates that when a campaign utilizing successful methodologies such as grass roots face to face presentations and interactions along with media reinforcement is used; donation rates can be increased and sustained. Emphasis on social media with the exclusion of face to face interaction may partially explain the decrease in other ethnic groups. The recommendation to overcome the decrease in ODM in the Latino/Hispanic; White and Asian ethnic groups in the face of the rising organ donor-recipient gap makes revitalization of the face to face grass roots methodology necessary in each of these ethnic populations.

552.4

Center effect on outcome of kidney transplantation from pediatric deceased donor in China

Huanxi Zhang[1], Longshan Liu[1], Liping Chen[2], Chuanhou Sun[2], Haibo Wang[3], Bingyi Shi[2], Changxi Wang[1,4,5].
[1]Organ transplant center, The First Affiliated Hospital of Sun Yat-sen University, Guangzhou, People's Republic of China; [2]Chinese Scientific Registry of Kidney Transplantation, Beijing, People's Republic of China; [3]China Organ Transplant Response System Research Center, Shenzhen, People's Republic of China; [4]Guangdong Provincial Key Laboratory on Organ Donation and Transplant Immunology, Guangzhou, People's Republic of China; [5]Institution of Organ Donation and Transplant Immunology, Sun Yat-sen University, Guangzhou, People's Republic of China.

Introduction: The optimal use of kidneys from pediatric deceased donors remains undetermined in China. Choice of single (SK) versus en bloc (EBK) transplantation was empirically determined in different transplant centers due to lack of standard criteria. This study was designed to demonstrate the transplant outcome of single versus en bloc transplantation from pediatric deceased donors using registry data from Chinese Scientific Registry of Kidney Transplantation (CSRKT).
Subjects and Methods: Registry data (2010-2015) of primary Kidney transplantation from pediatric deceased donors in Chinese Scientific Registry of Kidney Transplantation (CSRKT) was retrospectively analyzed.
Results: There were 772 cases of primary single (n=703) or en bloc (n=69) Kidney transplantation from pediatric deceased donors. They were performed in 74 transplant centers. However, only 12 centers were capable of performing EBK and 34 centers capable of performing kidney transplantation from donors weighted less than 20kg. About 88.1% (680/772) of recipients were over 18 years old. About 71.0% (49/69) of en bloc transplantation was performed in adult. Univariate Cox regression showed that a significant increase in risk of graft loss was identified in EBK group compared with SK group (Hazard ratio, 2.66; 95% confidence interval, 1.41-5.00; P=0.002). There was also increased risk of graft loss in recipients with donor weight of 5-10kg compared with recipients with donor weight of ≥20kg (Hazard ratio, 4.32; 95% confidence interval, 2.00-9.37; P<0.001). Multivariate Cox regression controlling confounding variable such as donor weight and recipient age showed that a significant increase in risk of graft loss was identified in EBK group compared with SK group (Hazard ratio, 2.18; 95% confidence interval, 1.08-4.39; P=0.029). Graft loss rate of en bloc kidney transplant varied among transplant centers from 0 to 100% with a median of 8.0%. Subgroup analysis based on donor weight demonstrated that in 5-10kg subgroup only 10% of EBK recipients (1/10) lost their allograft function while 23.5% of SK recipients (8/34) had their kidney allograft loss at the end of follow up. Graft loss rate of single kidney transplant from donors weighted 5-10kg was also various among transplant centers from 0-100% with a median of 10%. No significant difference was seen in patient survival, incidence of DGF and 1-year post-transplant allograft function between EBK group and SK group.
Discussion and Conclusion: Outcome of pediatric EBK recipients was not as good as SK recipients in terms of graft survival. It could be partly explained by the various outcome in different transplant centers, to which surgical difficulties in EBK in adult and disparity of surgeons' technical skills were attributed. Single kidney transplantation in low-weight recipients from small pediatric deceased donors (weighted 5-10kg) was a good way to expand donor pool. However, it had difficulties in identification of indication, surgical skills as well as peri-operational management. Both EBK and single kidney transplantation from small pediatric deceased donors should be performed in experienced transplant centers.

552.5

Expanding the donor pool through intensive care treatment to facilitate organ donation: results of a Spanish multicenter study

Beatriz Dominguez-Gill[1], Elisabeth Coll[1], José Elizalde[2], Jaime Herrero[3], Teresa Pont[4], Brígida Quindós[5], Bella Marcelo[6], María A.Bodí[7], Adolfo Martínez[8], Agustín Nebra[9], Francisco Guerrero[10], José M.Manciño[11], Juan Galán[12], Miguel Lebrón[13], Eduardo Miñambres[14], Rafael Matesanz[1].
[1]Organización Nacional de Trasplantes, Madrid, Spain; [2]Complejo Hospitalario de Navarra, Pamplona, Spain; [3]Hospital Universitari Son Espases, Barcelona, Spain; [4]Hospital Universitari Vall d´Hebrón, Barcelona, Spain; [5]Hospital Universitario Central de Asturias, Oviedo, Spain; [6]Hospital Infanta Cristina, Badajoz, Badajoz, Spain; [7]Hospital de Tarragona Joan XXIII, Tarragona, Spain; [8]Hospital Ramón y Cajal, Madrid, Spain; [9]Hospital Miguel Servet, Zaragoza, Spain; [10]Hospital de Torrecárdenas, Almería, Spain; [11]Hospital Germans Trias i Pujol, Badalona, Spain; [12]Hospital La Fe, Valencia, Spain; [13]Hospital General de Málaga, Málaga, Spain; [14]Hospital Marqués de Valdecilla, Santander, Spain.

Background: The decline in the pool of potential DBD donors is challenging the progression towards self-sufficiency in transplantation in many developed countries. Intensive care treatment to facilitate organ donation (ITD) may help to increase the pool of donors and to offer more patients the chance of donating their organs upon their death. However, there is limited information published on the implementation of ITD in practice.
Objective: To describe the Spanish experience with ITD.
Patients and Methods: ACCORD-Spain was a multicentre (68 hospitals), observational and prospective study on end-of-life decision-making in patients aged 1 month-85 years dead as a result of a devastating brain injury (possible donors) during 11/1/2014-4/30/2015. Information was collected from the ACCORD-Spain database on those possible donors in whom a family interview was held to pose the option of ITD, once intensive treatment with a therapeutic purpose was deemed futile.

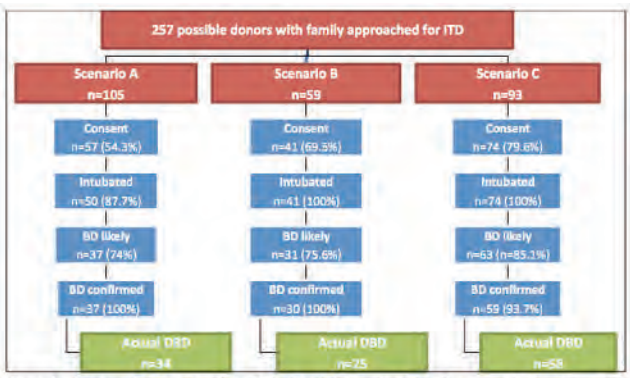


Figure 1: Process of Donation after Brain Death following a family approach to present the option of Intensive Treatment to facilitate organ Donation.
Scenario A: Family approached when intubation/ventilation not considered with a therapeutic purpose; Scenario B: Family approached with the patient intubated/ventilated when admission to an intensive care unit not considered with a therapeutic purpose; Scenario C: Family approached with the patient intubated/ventilated in the intensive care unit, when continuation of treatment is considered futile and brain death is a likely outcome.
BD: Brain Death; DBD: Donation after Brain Death; ITD: Intensive care treatment to facilitate organ donation

Results: 1970 possible donors were included in ACCORD-Spain. Interviews with the family to discuss organ donation were held in 765 cases. In 257 (34%), the family was interviewed once the decision had been made not to initiate intubation/ventilation with a therapeutic purpose (Scenario A: n=105), with the patient under intubation/ventilation but once admission to the ICU was considered not indicated with a therapeutic view (Scenario B: n=59), or with the patient intubated/ventilated in the ICU once further treatment was

deemed futile and brain death (BD) was a likely outcome (Scenario C: n= 93).
Mean age of these 257 possible donors was 69.1 (SD=14.7) years. The most frequent cause of brain injury was a cerebrovascular accident (79.8%).
Consent for ITD was obtained in 172 (66.9%) patients.
From the 172 patients with consent for ITD, 165 (95.9%) were finally intubated/ventilated, of whom 131 (79.4%) evolved to a BD condition in a median time of 1 day (IQR 1-3). BD was tested and confirmed in 126 (96.2%), of whom 117 (92.8%) transitioned to actual DBD. Main reasons why potential DBD donors did not transition to actual DBD donors were medical unsuitability (n=8), organs not suitable for transplantation (n=2), lack of appropriate recipients (n=2), haemodynamic instability with a cardiac arrest (n=1) and family decision not to continue with ITD (n=1). Results per Scenario are provided in figure 1.
From the 34 intubated/ventilated cases who did not evolve to BD, median time until death was 4 days (IQR: 2-6). DCD was considered in 5 (14.7%), 2 (40%) of them transitioning to actual DCD.
In total, 119 of the 172 (69.2%) possible donors with consent for ITD were converted into actual donors. ITD contributed to 24.2% of the total number of actual donors in the ACCORD-Spain study.
Conclusions: ITD can help to increase the donor pool and to ensure organ donation is posed at every end-of-life care pathway. A majority of approached families give consent for ITD. The practice poses significant challenges with regards to uncertainties in terms of evolution to BD and final medical suitability to organ donation. Transparent and comprehensive information to donor families is paramount.

Deceased organ donation performance in the Chinese community: An audit of hospital medical record in Hong Kong

Chi Yuen, Simon Cheung[1], Mei Lan Pong[2], Suk Fun Au Yeung[2], Ka Foon Chau[1].
[1]Medicine, Queen Elizabeth Hospital, Hong Kong, Hong Kong; [2]Central Nursing, Queen Elizabeth Hospital, Hong Kong, Hong Kong.

Introduction: The number of actual donors per million population was the most commonly used metric to measure organ donation rates and performances in different countries. However, it is deemed inadequate because it does not take into account the potential donor pool, which is dependent on the rates and causes of death. On the other hand, medical records review appears to be the most accurate method for estimating donor potential within a hospital or region[1]. Currently nearly all studies on deceased organ donation were performed in the Western countries and there had been lack of such data in the Chinese population. This study is the first to determine the true potential for solid organ donation from deceased brain-dead donors and the reasons for non-donation in the Chinese community.
Materials and Methods: A retrospective study using the critical pathway for deceased donation[2] was conducted in Queen Elizabeth Hospital, the largest regional hospital in Hong Kong. Medical records of all hospital deaths (including ICU and non-ICU areas) between 1st January and 31st December 2014 were reviewed by our two organ donation coordinators (ODC) and clinicians. Those who had been on mechanical ventilation with documented brain injuries and aged <= 75 years were classified as possible organ donors. The likelihood of progression to brain death was based on the Glasgow Coma Scale, absence of brainstem reflexes, rapidity of deterioration and findings of cerebral tomography.
Results and Discussions: Among 3659 patient deaths, only 233 patients were put on mechanical ventilation with documented brain injury. On initial review, 112 patients were excluded due to old age (>75 years old). The remaining 121 possible organ donors were then further analyzed. The mean age was 59.4 years and 72.7% were males. Majority (88%) were from non-ICU wards. One hundred and eight patients were classified as potential organ donors after excluding 13 unlikely to fulfill brain death criteria. Finally 11 patients became actual organ donors with an overall conversion rate 10%. The conversion rate was higher in ICU than non-ICU (23% vs 8%, p=0.10). The reasons for non-donation included medical contraindication (46%), failure to identify and inform our ODC (14%), failure of donor maintenance (11%), brain death diagnosis not established (18%) and relative's refusal (11%).
Conclusions: It is possible to increase organ donation rate considerably through different areas in the process of donation. Ongoing accurate audit of current practice is necessary.

Allocation of extended criteria deceased donor kidneys based on explant biopsy and Modified Remuzzi scores optimizes their utilization

Anantharaman Vathsala[1], Terence Kee[2], Ho Yee Tiong[1], Fang Jann Lee[2], M.S. Zaini[3], Audrey Ngau[3], Xiu Xian Koh[3], Sally Kong[3].
[1]National University Centre for Organ Transplantation, National University Hospital, Singapore, Singapore; [2]SingHealth Transplant, Singapore General Hospital, Singapore, Singapore; [3]National Organ Transplant Unit, Ministry of Health, Singapore, Singapore.

Introduction: Despite Singapore's adequate legislation and excellent infrastructure for deceased(DD) and living donor(LD) renal transplantation, the transplant rates are low at 16.2 pmp. While Extended Criteria Donors(ECD) are crucial to expand the DD pool, allocation of ECD kidneys is challenging due to difficulty in predicting donor quality and post-transplant(TX) outcomes.
Methods and AIms: Since 2009, all potential kidney DDs' are stratified as ECD if Age >60 yrs(ECD_Age); or if Age 50-59 yrs and meeting 2 of 3 criteria: medical cause of brain death, terminal creatinine >133 µmol/L or hypertension (ECD_UNOS); or if Diabetic and Hypertensive regardless of age (ECD_DM) or other clinical conditions (ECD_Others). The remainder were classified as Standard Criteria Donors (SCD). ECD evaluation included wedge explant biopsy of both kidneys, rapid processing of histology specimens and evaluation by a pathologist. Modified Remuzzi (mRemuzzi) scoring was performed fo each kidney in 4 domains (Glomeruli, Tubules, Interstitium and Arteries) to derive a Total Remuzzi Score (TRScore). Kidneys with TRScore of 0-4 were allocated as Single Implants; kidneys with TRScores of 5-7 were transplanted as Dual Implants.This study evaluated the impact of our allocation strategy on the DD pool and 1-yr graft and patient survivals and renal function.
Results: Of 85 DD from 2009-2014, 31(36.4%) were ECD. 15(48.4%), 8(25.8%), 4(12.9%) and 4(12.9%) were ECD_Age, ECD_UNOS, ECD_DM and ECD_Others respectively. Proportion of male and mean age was higher among ECD (71% vs 48%; P=0.034; 56.5yrs vs 39.3yrs; P=0). After evaluation, kidneys from 1 ECD were discarded; the remainder were implanted as Single(n=35, 52%) and Dual(n=14, 45%) respectively. Median glomeruli number per ECD kidney was 26 and median TRScore was 4. Of 54 ECD kidneys with adequate glomeruli for scoring, 21(38.8%), 32(59.3%) and 1(1.9%) had TRScore of <4, 4-7 and >7 respectively.
There were no significant differences in recipient demographics for Single vs. Dual Implants. Overall 1-year survival was 93.5%, with 1 graft loss due to primary non function and 1 patient death each due to AMI and sepsis at 2 and 12 months post-TX respectively. By 1 year, 34.7% were on mTORi-based immunosuppression (37.5% and 42.8% of Single and Dual Implants respectively). There were no differences in renal function for Single vs Dual Implants upto 1 year post-TX (median eGFR at 1, 3, 6 and 12 mths of 38, 40, 44 and 42 mL/min/1.73 m^2 vs. 43, 47, 41, 39 mL/min/1.73 m^2 for Single vs Dual Implants respectively; p=NS).
Conclusions: This strategy of allocating ECD kidneys based on mRemuzzi scoring of explant biopsies increased the DD rate by 29.8% in Singapore. 52% of "ECD" kidneys could be transplanted to standard recipients as Single Implants with excellent outcomes. As 1 year-eGFR for Single and Dual Implants was excellent, allocation based on donor explant histology and mRemuzzi scoring permits optimal utilization of scarce DD kidneys.

50 years of transplantation in Poland

Roman Danielewicz, Piotr Malanowski, Malgorzata Dudkiewicz, Dorota Lewandowska, Jarosław Czerwiński.
Polish Transplant Coordination Center, Poltransplant, Warsaw, Poland.

On the 26 of January 1966 first successful kidney transplantation was performed in Poland, about number 600 kidney transplant in the world at this time. From 1966 to the end of 2015 there were 28204 organ transplantation in Poland. Our country made large progress in area of legislation, organization and coordination, working towards and accommodating best practices in the field (including "Spanish model" for transplant coordinators). It worth to underline that to the best of our knowledge there were no cases of organ trafficking in our country. Currently all transplant programs are active in Poland with exception of small bowel transplantation. Donation rate is at 13,6 pmp in 2015, which is obviously not satisfactory, with nearly 1600 recipients on the active waiting list. Despite the number of transplant programs, donation rate in last years reached around 31 pmp only in most active regions of Poland, which is our great concern.
Currently in Poland there is a number of transplant programs - 21 for kidney, 6 for liver, 6 for heart, 5 for pancreas, 6 for lungs, 2 for forearm and 1 for face and trachea. In 2015 there were 1021 kidneys transplants (plus 60 from LD), 332 livers (plus 22 from LD), 98 hearts, 41 pancreas and 24 lungs transplantation. Besides, there are 11 bone marrow (BMTx) transplant programs performing in 2014 BMTx from 175 related donors and 397 from unrelated donors. There were also over 1150 BM donation in 2015 from polish donors, due to large number of potential BM donor in our register which reached over 900 thousands in the end of 2015 (7th register of BM donors in the world). The results of organ transplantation in Poland are well above the average, with 10 years recipients/graft survival for kidneys at the level of 76%/58%, for livers at 80%/76% and heart at 47%/46% in 2014
In Poland there is nearly 400 hospitals with donation potential, while in 2014 only 147 (36,75%) were active in organ donors referral to Poltransplant (national transplant organization). Overall 64% of procedures were multiorgan procurement. In the same time 276 organ retrievals in 2014 (46,5%) took place in only 18 of most active donors' hospitals.
For number of years Poland was actively participating in European programs devoted to increase organ donation (inter alia EU Action Plan, ETPOD, Donor Action, COORENOR, ACCORD etc.). There is also National Program of Development of Transplantation medicine for years 2011-2010, including social promotion of organ donation. The last is aiming at increasing the number of deceased and living donation in our country to meet the demand of waiting list. Despite this numerous efforts the self-sufficiency of our country in term of organ procurement and transplantation, is far from satisfactory. Further efforts and continuation of promotional programs of organ donation together with professional activities in the field of transplantation medicine are necessary to meet the demand for organ transplantation in Poland.

Risky organs: trends in comorbidities among potential and actual Australian organ donors in New South Wales

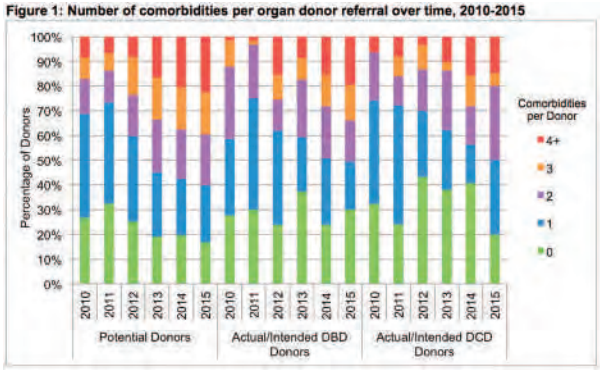
Imogen Thomson[1], Rebecca Hancock[2], Kate Wyburn[1,3], Michael O'Leary[1,4,5], Angela Webster[1,2,6,7].
[1]Sydney Medical School, University of Sydney, Sydney, Australia; [2]School of Public Health, University of Sydney, Sydney, Australia; [3]Renal Unit, Royal Prince Alfred Hospital, Sydney, Australia; [4]NSW Organ and Tissue Donation Service, Sydney, Australia; [5]Intensive Care Service, Royal Prince Alfred Hospital, Sydney, Australia; [6]Centre for Transplant and Renal Research, Westmead Hospital, Sydney, Australia; [7]Centre for Kidney Research, The Children's Hospital at Westmead, Sydney, Australia.

Introduction: The increase in organ donors in New South Wales (NSW) has been exceeded by a rise in the number of potential donors who do not proceed to donation. The overall burden of disease is an increasingly significant consideration when assessing the medical suitability of donor referrals. We sought to characterise the distribution of comorbidities among NSW organ donor referrals, and to explore changes over the past six years.

Materials and Methods: We undertook a cohort study of NSW Organ and Tissue Donation Service (OTDS) referral logs from 2010-2015 for the presence of donor comorbidities. We considered three groups of donors: potential donors (who were referred but did not proceed to donation), actual/intended donors after brain death (DBD), and actual/intended donors after circulatory death (DCD). Intended donors were those where donation was abandoned before organ retrieval, and actual donors those who proceeded to donate. We considered the presence or absence of ischaemic heart disease, non-ischaemic cardiovascular disease (e.g. cardiomyopathy, cardiac failure), cerebrovascular disease, chronic respiratory disease, chronic kidney disease, chronic liver disease, hypertension, diabetes and hyperlipidaemia. The overall burden of disease was estimated by summing the total number of comorbidities per referral. Non-parametric trend tests, logistic regression and a Kruskal-Wallis test were used to determine the significance of results between groups and over time.

Results: A total of 3005 referrals (2337 potential, 455 actual/intended DBD, 213 actual/intended DCD) between 2010-2015 were reviewed for the presence of comorbidities. The increase of donors with >2 comorbidities over this time was significant ($p<0.01$) for all groups of donors (figure 1). Potential donors had a greater comorbidity burden than both actual/intended donor groups ($p<0.01$). The comorbidities most strongly associated with not proceeding to donation were chronic kidney disease and non-ischaemic cardiovascular disease (figure 2). Conversely, hyperlipidaemia was associated with an increased likelihood of a donor referral proceeding to donation. However, this may reflect the more detailed reporting of the medical histories in actual and intended donor referrals, compared to those for potential donors. Our study was limited by an inability to easily differentiate comorbidity disease severity.

Figure 1: Number of comorbidities per organ donor referral over time, 2010-2015



Conclusion: Our results demonstrate that the distribution of comorbidities among NSW organ donors is changing. Of the comorbidities we considered, referrals with chronic kidney disease and non-ischaemic cardiovascular disease appeared least likely to proceed to donation. Overall, while donors with a greater burden of disease are increasingly being used for organ donation, an increasing proportion of donor referrals do not proceed for reasons of comorbidity.

Figure 2: Overall prevalence and time-trend of comorbidities among potential, actual/intended DBD, and actual/intended DCD organ donors

	Donor Type	N (of total 3005)	Odds Ratio (95%CI) *	P for change over time
Chronic Respiratory Disease	Potential	316	1.03 (0.78-1.36)	<0.001
	Actual/Intended DBD	46		0.95
	Actual/Intended DCD	29		0.88
Ischaemic Heart Disease	Potential	590	1.54 (1.21-1.96)	0.02
	Actual/Intended DBD	65		0.002
	Actual/Intended DCD	42		0.31
Non-Ischaemic Cardiovascular Disease	Potential	316	1.91 (1.47 - 2.47)	<0.001
	Actual/Intended DBD	55		0.001
	Actual/Intended DCD	30		0.005
Cerebrovascular Disease	Potential	959	0.91 (0.75-1.09)	0.005
	Actual/Intended DBD	226		0.24
	Actual/Intended DCD	74		0.37
Diabetes	Potential	400	1.34 (1.00-1.77)	<0.001
	Actual/Intended DBD	53		0.26
	Actual/Intended DCD	23		0.89
Hypertension	Potential	761	1.10 (0.87-1.38)	<0.001
	Actual/Intended DBD	143		<0.001
	Actual/Intended DCD	761		0.01
Hyperlipidaemia	Potential	296	0.54 (0.41-0.71)	<0.001
	Actual/Intended DBD	79		0.003
	Actual/Intended DCD	30		0.04
Chronic Liver Disease	Potential	121	1.69 (1.00-2.85)	<0.001
	Actual/Intended DBD	9		0.09
	Actual/Intended DCD	8		0.94
Chronic Kidney Disease	Potential	203	2.77 (1.60-4.79)	<0.001
	Actual/Intended DBD	11		0.21
	Actual/Intended DCD	4		0.63

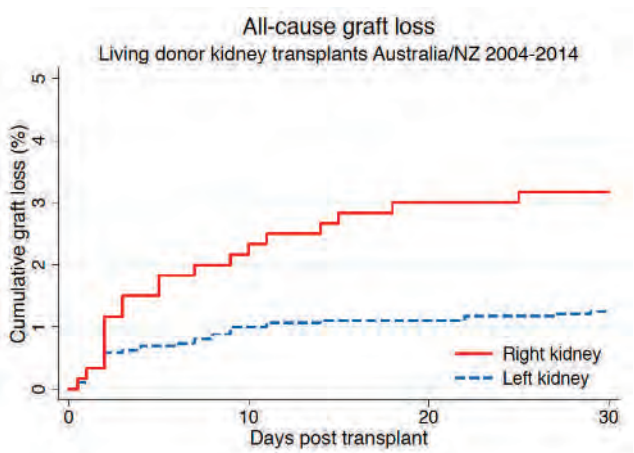
* Odds ratio was calculated as the likelihood of a donor referral not proceeding to donation given the presence of a particular comorbidity.

553.1

Adverse early outcomes for right-sided living donor kidney transplants

Deepak Chhabra[1,2], Philip Clayton[3], Arthur Vasilaras[1], Steven J.Chadban[1,2,3], Stephen McDonald[3], Henry Pleass[1,2], Richard Allen[1,2]. [1]Transplantation Services, Royal Prince Alfred Hospital, Sydney, Australia; [2]Sydney Medical School, University of Sydney, Sydney, Australia; [3]Australia and New Zealand Dialysis Transplant Registry, University of Adelaide, Adelaide, Australia.

Background: Kidney transplant surgeons prefer to transplant left rather than right-sided living donor (LD) kidneys because of the longer and more favourable left renal vein. Centre-specific data suggest that the results of right-sided LD kidney transplants may be inferior. We aimed to determine whether this is true for a large, multi-national cohort.
Methods: A retrospective analysis of all adult LD kidney transplants performed in Australia and New Zealand in the eleven-year period from 2004 to 2014 was undertaken to assess outcomes of left versus right LD kidneys. The data was reported prospectively to the Australia and New Zealand Dialysis and Transplant (ANZDATA) Registry. Cox proportional hazards models were used to examine the associations between kidney side and patient, graft and death-censored graft survival, adjusting for other donor, recipient and transplant characteristics.
Results: 23 kidney transplant centres performed 3315 living donor kidney transplants in adult recipients between 2004 and 2014. Of these, 600 (18.1%) involved use of a right-sided donor kidney. Higher volume transplant centres were more likely to undertake right-sided LD transplant procedures and 4 centres performed none. Donor nephrectomy was performed most commonly by pure laparoscopic surgery (54.1%), followed by hand-assisted laparoscopic surgery (33.8%) and open surgery (12.1%). Use of open nephrectomy was more common and laparoscopic nephrectomy less common for right-sided kidneys (p<0.001). Compared to recipients of left-sided LD kidneys, there were no significant differences in donor age or eGFR, or for recipient, race, primary renal disease, and degree of HLA mismatch or PRA for recipients of right-sided donor kidneys. All cause graft loss at 30 days was 3.2% (95%CI 2.0-4.9) versus 1.3% (0.9-1.8) for right and left LD kidneys respectively (adjusted HR=2.37, 95%CI 1.31-4.30, p=0.004) (Figure 1). Death-censored graft failure was also significantly greater in recipients of right-sided LD kidneys at 30 days after transplantation (HR 2.52, CI 1.34-4.76, p=0.004). After 30 days, there were no significant differences in all cause graft loss (HR=1.05, CI 0.81-1.36, p=0.72) or death-censored graft failure (HR=1.10, 95% CI 0.79-1.55, p=0.56). The overall uncensored graft survival for the 3315 LD kidneys at 5 years was 86.3% (CI 82.9-89.1) and 89.1% (CI 90.4-87.7) for right and left kidneys respectively.



Conclusions: This registry-based study demonstrates a small but significant inferior outcome for the transplantation of right living donor kidneys (p=0.004). This difference occurs only in the first 30 days after transplantation. Interpretation is limited by absence of data about reasons for transplant centres choosing right rather than left LD donor kidney, and, the presumed caution of others to limit or not use right-sided LD donor kidneys. Nevertheless, it is recommended that:
1. The patient consent process should include discussion about the increased risk of early adverse outcome for recipients of right-sided LD kidneys. There is a 1 in 50 greater chance of graft loss in the first 30 days.
2. When comparing outcomes LD kidney transplantation between different transplant centres, acknowledgement of the use of right-sided kidneys, or otherwise, should be made.

553.2

Global kidney exchange

M.A. Rees[1,3], T. Dunn[2], S. E.Rees[3], J. Rogers[4], L. J.Reece[3], A. E.Roth[5], C. Kuhr[6], O. Ekwenna[3], D. E.Fumo[1], K. Krawiec[7], S. Jain[1], C. Marsh[8], M. Tan[9], S. Paloyo[10].
[1]University of Toledo, Toledo, OH, United States; [2]University of Minnesota, Minneapolis, MN, United States; [3]Alliance for Paired Kidney Donation, Perrysburg, OH, United States; [4]Wake Forest, Winston-Salem, NC, United States; [5]Stanford University, Stanford, CA, United States; [6]Virginia Mason, Seattle, WA, United States; [7]Duke University, Durham, NC, United States; [8]Scripps Green Hosp, La Jolla, CA, United States; [9]Piedmont Hosp, Atlanta, GA, United States; [10]Phillipine Gen Hosp, Manila, Philippines.

Introduction: Instead of thinking of the developing world as a place where there are desperate people who will sell their kidneys for money, we propose a new approach where the developing world can be seen as a place where there are desperate patients with kidney failure who need kidney transplants and who have willing, living kidney donors, but insufficient financial resources to pay for their transplant and subsequent immunosuppression.
Methods: Kidney paired donation (KPD) is utilized to overcome barriers to transplantation due to immunological barriers such as blood type (BT) or donor specific antibodies, and also to optimize characteristics such as age or HLA-matching. We propose that the financial barrier faced by potential patient/donor pairs in developing countries could be another such barrier solvable by participation in KPD, when one considers the cost differential between dialysis and transplantation in the First World. By extending First World quality healthcare to impoverished patients in the developing world, we reverse the practice of transplant tourism and shed light and transparency on the black market organ trade by acknowledging that a kidney has financial value, while simultaneously protecting the fact that exchanging a kidney for a kidney transplantation for a desired patient is an altruistic gift and not a commercial exchange.
Results: A blood type (BT) O donor and a BT A, PRA 0% ESRD patient from the Philippines were unable to pay for dialysis or transplantation. A United States (US) non-profit paid for their evaluation and some dialysis in the Philippines. A nonsimultaneous extended altruistic donor (NEAD) chain was identified starting with a US BT A non-directed donor (NDD) with no match in the US KPD pool. The US NDD donated to the Filipino recipient, resulting in a BT O Filipino donor who simultaneously donated to continue the chain. To date the chain has resulted in eleven kidney transplants and an active bridge donor. Five recipients had the US government as their health insurance payer and five recipients had Commercial insurance. The transplant cost (including NDD nephrectomy and donor complication insurance) for the Filipino recipient was paid for by a US non-profit organization. An additional $50,000 was reserved for subsequent immunosuppression and donor/recipient follow-up in the Philippines. One year post-transplantation, the Filipino donor/recipient are doing well and $45,000 remains reserved for continuing care in the Philippines. The savings from transplanting 10 US patients compared with the cost of dialysis will exceed $3M over the next 5 years.
Conclusion: Global kidney exchange provides a unique solution to the lack of available donor kidneys. A very small fraction of the cost savings experienced by First World payers could be gifted to establish renewable funds for future efforts, in turn simultaneously enhancing further cost savings and the health of kidney donors and recipients in our global community.

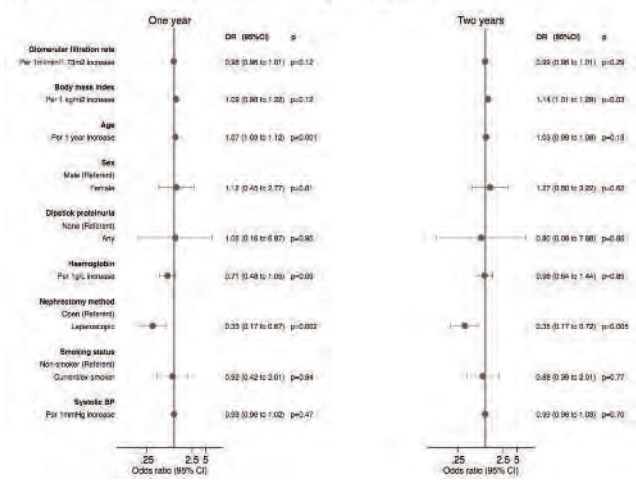
553.3

Chronic kidney disease among living kidney donors: a cohort study

Philip Masson, Lorna KHenderson, Alex Walker, Gabriel Oniscu.
Department of Renal Medicine and Renal Transplantation, Royal Infirmary of Edinburgh, Edinburgh, United Kingdom.

Background and Aims: How living kidney donation affects glomerular filtration rate (GFR) and proteinuria after donation is unclear. We aimed to identify risk factors for chronic kidney disease (CKD) among living kidney donors.
Methods: We performed a retrospective cohort study of all living kidney donors at the Royal Infirmary of Edinburgh. Demographic and clinical information at the time of kidney donation were recorded, along with GFR and urinary dipstick findings at one and two years following kidney donation. We calculated the risks of developing either CKD stage ≥3 or new dipstick proteinuria associated with specific baseline characteristics using multivariate-adjusted logistic regression models. Results were expressed as odds ratios (OR) with their 95% confidence intervals (CI).
Results: 376 people (52% female and 48% male) donated a kidney between 1993 and 2015. Mean age at donation was 49.5 years (SD, standard deviation 11.1) and mean GFR was 96.1ml/min/1.73m2 (SD 15.1). Only 12 donors (3.2%) had dipstick proteinuria at the time of kidney donation. By one year after donation 126 (34%) of donors had CKD ≥3. With each year of advancing age at the time of donation, people were 7% more likely to have CKD ≥3 (OR 1.07, CI 1.03 to 1.12). Donors undergoing laparoscopic nephrectomy were 67% less likely to have CKD ≥3 than donors undergoing an open nephrectomy (OR 0.33, CI 0.17 to 0.87) (**Figure 1**). By two years after donation, people with a higher body mass index (BMI) at the time of donation were more likely to have CKD ≥3, each 1kg/m2 increase in BMI being associated with a 14% increased risk (OR 1.14, CI 1.01 to 1.29). Donors undergoing a laparoscopic nephrectomy still had a 65% lower risk of CKD ≥3 than donors undergoing an open nephrectomy (OR 0.35, CI 0.17 to 0.72). Considering proteinuria, by one year after donation 36 (10%) of donors had dipstick proteinuria ≥ trace. People with a higher BMI at donation were more likely to have proteinuria, with each 1kg/m2 increase in BMI being associated with a 28% increased risk of proteinuria (OR 1.28, CI 1.09 to 1.53). Neither GFR nor systolic blood pressure at donation were associated with the risk of developing either CKD ≥3 or proteinuria at any time during follow-up.

Figure 1. Risk factors for living kidney donors having CKD stage ≥ 3



Conclusions: Our main novel finding was that living kidney donors undergoing laparoscopic nephrectomy were less likely to develop CKD

≥3 during follow-up than people undergoing open nephrectomy. This study should serve to generate hypotheses about possible mechanisms by which surgical technique might affect long term kidney outcomes for living kidney donors.

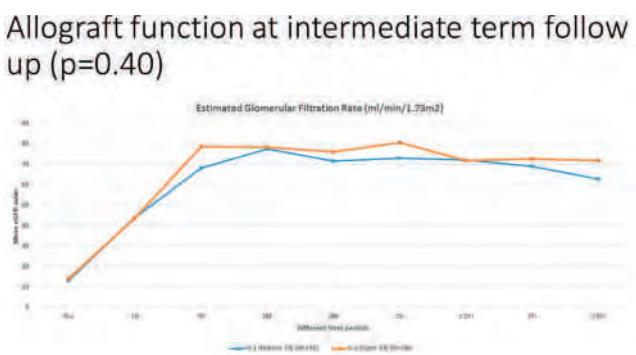
Technique and outcome of robotic kidney transplantation in 161 adult recipients

Pranjal Modi[1,2], Bipin Pal[1,2], Suresh Kumar[1,2], Yusuf Saifee[1,2], Ramya Nagarajan[1,2], Rohit Chauhan[1,2], Vivek Kute[1,2], Himanshu Patel[1,2], Manisha Modi[1,2], Veena Shah[1,2], Hargovind L.Trivedi[1,2].
[1]Transplantation Surgery and Urology, Smt G R Doshi and Smt K M Mehta Institute of Kidney Diseases and Research Centre, Ahmedabad, India; [2]Transplantation Surgery and Urology, Dr. H.L. Trivedi Institute of Transplantation Sciences, Ahmedabad, India.

Introduction: Robotic kidney transplantation (RKT) is emerging new modality of treatment for kidney recipient with intention to minimize the wound related morbidity in recipients[1],[2]. Here we present technique and outcome of RKT at a single surgical unit.
Materials and Methods: With permission of Internal Review Board, total 180 RKT and 243 open kidney transplants (OKT) in adult patients were performed between January 2013 and October 2015 at single surgical unit. In 19 female recipients different method of RKT was used and hence excluded from analysis. Deceased donor kidney was used in 21 and 47 cases of RKT and OKT respectively. For RKT, a 6 cm Pfannenstiel incision was placed to insert the kidney in the abdomen and da vinci(R) surgical platform was used for vascular anastomosis and ureteric reimplantation. Regional hypothermia was used in initial 68 cases of RKT. Primary end point was to evaluate estimated glomerular filtration rate (eGFR), graft and patient survival at 12 months. Tacrolimus based triple immunosuppressant regime was used in all patients.
Results: There was no difference in demography in either group. All but four patients in RKT group were transplanted successfully. Intra-operative bleeding from vein and thrombosis of artery in two cases each required conversion to open surgery. Anastomosis time and total operative time were 34.92±8.28 min. and 218.09±48.61 min. for RKT and, 31.52±13.54 and 199.52±69.38 min. for OKT respectively ($p<0.01$). Ureteric reimplantation time (33.30±8.85 min for RKT and 40.63±10.79 min. in OKT, $p<0.01$) and estimated blood loss (58.56±89.36 ml for RKT, 112.23±69.38 ml for OKT, $p<0.001$) were lower in RKT. Mean analgesic requirement was 2.5 mg and 5.6 mg morphine equivalent ($p<0.01$) in RKT and OKT group respectively. There was no difference in time to resume orally, time to ambulation, time to catheter removal and total hospitalization in either group. No lymphocele vs. 14 lymphocele were observed in RKT and OKT group respectively; one required laparoscopic defoofing. Four cases in OKT required re-exploration for perigraft hematoma. One case in RKT group required laparoscopy for renal allograft biopsy. There was no statistically significant difference in eGFR value and graft and patient survival in RKT and OKT group. Fig. 1 and 2 shows eGFR, graft and patient survival in RKT and OKT group having living donor.



On subgroup analysis, eGFR, graft and patient survival were not statistically different in patients with and without regional hypothermia.

Conclusion: RKT is having advantage over OKT in terms of less pain, early ambulation, no lymphocele or peri-graft collection. eGFR, graft and patient survival at one year are similar in both groups.

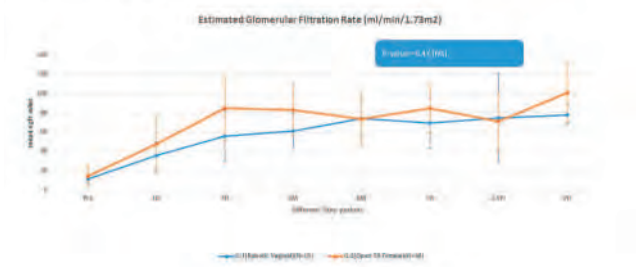
Transvaginal insertion of kidney and robotic kidney transplantation: First 19 cases

Pranjal Modi[1,2], Bipin Pal[1,2], Suresh Kumar[1,2], Yusuf Saifee[1,2], Ramya Nagarajan[1,2], Rohit Chauhan[1,2], Manisha Modi[1,2], Veena Shah[1,2], Vivek Kute[1,2], Himanshu Patel[1,2], Hargovind L.Trivedi[1,2].
[1]Transplantation Surgery and Urology, Smt G R Doshi and Smt K M Mehta Institute of Kidney Diseases and Research Centre, Ahmedabad, India; [2]Transplantation Surgery and Urology, Dr. H.L. Trivedi Institute of Transplantation Sciences, Ahmedabad, India.

Introduction: Robotic kidney transplantation (RKT) is emerging new modality of treatment for kidney recipient with intention to minimize the wound related morbidity in recipients. Feasibility and safety of kidney insertion through vagina and carrying out laparoscopic kidney transplantation has been demonstrated by our group[1]. We and others have demonstrated feasibility of transvaginal insertion of kidney and robotic kidney transplantation (V-RKT)[2],[3]. Here we present technical modifications and outcome of V-RKT.
Materials and Methods: With permission of Internal Review Board, 19 female recipients underwent V-RKT and 39 females had open kidney transplantation (OKT) between July 2013 and October 2015. Patient inclusion criteria were history of at least one normal vaginal delivery, capacious vagina on physical examination and consent for episiotomy/or insertion of kidney through abdomen. Exclusion criteria were nulliparous woman, atrophic vagina and previous hysterectomy associated with extensive intra-abdominal adhesions. Antibiotic prophylaxis (Inj Cefazolin 1.0 gm and Inj. Metronidazole 500 mg iv) was given for three days in all recipients along with povidone iodine vaginal pessary. For V-RKT, patient was placed in 300 Trendelenburg positon with both legs spreaded. Da Vinci Si(R) surgical platform was used. Following preparation of external iliac vessels for transplant, an incision is placed on the posterior vaginal wall. The assistant surgeon inserts the kidney through the vagina and close the vagina. The console transplant the kidney with external iliac vessels. Ureteroneocystostomy was done by Lich's method. The primary end point was to evaluate feasibility and safety of the procedure. The secondary end point was to evaluate estimated GFR and one year graft and patient survival.
Results: There was no difference in demography. Vascular anastomosis time, ureteric reimplantation time and total operative time were 32.74±5.67 min. and 32.38±12.08 min., 34.47±8.24 min. and 43.36±9.81 min., and, 237.37±64.88 min. ($p<0.01$) and 205.51±33.63 min. respective in V-RKT and OKT groups respectively. Mean analgesic requirement was 0.8 mg Vs. 3.2 mg of morphine equivalent ($p<0.01$) and Mean time to resume fluid orally was 9.2 hours and 14.12 hours ($p<0.01$) in V-RKT and OKT group respectively. There was no statistically significant difference between time for ambulation, time for catheter removal and total hospital stay. Sexual function was resumed after 30 days of transplantation by all recipients. No difference in eGFR ($p= 0.47$) in either group (Figure-1) with 100% graft and patient survival till the last follow up.

Estimated Glomerular Filtration Rate



Conclusion: V-RKT is feasible and safe in selected group of female recipients. It is associated with less pain. eGFR, graft and patient survival are similar in V-RKT and OKT group.

Preliminary results from a pilot study utilizing ERAS protocol in living donor nephrectomy

Aparna Rege[1], Jayanth Reddy[1], Deepak Vikraman[1], William Irish[2], Debra Sudan[1], Ahmad Zaroura[1], Todd Brennan[1], Kadiyala Ravindra[1]. [1]Surgery, Div of Abdominal Transplant, Duke University medical center, Durham, United States; [2]Health Outcomes Research & Biostatistics, CTI Clinical Trial and Consulting, Durham, United States.

Background and Introduction: Gastrointestinal (GI) recovery after major abdominal surgery can be delayed from ongoing need for narcotic analgesia thereby prolonging hospitalization. Enhanced recovery after surgery (ERAS) is a multimodal perioperative care pathway designed to facilitate early recovery after major surgery while showing equivalent morbidity, mortality and readmission rates in comparison to the traditional standard of care[1]-[3]. Laparoscopic living donor nephrectomy has significantly transformed the outlook for individuals considering kidney donation[4]. However, a 30% rate of Emergency Room visits / readmission was recorded at our center in 2014 largely from delayed GI recovery. Thus, a pilot trial to utilize ERAS protocols in living kidney donors was initiated.

Methods: This is a single-center retrospective analysis comparing the outcomes of the first 14 live kidney donors subjected to laparoscopic nephrectomy with ERAS protocol to 18 donors operated prior to ERAS with traditional standard of care. Both groups were matched by patient demographics. Our ERP includes reduced duration of fasting with preoperative carbohydrate loading, intraoperative fluid restriction to 3ml/kg/hr, target urine output of 0.5 ml/kg/hr, use of sub fascial Exparel injection(Bupivacaine liposome suspension) and postoperative narcotic free pain regimen with Acetaminophen, ketorolac, tramadol.

Results: ERAS protocol reduced postoperative median length of stay decreased from 2.0 to 1.0 days (P 0.001). Overall pain scores were significantly lower in the ERAS group (peak pain score 6.50 vs 9.00 - p 0.001, morning after surgery pain score 3.00 vs 7.00 - p 0.012) despite absence of narcotics in the postoperative period. Average duration of surgery was shorter with the ERP as compared to the standard protocol (241 vs 277 min - p 0.019). Average amount of intraoperative fluid used was significantly lower in the ERAS group in comparison to standard of care protocol (2000ml vs 3000ml, p 0.002), without affecting the donor urine output intraoperatively or the percent change in donor serum creatinine on postop day 1(70 vs 77, p 1.000). Incidence of delayed graft function was similar in the two groups (2 vs 1, p 0.597). A trend towards lower readmission was noted with the ERAS protocol. (2 vs 4, p 0.656). GI dysfunction was the most common reason for readmission.

Conclusion: Application of ERAS protocol in laparoscopic living donor nephrectomy was associated with reduced length of hospitalization. Improved pain scores resulted from intraoperative use of sub fascial Exparel and shorter duration of ileus. Optimizing intraoperative fluids minimized excessive third spacing & bowel edema reducing operative times and facilitating gut recovery without adversely impacting recipient graft function. This study suggests that ERAS has the potential to enhance the advantages of laparoscopic surgery for live kidney donation through optimizing donor outcomes and perioperative patient satisfaction and may further incentivize population for undergoing laparoscopic live kidney donation.

Obesity is associated with increased risk of ESRD among living kidney donors

JaymeE. Locke[1], Cora E.Lewis[1], Rhiannon D.Reed[1], Vineeta Kumar[1], Deirdre Sawinski[2], Allan Massie[3], Paul A.MacLennan[1], Roslyn B.Mannon[1], Robert Gaston[1], Dorry L.Segev[3].
[1]University of Alabama at Birmingham, Birmingham, AL, United States; [2]University of Pennsylvania, Philadelphia, PA, United States; [3]Johns Hopkins University, Baltimore, MD, United States.

Background: Living kidney donor (LKD) demographics have changed, and transplant centers have relaxed selection criteria to include LKDs who are obese. Prior studies of LKDs have failed to stratify donors by the presence of obesity. The goal of this study was to assess the risk of ESRD among LKDs with obesity at the time of donation.
Methods: 119,769 LKDs in the US (1988-2013) were studied. Obese LKDs were defined as donors with body mass index (BMI) ≥ 30kg/m2 at the time of donation. Donors were followed until the earliest of ESRD development, death, or administrative end of study. Multiple imputation using chained equations were used to impute BMI, systolic and diastolic blood pressure, relationship to recipient, eGFR, and smoking and insurance status when missing. Maximum follow-up was 20 years. Main outcome measures included cumulative incidence and adjusted risk of ESRD (adjusted for age, race, blood pressure, gender, eGFR, and relationship to recipient).
Results: Compared to non-obese LKDs, obese LKDs were more likely male, African American, and to have higher blood pressure (Table). Estimated risk of ESRD at 20 years after donation was 93.9 per 10,000 for obese LKDs and 39.7 per 10,000 in their non-obese LKD counterparts.

Table 1. Patient characteristics by obesity status at donation (N= 119,769)

	BMI ≥ 30 (N=29,575)	BMI < 30 (N=90,194)
	%	%
Age at donation, Mean (SD)	40.2 (10.8)	39.9 (11.3)
Female	55.1	60.0
Race		
African American	16.8	11.5
Non-African American	83.2	88.5
History of smoking	20.7	20.2
Insurance at donation	81.8	82.2
Systolic BP, Mean (SD)	124.9 (13.2)	120.8 (13.4)
Diastolic BP, Mean (SD)	76.3 (9.4)	73.7 (9.3)
BMI, Mean (SD)	33.7 (2.6)	24.8 (3.1)
eGFR, Mean (SD)	98.2 (19.5)	99.5 (19.4)
Related to recipient	81.4	81.9

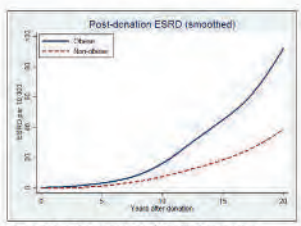

Figure 1. Cumulative incidence of ESRD by obesity status

On unadjusted analyses, LKDs with obesity had a 2.5-fold increased risk of ESRD compared to their non-obese LKD counterparts. After adjustment, the risk of ESRD among LKDs with obesity was 1.95-fold higher than non-obese LKDs (adjusted hazard ratio (aHR): 1.95, 95%CI: 1.37-2.78, $p < 0.001$). For each one unit increase in BMI there was an associated 8% increase in the risk of ESRD (aHR: 1.08, 95% CI: 1.05-1.12, $p < 0.001$).
Conclusions: Compared with non-obese LKDs, LKDs who are obese at the time of donation had an increased risk of ESRD within 20 years of donation. These findings may help to inform selection criteria and discussions with persons considering live kidney donation.

What distinguishes donors from non-donors? Analysis of 2306 potential living kidney donors

Hillary Braun[1], John Feiner[2], Garrett R.Roll[3].
[1]School of Medicine, University of California, San Francisco, San Francisco, CA, United States; [2]Department of Anesthesia, University of California, San Francisco, San Francisco, CA, United States; [3]Department of Surgery, University of California, San Francisco, San Francisco, CA, United States.

Introduction: UCSF implemented an online donor screening system to streamline the initial evaluation process for potential living donors in 2013 and make it easier for patients to successfully interact with us. A validated[1],[2] web-based software platform (BREEZE TRANSPLANT , MedSleuth, Inc.) performs automated pre-donation screening and post-donation monitoring of living donors. This software allows for a rapid and robust data collection, including comparison of characteristics between patients that eventually went on to become donors and those that did not. Here we present data collected during the first three years of this online system.
Methods: Potential living kidney donors initiated the process by completing an online questionnaire using the web-based system, Breeze (MedSleuth, San Francisco, CA). The questionnaire gathered basic demographics including age, gender, ethnicity, and relationship to intended recipient as well as components of the respondent's medical history that might affect donation including BMI, activity level, medical comorbidities, and substance use. Descriptive data was calculated as mean ± SD and n (%). Continuous data was compared with Wilcoxon rank sum test and proportions were compared with Chi square or Fisher's exact test.
Results: 2306 potential living kidney donors completed the screening form between 2013-2015, of which 11.9% (275/2306) went on to successfully donate. The average age was significantly greater among donors compared with non-donors (42.9 ± 12.2 vs. 40.8 ± 13.7, p=0.008) and donors were more likely to be married compared with non-donors (62.8% vs. 50.0%, p=0.001). Relationship to the recipient was also significant; 71.2% of donors were blood relatives with the recipient compared with 53.9% of non-donors (p<0.001). A greater majority of donors denied any history of tobacco use compared with non-donors (82.3% vs. 68%, p<0.001). Age, blood relationship, and amount of calculated exercise were significantly associated with successful donation (OR 1.01, 2.03, 1.14, respectively, p-values <0.05).
Discussion: Screening potential donors with a validated online system has enabled robust data collection and analysis, especially with regard to understanding what donor characteristics predict successful donation. Age, marital status, tobacco use, and activity level were the significant differences we observed between patients who went on to be selected as donors and those that were not. Interestingly, these variables have not historically been shown to correlate with differences in graft and recipient outcome.
Conclusion: Age, marital status, tobacco use, and activity level help predict who is likely to be selected as kidney donor and who is not. These variables can be weighted for use in web-based software algorithms to improve our donor selection efficiency.

Establishing a learning curve for laparoscopic living donor nephrectomy

Zubir Ahmed, Pankaj Chandak, Raphael Uwechue, Nicos Kessaris, NIzam Mamode.
Transplantation, Guy's Hospital, London, United Kingdom.

Introduction: Despite over 5000 hand assisted laparoscopic donor nephrectomies (HALDNs) having been performed in the UK a paucity of data still exists in establishing how many procedures are required in order to safely ascend the learning curve. The production of such parameters is essential to the development of appraisal, safety and training programmes in this expanding surgical programme within transplantation. Recent data from other equivalent surgical procedures suggests both intraoperative and postoperative outcome data parameters can be used to establish the learning curve.
Methods: The caseload of two surgeons who had individually performed over 180 HALDNS each was interrogated. Using cumulative sum analysis (CUSUM), operating time, hospital stay, the occurrence of major and minor complications and the need for readmission or reoperation were assessed. The learning curve was analysed using graphical representations to detect an inflexion point which would represent a stability of process. The number of procedures required to arrive at this point was assumed to represent successful ascent of the learning curve. Statistical analysis using the Pr > zL statistic was also used to quantify whether such a stability of process had been achieved.
Results: Surgeons 1 and 2 performed 189 and 183 cases over an 8 year period. All were intraperitoneal using a standardised technique. Patient demographics between the 2 surgical caseloads were similar (% female: 51 v 52%, mean age 44.1 v 44.7 yrs, mean BMI 26.5 v 27.2, % left sided cases 80 v 85%). CUSUM analysis revealed no discernible inflexion points for hospital stay (zL = 0.3 p=0.07), occurrence of clavien 2 and above complications (zL =0.84, p=0.337), readmission (zL=0.696 p=0.243) or reoperation (zL= -0.366 p=0.643). Operating time however demonstrated a visible stability of process initially at case 25 but this was more sustained by case 40 to 45 for both surgeons.
Discussion: A learning curve can be reproducibly established for HALDN using operating time as a surrogate marker. Contrary to popular belief true ascent of the learning curve may mean the performance of up to 50 procedures rather than 20 – 25. In our series the occurrence of stability in operating times at case 25 was likely biased by careful patient selection and hence by the stability occurring by case 50 is representative of normal surgical casemix. We anticipate this data will better inform the development of surgical training programmes in HALDN.

Robotic simultaneous pancreas kidney transplantation in obese recipient

Chun Chieh Yeh[1,2], Mario Spaggiari[2], Jose Oberholzer[2].
[1]Department of Surgery, China Medical University Hospital, Taichung, Taiwan; [2]Division of Transplant, University of Illinois at Chicago, Chicago, United States.

Introduction: Robotic simultaneous pancreas kidney transplantation in obese recipients has never been reported before.
Materials and Methods: Herein, we report a laparoscopic robot-assisted simultaneous pancreas kidney transplantation in a patient with class I obesity and diabetic nephropathy. This 49-year-old, insulin demanding diabetes complicated with end stage renal failure, African American male patient with a BMI of 34(kg/m2) was listed for simultaneous pancreas kidney transplantation. The pancreas and kidney graft were procured and benched in standard way. Methylene blue mixed in University of Wisconsin (UW) solution was used to search for any potential vascular leaks on the back table. The laparoscopic, robot-assisted pancreas transplantation was completed via two 12mm ports (one for laparoscopic bed-side assistance and the other for the camera), two 8mm ports for the robotic arms, and a hand port on a 7cm epigastric midline incision (Fig.1, blue marking).
Results: The arterial Y graft and portal vein of the pancreas were anastomosed to the recipient's left external iliac artery and vein, respectively. Enteric drainage was performed between the duodenum of graft and recipient's distal jejunum with a circular stapler (EEA 21/4.8mm). Duration of warm and cold ischemia in pancreas transplantation was 54min and 8.7hr, respectively. The robotic kidney transplantation was performed in similar approaching but with reversed port site positioning (Fig.1, green marking). The kidney graft was implanted to right external iliac artery and vein. Duration of warm and cold ischemia in kidney transplantation was 31min and 12hr, respectively. The whole procedure was recorded (surgical video clip). The patient was discharged uneventfully on day 11 without any wound related complications. Appropriate short-term metabolic control was achieved with achieving euglycemia without insulin supplement before discharge (Fig.2).
Conclusion: Robotic simultaneous pancreas kidney transplantation can be successfully applied in patients with obesity without compromising safety and short-term metabolic outcome.

Tips for a successful normothermic liver perfusion

David Nasralla[1], Hynek Mergental[2], Thamara Perera[2], Wayel Jassem[3], Annemarie Weissenbacher[1], Carlo Ceresa[1], Chris Morris[5], Les Russell[5], Constantin Coussios[4], Peter Friend[1].
[1]Nuffield Department of Surgical Sciences, University of Oxford, Oxford Transplant Centre, Oxford, United Kingdom; [2]Liver Transplant Surgery, Queen Elizabeth Hospital, Birmingham, United Kingdom; [3]Liver Transplant Surgery, King's College Hospital, London, United Kingdom; [4]Institute of Biomedical Engineering, University of Oxford, Oxford, United Kingdom; [5]OrganOx Ltd, OrganOx Ltd, Oxford, United Kingdom.

Normothermic Machine Perfusion (NMP) of the liver offers a potential solution to the global organ shortage crisis. Our group in Oxford have now perfused over 150 human livers that have gone on to be transplanted.
Meticulous surgical technique is required during preparation and cannulation of the liver if NMP is to be performed successfully.
We illustrate the process of connecting the liver to the OrganOx *metra*, achieving haemostasis during NMP, and give examples of common challenges encountered and how they are managed.

Contrast-enhanced intraoperative ultrasonic cholangiography in living donor hepatectomy

Takeshi Urade[1,2], Takumi Fukumoto[1], Masahiro Kido[1], Atsushi Takebe[1], Motofumi Tanaka[1], Kaori Kuramitsu[1], Hisoka Kinoshita[1], Shinichi So[1], Toshihiko Yoshida[1], Keisuke Arai[1], Daisuke Kuroda[2], Yonson Ku[1].
[1]Hepato-Biliary-Pancreatic Surgery, Kobe University, Kobe, Japan; [2]Surgery, Kita-harima Medical Center, Ono, Japan.

Introduction: Radiographic intraoperative cholangiography (IOC) has been widely used to reduce the biliary complications in living donor hepatectomy (LDH), but it has radiation exposure and difficulty with handling a C-arm machine, generating 3D images and delineating thin caudate branches. Recently, we have established a novel IOC technique, contrast-enhanced intraoperative ultrasonic cholangiography (CE-IOUSC) as a tool for real-time biliary navigation in hepatobiliary surgery[1],[2]. In this video, we demonstrate the usefulness of CE-IOUSC compared with radiographic IOC in LDH.
Materials and Methods: CE-IOUSC was performed using an AplioXG ultrasound imaging system with a 4D probe, a T-shaped linear probe and a micro-convex probe (Toshiba Medical Systems). After temporary clamping of the common bile duct, diluted ultrasound contrast agent Sonazoid (perfluorobutane) was injected via a 4Fr transcystic catheter. CE-IOUSC was performed followed by radiographic IOC before hepatectomy, before bile duct division, and after purocurement of the graft. We describe the case of a 29-year-old woman who was scheduled to undergo extended left hepatectomy as donor using CE-IOUSC and radiographic IOC.
Results: 3D CE-IOUSC could detect accurate biliary configuration as well as radiographic IOC. 2D CE-IOUSC could help us to determine an optimal cutting point of the hepatic duct at the hepatic hilum. In addition, 2D CE-IOUSC on the cut surface showed the patency of the hepatic duct in the remnant liver without biliary stricture. The postoperative course was uneventful in the donor and the recipient.
Discussion: CE-IOUSC can facilitate the surgeon's understanding of the biliary configurations with 3D mapping and 2D regional anatomy of biliary tree to reduce the potential risk of bile duct injury. In particular, 2D-CEIOUSC can facilitate understanding the spatial relationships between bile ducts and liver parenchyma simultaneously as opposed to radiographic IOC. CE-IOUSC is relatively safe without radiation exposure.
Conclusions: CE-IOUSC is a novel IOC technique that provides excellent visualization of the biliary tree for LDH. This biliary navigation technique facilitates identification of the biliary system, guidance for bile duct division and confirmation of the remnant biliary system.

Total artificial heart bridge to combined heart-liver transplantation for transthyretin amyloidosis

Amit Sharma, Adrian Cotterell, Daniel Tang, Chandra S.Bhati, Keyur Shah, Richard Stravitz, Marlon Levy, Vigneshwar Kasirajan.
Surgery, Virginia Commonwealth University, Richmond, VA, United States.

Introduction: Transthyretin amyloidosis (ATTR) associated cardiomyopathy is due to cardiac deposition of mutant transthyretin protein produced by the liver. In patients with severe cardiomyopathy and limited other organ involvement, combined heart-liver transplantation (HLT) is the preferred treatment. Due to limitations in available donor organs, many patients in need of a heart transplant require bridging with mechanical circulatory support. The vast majority is supported with left ventricular assist devices (LVAD). However, the restrictive cardiomyopathy associated with ATTR is anatomically suboptimal for LVAD support. We share our experience of four cases of combined HLT for ATTR. This video demonstrates one of the recipients' who was bridged with a total artificial heart (TAH) before under going HLT.
Materials and Methods: We retrospectively analyzed our center's databank for patients who received a combined heart-liver transplantation (2013-present). Primary outcomes included patient and graft survival. Secondary outcomes included allograft rejections and post-operative complications. Informed consent was obtained from all recipients as per institutional guidelines.
Results: Four patients (Table 1) received a combined heart-liver transplantation for ATTR associated cardiomyopathy. Two patients were bridged with TAH. The most common mutation in our patients was Ile122 (75% patients). One patient experienced renal failure requiring hemodialysis post-transplant. All four patients are alive with excellent cardiac and liver allograft function. None of the patients experienced any rejection episodes.
Heart-Liver Transplantation for ATTR Cardiomyopathy: Single center experience (2013-present)
Age/SexMutationPre-Tx Mechn. SupportDomino Liver TxFollow up (mo)ComplicationsRejection147 MAsp18AsnNoneYes63Ventral herniaNone257 FIle122NoneYes48Renal failureNone354 MIle122Total artificial heartNo38NoneNone461 MIle122Total artificial heartNo3Groin abscessNone
Discussion of Case Video Summary: 61 M (patient #4) with transthyretin amyloidosis (Ile122 mutation) presented with symptomatic cardiomyopathy. He underwent multidisciplinary evaluation and was listed for combined heartliver transplantation. He progressed to severe decompensated heart failure despite inotropes and underwent TAH implant as a bridge to transplant. He was discharged home with the TAH on a portable driver. After 109 days of TAH support, he matched to a brain dead deceased donor and successfully underwent combined heart-liver transplantation.
Conclusions: Combined heart-liver transplantation is the preferred treatment for ATTR associated cardiomyopathy. These patients have unique considerations that require multidisciplinary planning and coordination in the pre-, intra-, and post-operative phases for successful outcomes.

Robotic assisted kidney transplantation

Volkan V.Tugcu[1], SelcukS. Sahin[1], Abdullah Yavuzsan[1], Fatih Gokhan F.G.Akbay[2], Serdar S.Karadag[1], Ahmet Faysal A.F.Guler[1], Suheyla S.Apaydin[2].
[1]Urology Clinic, Bakirkoy Dr. Sadi Konuk Training and Research Hospital, Istanbul, Turkey; [2]Nephrology Clinic, Bakirkoy Dr. Sadi Konuk Training and Research Hospital, Istanbul, Turkey.

Purpose: Kidney transplantation is the best treatment of patients with end-stage renal disease. While open surgery remains the gold standard, minimally invasive surgery has recently been introduced for the recipient undergoing kidney transplantation. We present in this video kidney transplantation using da Vinci-Xi robotic system in our clinic.
Material and Methods: A left live donor kidney was transplanted into a 43-year-old male patient who had underwent hemodialysis for 2 months. Surgery was done with the help of the da Vinci-Xi robotic system. A GelPOINT access port was placed within a 4 cm periumblikal incision for delivery of ice-slush and introduction of the graft kidney. Vascular dissection and anastomosis as well as ureterovesical anastomosis was performed completely using robotic system.
Results: Operation time (incision to closure) was 230 minutes. Total blood loss was 170cc. There wasn't any perioperative or postoperative complications. The uretral catheter and 2 drains withdrawed at 3th day of the operation and the patient was discharged at 5th day of the operation.
Conclusion: Robotic assistance made anastomosis possible by its unique ability of stereoscopic magnification and ultra-precise suturing techniques due to the flexibility of the robotic wristed instruments. Robotic kidney transplantation(RKT) is a safe and feasible surgical alternative to the standard open approach of kidney transplantation. RKT is associated with reduced postoperative pain, analgesic requirement, and better cosmesis.

Reno- and splenoportal anastomosis for a retransplant patient with situs inversus

Hajime Uchida, Akinari Fukuda, Takanobu Shigeta, Kengo Sasaki, Mureo Kasahara.
Transplant Center, National Center for Child Health and Development, Tokyo, Japan.

Portal vein (PV) thrombosis following pediatric liver transplantation is a serious complication that may lead to graft loss. Living donor liver transplantation (LDLT) poses limitations with regards to the availability of vein grafts for complex PV reconstructions. We herein show a unique reconstruction of the portal vein inflow in a 1-year-old boy with situs inversus undergoing re-LDLT. The inflow was derived from the splenic vein and the right renal vein. A common channel was created utilizing a donor inferior mesenteric vein and the recipient explant left hepatic vein as vascular conduits. With the application of innovative surgical reconstructions, pre-existing portomesenteric thrombosis may be amenable to re-LDLT in the pediatric population.

A case of deceased donor liver transplantation using renoportal anastomosis in patients with diffuse portomesenteric thrombosis

Tae-Seok Kim, Keun Soo Ahn, Yong Hoon Kim, Hyun Ji Lee, Hyoung Tae Kim, Koo Jeong Kang.
Surgery, Dongsan Medical Center, Keimyung University School of Medicine, Daegu, Korea.

Introduction: Adequate portal inflow is essential for successful liver transplantation. However, portal vein thrombosis (PVT) is not uncommon in end stage liver disease and PVT was considered as relative contraindication of liver transplantation in past because of technical difficulties that induced an increased intraoperative bleeding and an inability to establish adequate portal inflow. However, with technical improvement such as venous eversion thrombectomy, vascular interposition grafts, and use of portal vein collaterals, PVT has not been accepted as contraindication of liver transplantation any more. Here, we describe a successful case of deceased donor liver transplantation (DDLT) with renoportal anastomosis in patient with diffuse portomesenteric thrombosis.
Case: A 67-year-old man was diagnosed with alcoholic liver cirrhosis 17 years ago and had been followed-up regularly. Segmental PVT was developed 8 years ago and had been extended to superior mesenteric vein and splenic vein. The patient had undergone endoscopic esophageal variceal ligation twice for hematemesis and paracentesis frequently for ascites control. Preoperative CT scan revealed features of diffuse mesoportal thrombosis, splenic vein thrombosis with splenomegaly, cavernous transformation of portal vein, and large splenorenal shunt. This patient underwent deceased donor liver transplantation. Inferior vena cava was anastomosed with piggy-back technique and portal flow was obtained from left renal vein (eno-to-end anastomosis) using iliac vein graft from . The anastomosis of hepatic artery and bile duct was performed rountine manner. Introperative and postoperative Doppler sonography showed adequate portal flow and liver function was improved gradually. CT which performed at postoperative 10 days and 1 month showed good portal inflow from left renal vein.
Conclusion: In case of diffuse portomesenteric thrombosis with splenorenal shunt, renal vein can be a good source for reconstruction of portal inflow.

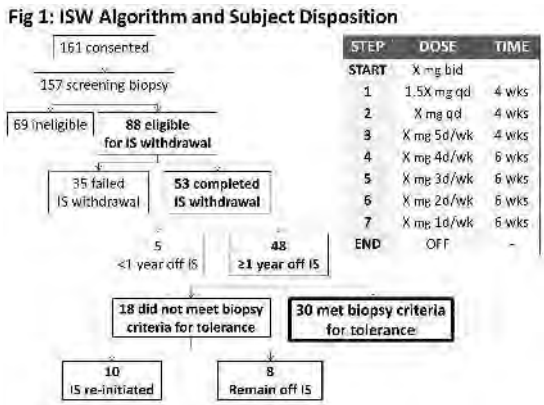
Primary outcome of iWITH: A 12 center North American clinical trial of immunosuppression withdrawal in stable pediatric liver transplant recipients

S. Feng[1], J. Bucuvalas[2], A.J. Demetris[3], K. Spain[4], J. Magee[5], G. Mazariegos[3], S. Kanaparthi[6], E. Doo[7], N. Bridges[8].
[1]UCSF, San Francisco, CA, United States; [2]Cincinnati Childrens Hosp, Cincinnati, OH, United States; [3]University of Pittsburgh, Pittsburgh, PA, United States; [4]RHO, Chapel Hill, NC, United States; [5]University of Michigan, Ann Arbor, MI, United States; [6]ITN, Seattle, WA, United States; [7]NIDDK, Bethesda, MD, United States; [8]NIAID, Bethesda, MD, United States.

Background and Aim: Considering the chronic and cumulative disease burden imposed by conventional immunosuppression (IS), it is intuitive that IS discontinuation would improve patient outcomes. A pilot study of pediatric parental living donor liver transplant (LT) recipients undergoing IS withdrawal (ISW) with 60% (12 of 20 subjects) success has been reported [1]. iWITH, a multi-center clinical trial funded by NIAID, NIDDK, and ITN, was designed to extend these preliminary results by:1) including deceased donor LT recipients 2) determining prevalence of operational tolerance (OT) within a clinically useful confidence interval for the specified population, 3) confirming the safety of ISW and 4) elucidating biomarkers and/or mechanisms of OT.
Methods: 88 highly selected pediatric LT recipients (39 boys/49 girls; 31 living/57 deceased grafts; Fig 2a) at 12 North American centers met clinical, biochemical, and histological eligibility criteria. ISW occurred in 8 steps over 36-48 weeks (Fig 1). ALT or GGT >100 IU/L mandated for cause liver biopsy. The 1° endpoint of OT was assessed 1 year after the last IS dose and was defined per protocol as stable ALT, GGT and histology compared to study entry 2 years earlier. Logistic regression analyses assessed for associations between completed ISW and baseline clinical, immunologic [Class II donor specific antibody (DSA)] and histological (including C4d score) factors.
Results: 35/88 (40%) subjects failed ISW prior to OT assessment, all 2° to rejection [31 biopsy-proven (24/6/1 Banff mild/moderate/inadequate per central pathologist) and 4 clinical; Fig 1]. No baseline clinical, immunological or histological factors, including living/deceased donor, Class II DSA presence/absence, or C4d score predicted completed (n=53) vs failed (n=35) ISW (Fig 2b). Five subjects are off IS <1 year and await OT assessment (last subject due before 4/1/2016). The remaining 48 subjects have been assessed for OT. All subjects met laboratory OT criteria; 30/48 (62.5%) subjects have also met histological OT criteria [Fig 1]. Of the 18 (37.5%) subjects who did not meet histological OT criteria,10 have re-initiated while 8 remain off IS. 5 subjects experienced 5 study-related serious adverse events: 3 related to liver biopsy (bile leak; cholangitis; cellulitis) and 2 related to ISW (in-patient rejection treatment with intravenous corticosteroids).

Fig 1: ISW Algorithm and Subject Disposition



Conclusions: Selected pediatric LT recipients from living or deceased donors can safely attempt ISW and may achieve OT. Notably, a significant proportion met biochemical but not histological criteria for OT, suggesting a pivotal role for biopsy to assess for OT and long-term safety. Although baseline clinical, immunological and histological features did not predict the outcomes of ISW, planned mechanistic assays including immunophenotyping and gene expression profiling of tissue and peripheral blood may identify an OT biomarker and/or elucidate OT mechanisms.

AT1R antibodies at 1-year negatively impact 5-year native renal function in liver transplant recipients

Duska Dragun[1,4], Aurelie Philippe[1], Harald Heidecke[3], Robert Freeman[2], Linda W.Jennings[2], Rusan A.Catar[1,4], Goran B.Klintmalm[2], Jacqueline G.O'Leary[2].
[1]Nephrology and Critical Care Medicine, Charité University Berlin, Berlin, Germany; [2]Annette C. & Harold C. Simmons Transplant Institute, Baylor University Medical Center, Dallas, TX, United States; [3]CellTrend GmbH, Luckenwalde, Germany; [4]Berlin Institute of Health, Berlin, Germany.

Angiotensin II Type-1 Receptor (AT_1R) antibodies have been associated with pulmonary hypertension, renal allograft loss, and fibrosis progression in liver allograft recipients especially if combined with HLA donor-specific alloantibodies (DSA). However, long-term outcome in liver allograft recipients is not only impacted by allograft fibrosis but also renal function. We therefore sought to determine if native renal function was impacted in liver allograft recipients by the presence of AT_1R antibodies.

Methods: Primary liver allograft recipients at Baylor University Medical Center from 1/00 to 4/09 had their prospectively collected pre-transplant (1269 patients) and year-1 post-transplant (795 patients) serum tested retrospectively for AT_1R (>10) antibodies. AT_1R-antibody testing was accomplished with standardized solid phase assay. Since AT_1R antibodies have been associated with hypertension this factor was not controlled for in multivariable modeling.

Results: Pretransplant AT_1R did not change the median delta creatinine from pretransplant to 3-months post-transplant. In patients with vs. without AT_1R at 1-year post-transplant a median unadjusted change in MDRD6 of -5.4. vs. -1.1mL/min (p=0.01) was found. In multivariable analysis when controlling for diabetes (DM) and calcineurin inhibitor (CNI) use at 1-year AT_1R-Ab at 1-year remained statistically significantly associated with a decline in GFR (calculated by MDRD6) from year 1 to 5 post-transplant (p=0.018, Table 1). This decline may have been more pronounced (p=0.06) in patients on a CNI; however, the decline was most pronounced in diabetic patients with AT1R at year-1 (p=0.004).

Conclusion: AT_1R antibodies post-liver transplant are associated in multivariable analysis with an increased risk of native renal function decline especially in diabetic patients. AT_1R positive patients may benefit from CNI free immunosuppression.

Multivariable at 1-year to predict decline in renal function at 5 years

555.3

The impact of preformed donor-specific antibodies in living donor liver transplantation depending on graft volume

Ryoichi Goto[1], Yasuyuki Koshizuka[1], Norio Kawamura[1], Masaaki Zaitsu[1], Minoru Ota[2], Toshiya Kamiyama[1], Kenichiro Yamashita[3], Akinobu Taketomi[1], Tsuyoshi Shimamura[3].
[1]Department of Gastroenterological Surgery I, Hokkaido University, Sapporo, Japan; [2]Division of Organ Transplantation, Hokkaido University Hospital, Sapporo, Japan; [3]Department of Transplant Surgery, Hokkaido University, Sapporo, Japan.

Background: Preformed donor specific antibodies (DSAs) have been reportedly associated with poorer outcome in heart and kidney transplantation. On the contrary, the correlation between DSA and the liver graft outcome remains controversial because large size of organ, liver graft may be able to absorb antibodies. It is likely that smaller graft size has a relatively higher risk of preformed DSAs on graft survival.
Aim: To identify the prognostic factor of the recipients who developing the preformed DSAs in living donor liver transplantation (LDLT).
Patients and Methods: Adult recipients who underwent LDLT (n=175) in our institute from Sep. 1997 to Jan. 2016 were studied. To assess the preformed DSAs, T (T cell CM) and B (B cell CM) lymphocyte cytotoxicity test (LCT) and T cell IgG flow cytometric cross match (FCXM) test were examined. The cut-off value in LCT and FCXM was 40% and 20% respectively. Results. Of adult LDLT recipients, 28 (16.6%) were pre-transplant FCXM positive alone (i.e. LCT negative). Sixteen (9.1%) were detected as LCT positive. Of 16 LCT (+) patients, 15 were T cell CM positive. There was a trend toward worse graft outcome of FCXM (+) alone (Fig. 1, 5 y graft survival rate; 71.1%) as compared to that of control (79.0%). Notably 7 of 15 T cell CM (+) were died with graft failure (median survival time was 135 days) and the graft outcome was significantly poorer (Fig. 1). Four of 7 graft loss cases with T cell CM (+) were correlated with severe graft rejection. All of cases with T cell CM (+) were performed LDLT before 2006 so that the pre-transplant treatments has not been appropriately evaluated. To identify the risk factors of poorer graft survival, we compared the pre-transplant status and donor factors between graft loss and alive in T cell CM (+) patients. Indeed, 3 of 7 graft loss cases were critically ill in intensive care unit although 5 of 8 were outpatients in alive group. Also MELD score tends to be higher in graft loss group (24±4.7, P=0.12, vs. 15.5±3.4 in alive, medain±SEM). In terms of living donor graft, 6 of 7 graft loss cases (85.7%) were transplanted with a left hepatic lobe. In contrast, 6 of 8 patients (75%) were used a right lobe of living graft in alive patients. Actually Gv/Sv ratio (36.2±2.1%) and graft volume (368.0±23.6g) of graft loss cases were significantly lower than those of alive cases (Fig. 2, *p<0.03, 52.8±6.7% and 563.5±63.4g respectively, median ± SEM).

Fig.1

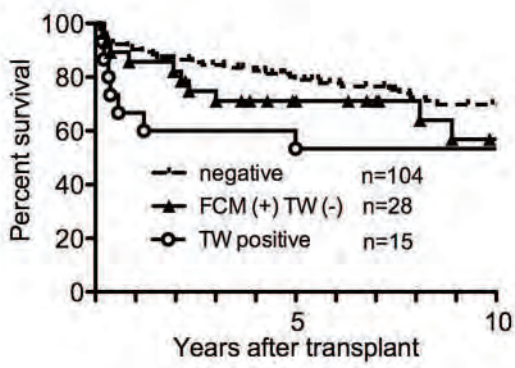

Fig. 2

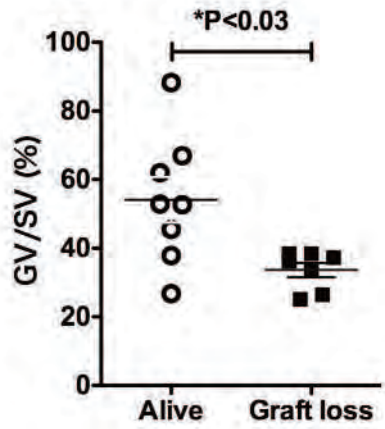

Conclusion: With recent acvances in immunotherapy, pre-transplant desensitization may reduce the risk of graft loss in preformed DSA patients. However our data suggests that smaller graft volume such as left partial grafts in the presence of preformed DSAs can predict the graft failure. Under the preformed DSAs, the living donor selection should be consider the graft volume.

555.4

The strategy for living donor liver transplantation in the recipients with preformed donor specific antibodies

Atsushi Yoshizawa[1], Eri Ogawa[1], Shintaro Yagi[1], Koichiro Hata[1], Aya Miyagawa[2], Hideaki Okajima[1], Toshimi Kaido[1], Hironori Haga[2], Shinji Uemoto[1].
[1]Department of Surgery, Kyoto University Hospital, Kyoto, Japan; [2]Department of Diagnostic Pathology , Kyoto University Hospital, Kyoto, Japan.

Introduction: The impact of preformed donor-specific anti-HLA antibodies (DSA) on the survival rate of liver transplantation is controversial. We previously reported that the one-year survival rate of those with preformed DSA was 60%, significantly lower than those without preformed DSA, and that the quantity of DSA influenced on the prognosis[1]. We also reported the cases with perioperative fatal antibody mediated rejection (AMR)[2]. We have adopted the strategy to prevent fatal AMR; the sera are preoperatively examined in various ways and if DSA are detected strongly, we change the donors or performed preoperative desensitization by Rituximab.
Methods: 315 recipients underwent liver transplant between 2009 and 2014, including 289 cases of living-donor liver transplantation (LDLT), 26 cases of deceased-donor liver transplantation (DDLT). The sera were examined to detect preformed DSA by complement-dependent cytotoxicity (CDC), flow cytometry crossmatch (FCXM), and Luminex method using Labscreen single antigen beads. The current strategy for DSA-positive patients is as follows. For LDLT cases, we change the CDC-positive donors, if possible. Otherwise, we administer Rituximab prophylactically. When DSA are detected by FCXM or Luminex, but negative in CDC, we will examine DSA successively after operation and we will perform liver biopsy and diagnose AMR as soon as possible when liver function tests are abnormal. For DSA-positive DDLT cases, we closely examined HLA antibodies by Luminex, and we diagnosed AMR as soon as possible after DDLT. We diagnosed AMR by the pathological findings, the positive C4d staining, and the existence of DSA in the serum. We treated AMR by steroid pulse therapy and intravenous immunoglobulin.
Results: As for LDLT cases, the positive cases of examination of DSA were 10 in CDC, 17 in FCXM, 25 in Luminex method, respectively. In CDC-positive cases, the donors of 5 cases were changed, and Rituximab was preoperatively administered in 6 cases. One year survival rate was 78.8% in DSA-positive recipients, while 82.4% in DSA-negative patients. (p=0.638) Five cases with preformed DSA were diagnosed as antibody mediated rejection and successfully treated by intravenous immunoglobulin, steroid pulse therapy, and plasma exchange. Acute cellular rejection (ACR) was diagnosed in 27% of DSA-negative cases and in 43.8% of DSA-positive cases within one year after operation. (p=0.242) On the other hand, as for DDLT, five cases were positive in the examination of DSA by CDC and Luminex method. One case died one month after DDLT due to infection. And the other two cases were diagnosed as AMR by liver biopsy and treated successfully by steroid pulse therapy and intravenous immunoglobulin. The other two cases were free from AMR, but they were diagnosed as ACR three and seven months after operation and treated by steroid pulse therapy. All cases with preformed DSA turned to be negative DSA one year after operation.
Conclusion: The current strategy for prevention from AMR significantly has improved the survival rate of the patients with preformed DSA. The preoperative examination of DSA is essential to avoid fatal AMR and to diagnose and treat AMR immediately after operation.

Outcomes of sirolimus conversion for calcineurin inhibitor induced neurotoxicity in liver transplantation

Greg McKenna, Peter TKim, Giuliano Testa, Richard Ruiz, Nicholas Onaca, Tiffany Anthony, James Trotter, Robert MGoldstein, Goran BKlintmalm.
Simmons Transplant Institute, Baylor University Medical Center, Dallas, TX, United States.

Introduction: Calcineurin Inhibitor (CNI) neurotoxicity is a complication affecting up to 15% of liver recipients and can be treated with conversion to sirolimus (SRL) along with CNI discontinuation. Symptoms include headache, confusion, dysarthria, seizures, and coma. Concerns of rejection (ACR) and other mTOR inhibitor complications often deter clinicians from making this conversion. We report outcomes of the largest experience of SRL conversion for CNI neurotoxicity.
Materials and Methods: All 3910 pts from 1988-2015 were retrospectively reviewed using a prospectively obtained database, to identify a cohort where CNI was discontinued and SRL was initiated for neurotoxicity symptoms. This was compared to a control group where SRL conversion was done for non-neurotoxicity causes. This cohort was evaluated for ACR, other complications and post-conversion survival.
Results: From 11/1999–12/2014, there were 679 pts converted to CNI-free SRL immunsuppression, with 58 pts (8.5%) converted for CNI neurotoxicity. Median time to SRL conversion was 25 d post OLT (range 6 d–10 yrs) vs 736 d in those converted for non-neuro reasons. 56/58 pts (96.6%) improved/resolved neurotoxicity symptoms following CNI discontinuation.

Complications Post Conversion to SRL-Based CNI Free Regimen

Complication	SRL for Neurotoxicity (n=58)	SRL for Non-Neuro (n=621)	p value
ACR	13 (22.4%)	48 (7.7%)	<0.001
CMV	3 (5.1%)	22 (3.5%)	NS
TA-I	0 (0%)	5 (0.8%)	NS
BD Stricture/Leak	2 (3.4%)	15 (2.4%)	NS
Incisional Hernia	11 (15.5%)	58 (9.3%)	0.04

All 13 ACR episodes in those converted for neurotoxicity occurred when converted in the first 47d post OLT; 53% occurred in conversions in the first 2 weks. Median time to ACR development post SRL conversion, was 13 d vs 79 d for neuro vs non-neuro based conversion.

ACR and Hernia Incidence of ACR by Timing from OLT to SRL Conversion

Timing of Conversion Post OLT	# of Pts	ACR Incidence	Incisional Hernia Incidence
< 30 d	30	12 (40.0%)	6 (20.0%)
> 30 d	28	1 (3.6%)	5 (17.9%)

Comparing SRL conversion for neuro vs non-neuro reasons, the 1 yr pt survival was 92.0% vs 90.1% (p=NS) respectively, while 55% vs 77% remained on SRL for >1 yr (median duration 658 d vs 1721 d). The reason for eventual SRL discontinuation in neuro vs non-neuro pts: pending surgery (13.6% vs 12.8%), ACR (18.9% vs 4.7%), infection (5.2% vs 3.7%) and patient death (1.7% vs 8.5%).
Conclusion: SRL conversion for CNI neurotoxicity can be successful but with a higher ACR and incisional hernia rates compared to other SRL conversion pts. Delaying the conversion after the first 30d post OLT may reduce this risk.

555.6

Comparison of the effects of brand name versus generic immunosuppressants on long-term graft failure risk among U.S. liver transplant recipients: analysis of SRTR and Medicare claims data

Jarcy Zee[1], Ghalib A.Bello[1], Murewa Oguntimein[2], Charlotte A.Beil[1], Qian Liu[1], Jeong Park[3], Adam R.Saulles[4], Sangeeta Goel[4], Rajesh Balkrishnan[5], Melissa Fava[1], Robert M.Merion[1], Alan B.Leichtman[1], Pratima Sharma[6].
[1]Arbor Research Collaborative for Health, Ann Arbor, MI, United States; [2]Food and Drug Administration, Silver Spring, MD, United States; [3]Clinical Pharmacy, University of Michigan, Ann Arbor, MI, United States; [4]Specialty Pharmacy Services, University of Michigan Health System, Ann Arbor, MI, United States; [5]Public Health Sciences, University of Virginia, Charlottesville, VA, United States; [6]Medicine, University of Michigan, Ann Arbor, MI, United States.

Introduction: The use of generic immunosuppressants for liver transplantation (LT) has increased in some countries following expiration of brand name patents. However, the reported risks and benefits of generic substitution have been inconsistent, particularly because bioequivalence requirements differ across countries and only small, short-term studies have examined the effects of substitution on transplant outcomes. Our aim was to compare the effects of brand name and generic tacrolimus on the long-term risk of graft failure in a large, national cohort of U.S. LT recipients.
Methods: Data from the Scientific Registry of Transplant Recipients (SRTR) were used to identify LT recipients who were transplanted from 2008-2013 and Medicare Part D claims data were used to identify patterns of generic and brand name tacrolimus use. LT recipients were followed from the time of transplant until the earliest of repeat transplant, death, loss to follow-up, or end of the study period. Generic or brand name tacrolimus use was recorded at each month of follow-up. Analysis was limited to recipients who had Medicare Part D claims for tacrolimus at any time after transplant and who had graft function at 30 days after transplant. We used a joint model to test the association between brand/generic tacrolimus use and a composite graft failure outcome defined as the earlier of repeat transplant or death. The model was constructed by linking a longitudinal model for the pattern of long-term brand name or generic tacrolimus use with a Cox proportional hazards model for graft failure, adjusted for recipient, donor, and transplant program characteristics.
Results: Table 1 shows descriptive summary statistics on the study cohort (N=4,421). The cohort was predominantly male, white, and aged 50-64 years. The most common primary cause of end-stage liver disease was hepatitis C.

Table 1: Descriptive Statistics on Study Cohort

Age, years, Mean (SD)	54.8 (10.28)
Male, % (N)	63.6 (2811)
Previous Liver Transplant, % (N)	5.4 (237)
Race/Ethnicity, % (N)	
White	67.8 (2996)
Black	10.3 (457)
Asian/Other	5.5 (241)
Hispanic/Latino	16.4 (727)
Primary Cause of Liver Disease, % (N)	
Acute Hepatic Necrosis	3.7 (163)
Alcoholic Liver Disease	12.8 (567)
Cholestatic Disease	7.6 (334)
Hepatitis C	30.9 (1365)
Malignancy	19.3 (852)
Other	25.8 (1140)
Follow-up Time, years, Median (IQR)	3.6 (2.4-4.9)

SD: Standard Deviation, IQR: Interquartile Range (25th 75th percentiles)

There was no significant difference in the long-term risk of graft failure when comparing the use of generic and brand name tacrolimus in LT recipients (Hazard Ratio=1.002, 95% Credible Interval=(0.998-1.006), p-value=0.381).
Conclusion: Our study of a large, national cohort of U.S. LT recipients shows that generic substitution of tacrolimus does not result in a significant difference in the long-term risk of graft failure. Generalizability of the study results beyond the U.S. may be limited by differences between generic tacrolimus formulations used in the U.S. compared with those used in other countries.

Normal liver enzymes do not exclude significant pathology in liver transplant recipients

Richard Gilroy[1], Czarina Sanchez[1], Phillip Johnson[2], Atta Nawabi[1], Bart Kane[1], Shelbi Olson[1], Sean Kumer[1], Timothy Schmitt[1].
[1]Center for Transplantation, University of Kansas Medical Center, Kansas City, KS, United States; [2]Department of Radiology, University of Kansas Medical Center, Kansas City, KS, United States.

Background: Liver biopsies serve a variety of roles in post-transplant analysis and most often are used to evaluate abnormal liver enzymes (LE); however biopsies are not without risk. In the post-transplant setting protocol biopsies (PB) are employed by some centers however their role remains controversial. This study evaluates whether PBs serve any purpose in those with normal LEs at the time biopsy by assessing for the frequency of abnormal pathologies, the significance of these pathologies and for what factors might predict a significant pathology being present with normal LEs.
Methods: A 3 year analysis of a prospectively maintained medical record was queried in all patients enrolled in a PB pathway. All patients included in th analysis were post-liver transplant with normal LEs on 2 occasions immediately prior to PB being performed. Normal LEs were defined as AST < 40, ALT <45 and Alkaline Phosphatase <100 and imaging with Doppler ultrasound also had to be normal. All demographic data on the cases and all complications, histology, and clinic actions generated from the histology identified were collected. A statistical analysis using SPSS was then used to evaluate for both predictors of abnormal histology and clinical action.
Results: 400 PBs were performed in 178 patients of which 84 PBs were associated with normal LEs. Of these patients the most common liver diseases were HCV, alcohol, NASH, AIH, and PSC and the average time from transplant to PB was 2 years (range 6 months to 8 years). A total of 2 episodes of cholangitis occurred with PBs and there were no bleeding episodes requiring hospitalization or transfusion. 79% of the PB had abnormal histology findings including varying grades of steatosis, inflammation, hepatic fibrosis and in 6 cases cirrhosis were identified. The presence of abnormal LEs at 3 months post-transplant (n=29) was associated with higher inflammatory (p=0.027) and fibrosis (p=0.003) scores at the time of any PB when compared to those with normal LEs at 3 months. In those with normal LEs and abnormal PBs, interventions including treatment of HCV, evaluation for biliary stricture disease, treatment of rejection or changes to immunosuppression management occurred in over 50% of patients. in performing the PBs these were equally likely to be performed by hepatology and interventional radiology and no difference in complications seen.
Conclusions: The early clinical course, donor characterists, and the presence of abnormal LEs at 3 months influence the probability of a PB being abnormal. PBs are infrequently associated with complications and provide useful clinical information that does impacts clinical care pathways in those with normal LEs. A terminology change to management biopsies rather than PBs might be considered in our era of immunosuppression minimization strategies and the greater use of extended criteria donors as a role for PBs appears evident.

Preferential accumulation of T helper cells but not cytotoxic T cells characterizes benign subclinical rejection of human liver allografts

Anna K.Baumann[1], Fatih Noyan[1,2], Matthias Hardtke-Wolenski[1], Jerome Schlue[3], Frank Lehner[2,4], Juergen Klempnauer[4], Michael P.Manns[1], Elmar Jaeckel[1,2], Richard Taubert[1,2].
[1]Gastroenterology, Hepatology and Endocrinology, Hannover Medical School, Hannover, Germany; [2]Integrated Research and Treatment Center Transplantation (IFB-Tx), Hannover Medical School, Hannover, Germany; [3]Pathology, Hannover Medical School, Hannover, Germany; [4]General, Abdominal and Transplant Surgery, Hannover Medical School, Hannover, Germany.

Introduction: Subclinical rejection (SCR) is a common event in protocol biopsies after liver transplantation. So far the understanding of its underlying histological changes, immune regulation and clinical significance is very limited. Previous studies were restricted to SCR manifestations within the first weeks after transplantation and showed no consequences on clinical outcome even when SCR was left untreated.
Materials and Methods: We included all 94 patients from our prospective protocol biopsy program from 2008 until 02/2013 who received at least one liver biopsy and who had no viral hepatitis (HBsAg and HCV-RNA negativity). To allow for a longer follow-up these patients we then observed for another 30 months. SCR was defined as histological rejection with liver enzymes (AST, ALT, AP) below the two times upper limit of normal, while acute cellular rejection (ACR) was defined as rejection with liver enzymes above this threshold. Patients with late SCR were compared to late ACR regarding the intrahepatic and peripheral blood T cell compartment (CD4+FOXP3+ regulatory T cells, CD4+ and CD8+ cells).
Results and Discussion: Late SCR, at least 3 months after transplantation, was a common event (41/94 patients) in our program. SCR manifested with in mean 27 (4-83) months after liver transplantation much later than ACR. In the second year after transplantation the SCR incidence in protocol biopsies reached a plateau of about 25% and remained there until the latest observed manifestations more than 5 years after transplantation. During a mean follow-up of 36 (12-73) months after SCR no acute or chronic rejection, no progressive graft fibrosis, graft loss or liver related death occurred even without specific therapy for SCR. Immunophenotyping of liver biopsies during SCR showed that similar to ACR, the composition of intrahepatic T cells was depended on the severity of histological rejection. However, SCR showed a different pattern of infiltrating T cells with a stronger accumulation of CD4+ cells, an increasing CD4+/CD8+ ratio, and an increasing CD4+FOXP3+ regulatory T cell/CD8+ ratio with the severity of histological rejection, which was not seen in ACR. These intrahepatic T cell patterns were not reflected in the peripheral blood.
Conclusion: Late SCR after liver transplantation has a good prognosis and it seems save to leave it untreated. This benign clinical course compared to ACR is associated with T cell infiltration patterns in the graft that point to a stricter regulation of the cytotoxic T cell compartment.

Experience with mTOR inhibitors in pediatric liver transplantation

Figen Özçay[1], Zeren Barış[1], Meltem Gülşan[1], Gökhan Moray[2], Mehmet Haberal[2].
[1]Department of Pediatric Gastroenterology, Baskent University Hospital, Ankara, Turkey; [2]Department of General Surgery, Baskent University Hospital, Ankara, Turkey.

Aim: We evaluated the use of mTOR inhibitors in pediatric liver transplanted patients.
Methods: We retrospectively collected the data of children who underwent liver transplantation between 2003-2015 in Baskent University Hospital and used mTOR inhibitors as a part of immune suppressive treatment. We evaluated the demographic features of the patients, indications for use and complications of mTOR inhibitors and changes in leucocyte, thrombocyte counts and glomerular filtration rates (GFR) of patients during treatment course.
Results: There were a total of 21 patients (male/female ratio:11/10) who used mTOR inhibitors during course of immune suppressive treatment. Patients were between 147,57±72,17 months old. The mean age at transplantation was 81,23±71,46 months.
Fourteen patients used sirolimus, while 7 patients used everolimus. The reasons to switch to sirolimus was posttransplant lymphoproliferative disease (PTLD) in five patients (35,7%), chronic rejection and decrease in graft functions in two patients (14,3%), malignancy in two (14,3%) (relaps of Langerhans cell histiocytosis and hepatocellular carcinoma), inflammatory bowel disease in two (14,3%), neuropathy due to calcineurin inhibitors (CNI) use in two (14,3%) and recurrent acute rejection in one (7,1%) patient. The reasons to switch to everolimus was nephrotoxicity of CNI in three patients (42,8%), recurrent acute rejection in two (28,6%), chronic rejection in one (14,3%) and sepsis in one (14,3%) patient.
Sirolimus was used as the only immune suppressive drug in 11 patients and combined with tacrolimus in three patients, and everolimus was combined with low dose tacrolimus in all patients. Postoperative times to introduce sirolimus and everolimus were 26,46±24,49 months (min-max: 3-78 mo) and 14,78±28,97 months (min-max: 1-80 mo) respectively.
The mean trough levels of sirolimus were 8,67±3,37 ng/ml. The mean trough levels of everolimus were 4,49±1,58 ng/ml. Postoperative starting time was significantly shorter (p=0,031), mean period of time of use was significantly shorter (p=0,006) and the mean GFRs at the beginning of the treatment were significantly lower (p=0,015) in everolimus group when compared to sirolimus group.
Complications of sirolimus treatment were noted as acute rejection, infection and aphtous stomatitis, while infection, aphtous stomatitis and growth failure were recorded as complications in patients using everolimus. We did not observe any complications in 9/14 patients who used sirolimus and 5/7 patients who used everolimus.
Sirolimus was discontinued in three patients because of health insurance problems (one patient) and rejection (two patients) after 6,5 years, 5 months and 8 months respectively. Everolimus was discontinued in one patient due to severe candida esophagitis after 5 months.
Conclusion: Use of mTOR inhibitors in pediatric liver transplantation is safe and efficacious and offers promising results.

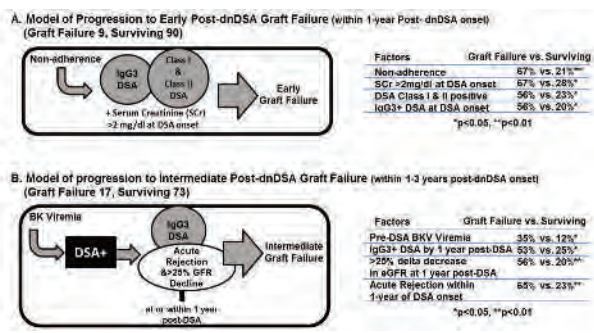
Models of allograft failure in primary renal transplant recipients with anti-HLA alloantibodies (DSA)

Matthew Everly[1], Lorita M.Rebellato[2], Carl E.Haisch[2], Kimberly P.Briley[2], Paul Bolin[2], Scott A.Kendrick[3], Claire Morgan[2], Angela Q.Maldonado[4], Anh Nguyen[1].
[1]Terasaki Foundation Laboratory, Los Angeles, CA, United States; [2]East Carolina University, Greenville, NC, United States; [3]Eastern Nephrology Associates, Greenville, NC, United States; [4]Vidant Medical Center, Greenville, NC, United States.

A better understanding of which patient and alloantibody characteristics correlated to timing of graft failure (early, intermediate, and late post-dnDSA) is needed to help in making an informed decision regarding treatment. In our study we aimed to descibe the most common model of post-dnDSA graft failure (and non-failure).
Methods: We performed a single center retrospective analysis of 99 dnDSA positive patients receiving a primary transplant between 3/99 to 12/10 that had 3 years of post-dnDSA follow-up. All patients had HLA antibody monitoring by single antigen beads pre-txp, post-txp at 1,3,6,9,12 months, and annually, thereafter. IgG subclass testing was performed on samples following dnDSA. All patients were pre-txp DSA (-).
Results: Of the cohort, 9% of patients developed early post-dnDSA graft failure (<1 year post-dnDSA). This was triggered by non-adherence ($p<0.01$ vs grafts surviving beyond 1 year post-dnDSA, Fig A). The early graft failure group's profile at dnDSA onset had higher rates of IgG3 dnDSA, HLA Class I + II dnDSA, and serum creatinine above 2 mg/dL.
Of the cohort, 17% of patients developed intermediate post-dnDSA graft failure (1-3 year post-dnDSA). The intermediate graft failure group (n=17) was compared to the group with good graft function at least 1-3 years post-dnDSA (n=70) (Fig B). The intermediate graft failure patients had a higher rate of BK viremia (p=0.02). The development of IgG3 dnDSA by 1 year post-dnDSA occurred in two times as many intermediate graft failure patients [hazard ratio (HR) 3.4, 95%CI 1.2-9.0]. Additionally, acute rejection by 1 year post-dnDSA (HR 5.0, 95% CI 1.9-13.7) and >25% eGFR decline at 1-year post-dnDSA (compared to eGFR at dnDSA onset, HR 6.5, 95% CI 2.4-17.5) predicted graft failure between 1 - 3 years post-dnDSA.
Finally, 15% of dnDSA positive cases developed late graft failure >3 yeats post-dnDSA). This group (n=15) was compared to dnDSA + grafts functioning > 3 years post-dnDSA (n=58). Acute rejection by 1 year post-dnDSA and IgG3 dnDSA by 1 year post-dnDSA were good predictors of late graft failure. In late graft failure, 87% eventually developed IgG3 (vs 21% in. Long-term function grafts).



Conclusions: Identifying BK virus viremia, non-adherence, IgG3 DSA, and post-DSA acture rejection or >25% decrease in eGFR may be useful when trying to prevent early and intermediate allograft failure after the appearance of dnDSA.

Tubulointerstitial expression of connective tissue growth factor in renal allograft protocol biopsies at 3 months predicts interstitial fibrosis at 5 years

Thomas Vanhove[1], Hiroshi Kinashi[3], Tri Q.Nguyen[2], Evelyne Lerut[4], Roel Goldschmeding[2], Dirk R.J.Kuypers[1].
[1]Nephrology and Renal Transplantation, University Hospitals Leuven, Leuven, Belgium; [2]Pathology, University Medical Center Utrecht, Utrecht, Netherlands; [3]Nephrology, Nagoya University Hospital, Nagoya, Japan; [4]Pathology, University Hospitals Leuven, Leuven, Belgium.

Introduction: Connective tissue growth factor (CTGF) is an important mediator of renal allograft fibrosis and urinary CTGF levels correlate with the development of human allograft interstitial fibrosis. We set out to evaluate the added predictive value of CTGF protein expression in early protocol biopsies for the subsequent development of allograft fibrosis.
Methods: Single center observational cohort study of 171 kidney transplant recipients with paired protocol biopsies at 3 months as well as 5 years after transplantation. Biopsies were scored according to the revised 1997 Banff criteria. Three month biopsies were immunohistochemically stained for CTGF. Tubulointerstitial CTGF positive surface area was scored visually and categorized as absent (<1%), minimal (1-10%), moderate (10-25%) or extensive (>25%). Urinary CTGF at 3 months after transplantation was measured using a sandwich ELISA (Fibrogen, South San Francisco, CA).
Results: In multivariate multinomial regression analysis, the only predictors of interstitial fibrosis at 5 years were donor age (OR 1.04 [1.01-1.07], OR 1.06 [1.03-1.11], OR 1.05 [1.01-1.08] for ci score 1, 2 and 3 vs. 0, respectively; $p<0.01$ for all) and moderate to extensive CTGF positivity (OR 2.48 [1.09-5.61], p=0.03; OR 4.57 [1.33-16.63], p=0.016; OR 2.12 [0.77-5.81], p=0.15 for ci score 1, 2 and 3 vs. 0, respectively). In the subgroup of patients (n=126) with no interstitial fibrosis at 3 months (ci score 0), independent predictors of progression to any degree of interstitial fibrosis (ci score ≥ 1) at 5 years were donor age (OR 1.04 [1.02-1.07], p=0.001), moderate to extensive CTGF positivity (OR 2.68 [1.12-6.42], p=0.027) and urinary CTGF concentration (OR 5.51 [1.52-19.99] per 10-fold increase, p=0.009). Independent predictors of renal function at 5 years were donor age ($p<0.001$), renal function at 3 months ($p<0.001$) and occurrence of biopsy-proven acute rejection in the first 3 months (p=0.019).
Conclusion: CTGF expression in protocol biopsies 3 months after transplantation predicts interstitial fibrosis in protocol biopsies at 5 years, independent of donor age. CTGF staining might contribute to early detection of patients at high risk for chronic allograft injury.

556.3

Effect of epigenetic modifications in graft kidneys progressing to chronic allograft dysfunction

Sai Vineela Bontha[1], Daniel G.Maluf[1], Erika Rhone[2], Kenneth Brayman[1], Valeria Mas[1].
[1]Transplantation, UVA, Charlottesville, VA, United States; [2]Pediatrics / Nephrology, UVA, Charlottesville, VA, United States.

Background: Interstitial fibrosis with tubular atrophy (IF/TA) is a final event leading to graft loss post-kidney transplantation (KT) and represent the result of continuous immunological and non-immunological insults to the graft. DNA methylation is an epigenetic factor that regulates downstream gene expression in response to environmental/metabolic stimuli and may provide important insight into the gene expression pattern associated with allograft dysfunction. Herein, the effect of methylation patterns on gene expression in renal allograft with IF/TA when compared to grafts with normal function and histology and pre-implantation biopsies.
Methods: 62 Illumina 450K methylation and 22 Gene expression (n=22) (Affymetrix HG-U133Av2 Gene Chips) array analyses were performed on samples obtained from allograft nephrectomies/biopsies from KT recipients. 40 pre-implantation tissue samples were classified based on the consequent development of IFTA post-transplantation (n=20 IFTA, n= 20 normal histology). Using 1-Pearson's correlation supervised cluster analysis, the methylation pattern in pre-implantation biopsies was compared to a separate cohort of 22 biopsy samples obtained at 24 months post-transplantation (n=11 IFTA, n=11 normal graft function (NFA)). Gene expression was also donein same biopsies Differentially methylated CpG regions were identified using Minfi Bioconductor package and Subset within array normalization method was used. For gene expression analysis, the two groups were compared using a moderated t-test using the limma Bioconductor package and probe sets were considered significant when the false discovery rate (FDR) was <0.01. DNA methylation and gene expression data integration a probeset analysis were conducted using IPA.
Results: Cluster analysis of differentially methylated CpGs showed all 24 month IF/TA biopsies in one cluster. All of the pre-transplant biopsies and 24 month NFA biopsies formed a separate cluster. This suggests that the change in methylation pattern of allograft may drive progression towards IF/TA. The role of differential allograft methylation on gene expression was addressed by paired methylation and gene expression analysis in biopsies from IF/TA and NFA. A total of 21,351 CpG sites associated with 6235 genes were differentially methylated in renal allografts with IF/TA in comparison to NFA (FDR < 0.01). 48.6% of the CpG sites were hypermethylated and involved genes like NPNT, LAMC1, ENaC, SLC9A1 that are important for repair and functioning of the kidney. The 51.3% that were hypomethylated involved immune response, apoptosis and antigen presentation related genes. Using gene expression analysis 2412 genes were differentially expressed between IF/TA and NFA allografts of which 648 genes had associated CpG sites differentially methylated. Integration analysis resulted in 31 genes that mapped to >10 significant CpG sites. These include genes like TAP1, PSMB8, HLA-DPA1 associated with Antigen presentation pathway (pvalue = 2.66 E-07), PTPN6, PIK3CD associated with cytokine signaling and upstream regulator like SP1 involved in differentiation or activation of B cells and macrophages.
Conclusion: DNA methylation modifications of allografts associate withprogression to IF/TA possibly by regulating genes related to inflammatory response, kidney tissue atrophy and apoptosis.

Inflammation in scarring on 1 year surveillance biopsies does not change the 5 year prognostic of kidney transplantation

Grégoire Couvrat-Desvergnes[1,2,3], Karine Renaudin [4], Aurélie Le Thuaut[5], Jacques Dantal [2,3], Anne Devys[7], Stéphanie Castagnet[7], Richard Danger[3], Sophie Brouard[3], Yohann Foucher[6], Magali Giral[2,3].
[1]Nephrology, CHD La Roche sur Yon, La Roche sur Yon, France; [2]ITUN, CHU Nantes, Nantes, France; [3]INSERM UMR 1064, University Nantes, Nantes, France; [4]Anatomopathologie, CHU Nantes, Nantes, France; [5]Unité de Recherche Clinique, CHD La Roche sur Yon, La Roche sur Yon , France; [6]EA-SPHERE Laboratory EA 4275 – Biostatistics, Clinical Research and Pharmaco-Epidemiology, University Nantes, Nantes, France; [7]Laboratoire HLA, Etablissement Francais du Sang, Nantes, France.

Introduction: Interstitial Fibrosis and Tubular Atrophy (IFTA) is a common histologic lesion present on one year surveillance biopsies in kidney transplantation. Occurrence of inflammation in the scarred compartment is not a rare situation on this type of biopsy without any other lesion of subclinical rejection or borderline changes. After identifying clinical features associated with IFTA with inflammation in scarring, without superimposed lesions of subclinical rejection, on one-year surveillance kidney biopsies, we studied allograft survival and renal function at 5 years follow-up.
Patients and Methods: We enrolled recipients between 2004 and 2011 with a functionnal kidney and having a one year surveillance biopsies. Biopsies were classified as isolated IFTA with inflammation (infl-isoIFTA) or without inflammation (IFTA) according to the Banff 2011 classification. Normal histology and lesions classically related to alloimmunity (including humoral and/or cellular acute or chronic rejection and borderline changes) were excluded. "infl-isoIFTA" was defined presence of IFTA and inflammation according to the ti-score previously defined in Banff 2007 classification with including the low"i-banff" score (i=0 or 1) without a sufficient scoring to retained borderline changes or TCMR diagnosis.
Results and Discussion: Finally 155 patients were included (76 in infl-isoIFTA group and 79 in IFTA group). We showed that patients who presented infl-isoIFTA shared similar clinico-biological profiles with those with non inflammatory IFTA except a higher one year daily proteinuria (p=0.02). The allograft survival seemed decrease in infl-isoIFTA compared with IFTA alone, but not significantly in multivariate analysis (HR=2.02 [0.82-4.94]; p=0.12). Patients with infl-isoIFTA did present a similar decrese of renal function evolution of e-GFR (coeff= -0.18) throughout the first 5 years of follow-up than patients with IFTA (coeff= -0.14) (p=0.216).
This is the first study that evaluates graft outcome of patients with infl-isoIFTA in systematic biopsies, contrary to previous publicions concerning the impact of the "classical immunologic inflammation" i-banff[1],[2]. Moreover all studies concerning inflammation in scarring, on biopsies for clinical indications, analyzed infiltrates disclosing other damage (glomerular, TCMR, ABMR…) but never excluding the lesions due to allo-immune processes[3],[4].
Conclusion: Thus occurrence of inflammatory infiltrates in the scarred compartment observed for one-year surveillance biopsies seems to be insufficient by itself to justify immunosuppressive therapeutic changes.

556.5

The One year Renal Biopsy Index (1-RBI): a clinical marker to screen patients for one year surveillance biopsy indication after the transplantation

Magali Giral[1], Karine Renaudin[2], Christophe Legendre[3], Henri Kreis[3], Emmanuel Morelon[4], Fanny Buron[4], Maartens Naesens[9], Redmer Luning[9], Alexandre Huneau[5], Chloe Paul[6], Sophie Brouard[6], Grégoire Couvrat-Desvergnes[17], Yohann Foucher[8], Etienne Dantan[8].
[1]Kidney Transplantation , Nantes University Hospital, Nantes, France; [2]Anatomo Pathology, Nantes University Hospital, Nantes, France; [3]Kidney Transplantation, Necker University Hospital, Paris, France; [4]Kidney Transplantation, Lyon University Hospital, Lyon, France; [5]Biostatistics, Nantes University , Nantes, France; [6]Kidney Transplantation, Inserm 1064, Nantes, France; [7]Nephrology, La Roche sur Yon Hospital, La Roche sur Yon, France; [8]Biostatistics, Nantes University, Nantes, France; [9]Kidney Transplantation , Leuven University Hospital, Leuven, Belgium.

Introduction: Surveillance biopsy remains debated after renal transplantation since the histological diagnostic do not lead to clear therapeutic recommendations. The objective of our study was to propose a medical decision signature to predict histological lesions on one year surveillance biopsy for which therapeutic intervention could be considered.
Patients and Methods: From the French multicenter DIVAT cohort, we studied 467 adult recipients of kidney, transplanted between 2006 and 2012 from deceased donor. From one year surveillance biopsy, patients displaying major histological lesions of "allo-immunity" (i.e. Borderline, acute or chronic humoral and/or cellular rejection), IFTA grade 2 or 3 and glomerulonephritis composed the Interventional Group (IG) that was compared to the Non-Interventional Group (NIG) including minor lesions (i.e. normal histology or IFTA grade 1). The predictive signature was identified using a lasso penalized logistic regression and internally validated by ROC 0.632+ bootstrap. A discriminating threshold was proposed from predictive values and externally validated from an independent cohort of 645 French and Belgian kidney recipients.
Results: 229 patients (49%) were considered in the interventional group among the 467 recipients. The predictive signature, named 1-Year Renal Biopsy Index (1-RBI), included 5 variables. Women recipient (OR=2.27), patients with current pre-transplantation anti-class I immunization (OR= 1.26), those receiving transplant from a male donor (OR=1.20), those who displayed high serum creatinine level at 6 month (OR=1.34) and 12 months (OR=1.53) have a higher probability to belong to the IG, than to be classified NIG. Area under the associated ROC curve was estimated at 0.69. In a medical decision making perspective, we assumed a minimal positive predictive value at 80% leading to a discriminating threshold at 0.44. This medical decision rules was internally and externally validated.
Conclusion: The use of the 1-RBI could be proposed for medical teams that do not perform routine surveillance 1 year biopsy in their follow-up policy. It may help physicians to recommend 1-year surveillance biopsy with a good confidence to patient presenting a 1-RBI higher than the discriminating threshold since they are considered at high risk of abnormal histological lesions. The 1-RBI calculation is possible from online calculator (www.divat.fr/en/online-calculators/1-RBI).

556.6

Angiotensin system blockade reduce proteinuria in kidney transplant recipients: A meta-analysis

Guodong Chen, Longhui Qiu, Changxi Wang, Jiang Qiu, Lizhong Chen.
Organ Transplant Center, The First Affiliated Hospital of Sun Yat-sen University, Guangzhou, People's Republic of China.

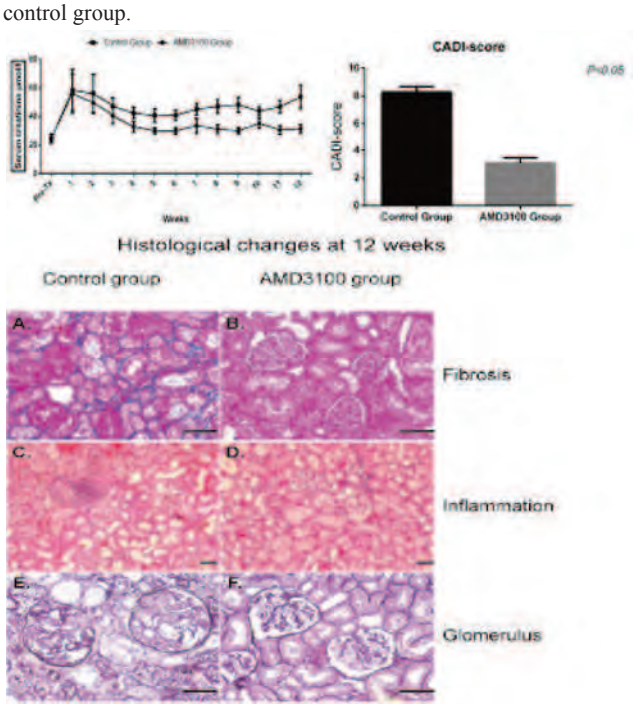
Background: Proteinuria is a common complication after kidney transplantation. Angiotensin system blockadeincluding Angiotensin-Converting Enzyme Inhibitors (ACEI) or Angiotensin Receptor Blockers (ARB), have been reported to be effective on reducing proteinuria in chronic kidney diseases. We carried out this meta-analysis to evaluate theanti-proteinuric effect of angiotensin system blockade on kidney transplant recipients.
Methods: Databases including Pubmed, Embase, Scopus, Cochrane Library, and Web of Knowledge were comprehensively retrieved. 17 randomized controlled trials (RCTs) involving 1299 kidney transplant recipients were contained.Both Review Manager 5.2 and Stata Version 18.0 were utilized in trial synthesis.
Results: Our results showed that comparing with other hypertensive agents or placebo, either short-term or long-term treatment with ACEI or ARB significantly decreased proteinuria(mean difference [MD] -0.30 g/24h, 95% confidence intervals [CI] -0.41 to -0.20, $\rho<0.00001$, $I2 = 44\%$),with no significantchange in serum creatinine (Scr) levels. However, we found no significant difference in graft failure or patient mortality between ACEI/ARB and control group. Hemoglobinand glomerular filtration rate (GFR) level were decreased in ACEI/ARB group, while serum potassium level was significantly higher in ACEI/ARB group.
Conclusion: ACEI or ARB caneffectively reduce proteinuriain kidney transplant recipients.However, they can not improve long-term graft and patient survival.

556.7

Chemokine receptor CXCR4 antagonist, a novel pathway to prevent chronic allograft nephropathy.

Yue Xu, Qiang Zhang, Wenrui Xue, Zijian Zhang, Song Zeng, Xiaopeng Hu.
Urology, Beijing Chao-yang hospital, Beijing, People's Republic of China.

Background: Chronic allograft nephropathy (CAN) remains a major problem for long term graft survival and different pathways participate in its development. CXC chemokine receptor 4 (CXCR4) is significantly upregulated following renal injury and fibrotic response. We investigated the effect of AMD3100, a CXCR4 antagonist, on the development of CAN in rat models.
Methods: CAN rat models (n=20) were established using male Fisher 344 to Lewis rats. Rats in experimental group (n=10) were treated by AMD3100 (1mg/kg/day subcutaneously, 0-12 weeks), rats in control group (n=10) were treated by saline. The serum creatinine levels were monitored every week. Kidney grafts were harvested 12 weeks after modeling for histological analysis. We used chronic allograft damage index (CADI) scores to evaluate each group. QPCR and western blotting were used to measure SDF-1/CXCR4 axis, TGF-β1/Smad3 signaling pathway and α-smooth muscle actin (α-SMA) expression in renal allograft tissue.
Results: CXCR4 expression was increased significantly in control group which developed intense chronic changes after 12 weeks. Histological changes of CAN in experimental group were ameliorated by AMD3100 which also made better graft function compare to the control group.



AMD3100 significantly blunted the increase in the mRNA expression level of SDF-1/CXCR4 axis, TGF-β1 and Smad3. A significant reduction in TGF-β1 and α-SMA protein content was observed only in experimental group as shown in a representative western blot.
Conclusion: Based on these findings, CXCR4 expression may mediate in part the development of CAN. AMD3100 may ameliorate histological changes of CAN and maintain better allograft function. Its treatment blunts downstream effects of TGF-β1 signaling and fibroblast activation. Therefore, antagonism of CXCR4 may provide a novel way to prevent the development of CAN.

556.8

Peripheral NK-cell repertoire distribution in chronic allograft dysfunction after renal transplantation

Sailaja Kesiraju[1,3], Uma Maheswara Rao Ch[2], Purna Paritala[2], Shreedhar Reddy[2], V.S. Reddy[2], Sahariah Sarbeshwar[2].
[1]Dept of Immunology , Bhagwan Mahavir Medical Centre, Hyderabad, India; [2]Transplantation Immunology& Research Centre, Transimmun, Hyderabad, India; [3]Department of Nephrology and Transplantation, Krishna Institute of Medical Sciences, Hyderabad, India.

Introduction: Recent studies demonstrated that NK-cells play a major role in acute and chronic rejection /tolerance of allograft. Nkcells have a potent cytolytic function and can produce pro-inflammatory cytokines. It has been noted that NK-cells become activated early after transplantation and can contribute in the development of cell mediated allo response by secreting pro-inflammatory cytokines thereby causing acute rejection. Antibody mediated rejection is associated with microvascular damage, and NK-cell antibody dependent cell mediated cyto-toxicity (ADCC) could be one of the contributing factors. Recent work has clearly recognized donor specific antibodies (DSA) as the main cause of chronic rejection.
Aim: Assessing distribution of NK and NKT cells and the possible relationship between peripheral NKcell subsets and circulating donor-specific and non-donor-specific anti HLA class I&II antibodies in the development of chronic allograft dysfunction.
Methods: Prospective observational study of 61 kidney transplant recipients who have been transplanted more than one year and whose graft biopsy was performed. Of them, 18 patients were with DSA class II anti-HLA, 21 were with DSA class I anti-HLA and 22 were without HLA antibodies: all of the former were compared with 18 healthy donors. Analysis of anti HLA antibodies was performed by ELISA. The percentages and absolute counts of Tcell (CD3+), natural killer (CD3-CD16CD56+), NKT(CD3+/CD56+) lymphocytes in erythrocyte lysed whole blood NKG2A in peripheral blood mononuclear cells(PBMC) were performed using multi-test CD3FITC/CD16+CD56PE/ with a four colour direct immunofluorescent reagent. Cytokine levels of IFNγ, TNFα TGFβ and IL10 were estimated by ELISA method.
Results and Discussion: Nk-cell phenotypes differ significantly between healthy donors and kidney transplant recipients. There was no significant difference in the percentage of NK-cells in the lymphocyte population among these patients. However patients with DSA had significantly lower NK-cell numbers compared to patients without any HLA antibodies. Lower number of NKcells and presence of donor alloantigens promotes the adaptive immune responses. The number of NKG2A was increased while their percentage decreased in both the groups containing anti HLA antibodies. Cytokine levels were low when compared to healthy donors: especially IL-10 levels, which were significantly low (p=>0.05)
Conclusion: Decreased number of NKcell repertoire supports the hypothesis that there is a functional link between DSA and NKcells, and that DSA are strongly associated with chronic rejection. Identifying the molecular mechanisms that trigger the rejection process and tissue injury could facilitate individualized adjustment of immunosuppression.

Progressive allograft dysfunction is associated with an early (12 months) increase in levels of VEGF-C, PLGF and follistatin after renal transplantation

G.J. Dreyer[1], J.W. de Fijter[1], DM Briscoe[2], K.P. Daly[2], M.E.J. Reinders[1].
[1]Nephrology, LUMC, Leiden, Netherlands; [2]Transplant Research Program, Boston Children's Hospital, Boston, MA, United States.

Introduction: The integrity of the microvasculature is critical for long term survival after solid organ transplantation and biomarkers of endothelial injury and repair have been reported to be associated with chronic rejection after cardiac allograft vasculopathy. Here, we investigate if early angiogenic biomarkers are predictive of later allograft dysfunction in a large cohort of renal transplant recipients.
Methods: Levels of 17 angiogenic proteins and donor specific HLA-antibodies (DSA) were measured by multi analyte profiling 12 months after renal transplantation in sera of 152 recipients. Forty five patients had progressive renal dysfunction, defined as at least 20 ml/min/1.73m2 eGFR loss between year 1 and 5 (mean baseline eGFR 54±22 ml/min/1.73m2) post transplant;107 control patients had stable function (mean baseline eGFR 48±15 ml/min/1.73m2) during this follow up period. All patients had standard immunological risk and started on triple therapy with calcineurin inhibitors. Six months post-transplant 33 patients switched to dual therapy, including 13 with mTOR inhibitors.
Results: 5-year death-censored graft survival was 100% in the control group and 79.2% in the progressors. The angiogenic and pro-inflammatory factors VEGF-C (median(IQR) = 276(372) vs 183(274) resp, p=0.029) and PLGF (median(IQR) = 16(37) vs 10(26) resp, p=0.019) were increased in the progressors, independent of treatment regimen. Also Follistatin, a promoter of tubular regeneration, was significantly increased in recipients with progressive renal dysfunction (median(IQR) = 1146(1060) vs 826(1341) in controls, p=0.033). Remaining biomarkers including endothelin1, FGF1/2 and VEGF-A showed no association with loss of renal function. In total 46 patients had allograft rejection. Late, but not early rejection, was associated with progressive renal decline at 5 years (OR 3.15, 95%CI 1.27–7.81, p=0.013). De novo DSAs were found in 22 patients (14.5%), however no association with biomarkers was found.
Conclusion: Increased levels of VEGF-C, PLGF and Follistatin 12 months post-transplant were associated with progressive renal dysfunction at 5 years. These specific biomarkers have been reported to play important roles in endothelial and lymphatic angiogenesis and inflammation and have the potential to identify patients with progressive renal dysfunction at early times post-transplant.

Quantification of lymphatic flow using SPECT/CT lymphoscintigraphy reveals increased lymph flow during chronic rejection

Lindsey A.Edwards, Anna K. Nowocin, Nazila V.Jafari, Lucy L.Meader, Kathryn Brown, Aurélien Sarde , Carolyn Lam, Alex Murray, Wilson Wong.
MRC Centre for Transplantation, Division of Transplantation Immunology & Mucosal Biology, King's College London, School of Medicine at Guy's, King's and St. Thomas' Hospitals, London, United Kingdom.

Background: Chronic rejection leading to cardiac allograft vasculopathy (CAV) remains a major cause of cardiac graft loss[1]-[3]. The lymphatic system plays a crucial role in the alloimmune response by facilitating trafficking of antigen presenting cells to draining lymph nodes, where they encounter T lymphocytes and initiate alloimmunity[4]. Donor lymphatic vessels are not anastomosed to that of the recipient during transplantation. The pathophysiology of lymphatic disruption is unknown and whether disruption enhances or hinders the alloimmune responses is unclear[5]. Although histological analysis can yield structural information of the lymphatics, the function following cardiac transplantation is completely unknown.
Methods: Female C57BL/6 $EYFP^+$ recipient mice received either wild-type gender mismatched male or female heart grafts. The male antigen HY evokes a chronic rejection response, resulting in CAV[6]. Using Single photon emission computed tomography/CT (SPECT/CT) lymphoscintigraphy we quantified the lymphatic flow index following cardiac transplantation[7]. Subsequently, we quantified the number of male donor cells trafficking to the draining mediastinal lymph nodes using the Y-chromosome specific gene, Zfy1, amplified by QPCR[8]. Immunohistochemistry was performed to determine the origin of lymphatic vessels (donor or recipient), number of infiltrating inflammatory cells and allograft vasculopathy.
Results and Discussion: Following transplantation of HY-mismatched heart grafts, the lymphatic flow index was significantly increased compared with gender-matched controls. Furthermore, the enhanced lymphatic flow index strongly correlated with an increased in male donor cells in the draining mediastinal lymph nodes (p<0.0001). Lymphatic density by LYVE-1 expression was higher in HY-mismatched grafts indicative of lymphangiogenesis and the lymphatic flow index correlated with vessel area. However, no correlation was observed between vessel number and donor cells trafficking to the draining mediastinal lymph nodes; the lymphatic flow index; or the number of inflammatory cells infiltrating the graft. The increased percentage of male donor-derived cells correlates with enhanced numbers of $CD8^+$ T cells within the donor graft (p=0.0081); In turn, the number or $CD8^+$ T cells strongly correlates with the lymphatic flow index (p<0.0001) and the level of CAV, determined by vessel occlusion (p<0.0001). Therefore, in our model the lymphatic flow index provided a good predictor of CAV.
Conclusions: SPECT/CT lymphoscintigraphy allows quantitative measurement of lymphatic function following transplantation. Increased lymphangiogenesis is observed during chronic rejection and this is associated with increased lymph flow towards draining lymph nodes. Lymph flow from donor grafts correlates with donor passenger cells trafficking to lymph nodes as well as graft inflammatory infiltration, suggesting a cause and effect relationship.

Receptor tyrosine kinase mer mediates expansion of MDSCs critical for transplantation tolerance

Lei Zhang[1], Mathew DeBerge[2], Xiaomin Zhang[3], Jiaojin Wang[3], Zheng Zhang[3], Edward Thorp[2], Xunrong Luo[1,2,3].
[1]Division of Nephrology and Hypertension, Northwestern University Feinberg School of Medicine, Chicago, IL, United States; [2]Department of Microbiology and Immunology, Northwestern University Feinberg School of Medicine, Chicago, IL, United States; [3]Comprehensive Transplant Center, Northwestern University Feinberg School of Medicine, Chicago, IL, United States.

Introduction: The TAM (Tyro3, Axl and Mer) receptor tyrosine kinases (RTKs) mediate homeostatic phagocytosis of apoptotic cells, and transmit regulatory signals that modulate immune response. Currently, their role in transplant tolerance is unknown.
Methods: In this study, we address the role of Mer in transplant tolerance in a BALB/c à B6 heart transplant model in which tolerance is induced by recipient treatment with donor splenocytes (SP) treated with 1-ehtyl-3-(3-dimethylaminopropyl) carbodiimide (ECDI).
Results: While baseline expression of Mer was primarily only detected on the red pulp macrophages, recipient mice treated with donor ECDI-SP significantly up-regulated Mer expression on both the CD68+SIGN-R1+ marginal zone macrophages and CD68+CD169+ metalophilic macrophages. This up-regulation was most prominent in macrophages that had phagocytosed the injected donor ECDI-SP. To determine the role of Mer in mediating transplant tolerance by donor ECDI-SP, we utilized Mer-/- mice. Bone marrow derived macrophages (BMDM) from Mer-/- and Mer+/+ were cultured with allogeneic ECDI-SP. While Mer+/+ BMDM exhibited marked up-regulation of M-CSF and essentially completely inhibited expressions of IFN-g and TNF-a following culturing with allogeneic ECDI-SP, Mer-/- BMDM exhibited an opposite pattern, i.e. inhibited up-regulation of M-CSF but marked up-regulation of IFN-g. This altered pattern of expressions of M-CSF and inflammatory cytokines correlated with an absence of the expansion of myeloid derived suppressor cells (MDSCs) that were otherwise induced in recipients treated by donor ECDI-SP. Consistent with a critical role of Mer signaling in the induction of transplant tolerance, recipient Mer deficiency completely abolished allograft protection provided by donor ECDI-SP.
Conclusion: The receptor tyrosine kinase Mer plays a critical role in tolerogenic signaling in splenic macrophages, MDSC expansion, and consequently in the induction of transplantation tolerance.

The role of PI3kγ and PI3kδ in alloimmunity

Mayuko Uehara[1], Azzi Jamil[1], Shunsuke Ohori[1], Zhabiz Solhjou[1], Martina McGrath[1], Naima M.Banouni[1], Catherine A.Evans[2], Jonathan P.Dinitto[2], David G.Winkler[2], Reza Abdi[1].
[1]Transplantation Research Center, Renal Division, Brigham and Women's Hospital/Harvard Medical School, Boston, MA, United States; [2]Infinity Pharmaceuticals, Inc, Boston, MA, United States.

We studied the role of phosphatidylinositol-3-kinases (PI3k) γ and δ pathway in alloimmunity. Generated Foxp3-GFP-PI3kγ and -PI3kδ knockout mice (C57BL/6 background) were used in heart transplant models and GVHD models. Multiple experiments were done using FACS sorting, flow and phospho-flow, ELISpot, Luminex and Western Blot assays. While PI3kγ$^{-/-}$ and PI3kδ$^{-/-}$ recipients of BALB/c hearts exhibited significant heart allograft survival prolongation compared to WT (MST: 14 vs. 14 vs. 7 days, respectively), the administration of single dose CTLA4Ig (sCTLA4Ig: 250μg on day 2) induced indefinite allograft survival of the PI3kγ$^{-/-}$ recipients compared to WT (MST: >100 vs. 41 days, respectively) with a marked increase in Tregs and a reduced % of CD4^{+} and CD8^{+} Teff along with significant suppression of Th1/Th17 cytokines in the spleen and draining lymph nodes (DLN). Surprisingly, the absence of PI3kδ abrogated the effect of CTLA4Ig treatment with a marked decrease in Tregs with significant increase in CD4^{+} and CD8^{+} Teff in the spleen and DLN of the PI3kδ$^{-/-}$ recipients along with significant upregulation of Th1/Th17 cytokines. Adoptive transfer of Foxp3-GFP-PI3kδ$^{-/-}$ and Foxp3-GFP-PI3kγ$^{-/-}$ Tregs into a GVHD model showed that PI3kδ$^{-/-}$ Tregs went more into apoptosis compared to PI3kγ$^{-/-}$ and WT Tregs. We also examine the effect of pharmacologic inhibition of PI3k isoforms using IPI-1828 (PI3kδ selective inhibitor) and INK-055 (PI3kγ and PI3kδ inhibitor). BALB/c heart allografts were transplanted into C57BL/6 and PI3kγ$^{-/-}$ mice respectively and each recipient was treated with IPI-1828 or INK-055 with or without sCTLA4Ig respectively. WT and PI3kγ$^{-/-}$ recipients treated with IPI-1828 and PI3kγ$^{-/-}$ recipients treated with IPI-1828 plus sCTLA4Ig showed similar allograft survivals as previous model (MST: 13.5 vs. 20 vs. >100 days, respectively). Furthermore, the allograft survival of WT recipients treated with INK-055 plus sCTLA4Ig confirmed that PI3kδ abrogates the effect of CTLA4Ig treatment. Using double knockout recipients (CD28$^{-/-}$PI3kγ$^{-/-}$ and CD28$^{-/-}$PI3kδ$^{-/-}$ mice), allograft histology was observed and showed less lymphocyte infiltration in CD28$^{-/-}$PI3kγ$^{-/-}$ recipient compared with CD28$^{-/-}$PI3kδ$^{-/-}$. Allograft survival data also reflected the histology data of CD28$^{-/-}$ PI3kγ$^{-/-}$ and CD28$^{-/-}$PI3kδ$^{-/-}$ (MST: >30 vs. 27.5 days, respectively). Our data shows a differential role of PI3kγ and PI3Kδ in Tregs homeostasis and function with significant application in the future of PI3k based therapies in solid organ transplantation.

Regulatory T cells with HLA-A*02-specific chimeric antigen receptors can control strong allogeneic immune responses and induce operational tolerance

Experimental Haematology, Hannover Medical School, Hannover, Germany; [7]Dept. of Plastic Surgery, Hannover Medical School, Hannover, Germany.

Introduction: CD4+CD25high FOXP3+ regulatory T cells (Tregs) are involved in graft-specific tolerance after solid organ transplantation. Recent data from Todo et al. has proven the clinical feasibility of Tregs-supported weaning, by achieving operational tolerance in 7/10 patients after liver transplantation. However, the adoptive transfer of polyspecific Tregs alone was so far unable to prevent graft rejection even in rodent models. Instead graft-specific Tregs will be needed. This poses the question how to obtain large numbers of stable, donor-reactive Tregs with long-term survival after adoptive transfer. We have developed a highly specific chimeric antigen receptor recognizing the HLA molecule A*02 (referred as A2-CAR).
Methods: The A*02-specific single chain variable fragment (scFv) was obtained from a phage display library generated from an A*02 sensitized patient. It was highly specific for A*02 alleles. The scFv was cloned into a new 2nd generation CAR cassette consisting of a modified CD8 hinge and CD28/CD3 intracellular activation motifs.
Results: We could demonstrate surface expression and strong signal transduction of the A2-CAR. Transduction into nTregs changed the specificity of the Tregs without changing the regulatory phenotype of the cells as assessed by transcriptome analysis. nTreg activation via the A2-CAR caused strong activation, proliferation and suppressor function of modified nTregs. A2-CAR Tregs were superior to nTregs in controlling strong allospecific immune responses in vitro and in humanized mouse models. They completely prevented the rejection of allogeneic targets in immune reconstituted humanized mice in the absence of any immunosuppression (operational tolerance). They could be generated with a short in vitro transduction protocol without the need for prolonged in vitro expansion.
Conclusion: A2-CAR Tregs therefore offer the possibility to induce graft-specific tolerance without the perturbation of the general immune competence of the recipient. They might have a huge potential in clinical trials of Treg supported weaning in HLA-A*02- recipients receiving an HLA-A*02+ graft. The findings could be further extended to other HLA-mismatch transplantations.

miRNA-181 promotes graft prolongation by plasmacytoid dendritic cells by decreasing marginal zone B cells and plasmablasts

Audrey H.Lau[1,2], Matthew Vitalone[2], Xiumei Qu[2], Todd Shawler[2], OliviaM. Martinez[2], Carlos O.Esquivel[2], Sheri M.Krams[2].
[1]Department of Pediatrics, Division of Gastroenterology, Hematology and Nutrition, Stanford University, Stanford, CA, United States; [2]Department of Surgery, Division of Abdominal Transplantation, Stanford University, Stanford, CA, United States.

Introduction: Liver allografts are well tolerated and other solid organ allografts, when transplanted concurrently with livers, show improved outcomes. However, the mechanisms underlying "hepatic tolerance" have yet to be elucidated. Previous data show that hepatic dendritic cells (DC) have diminished antigen presentation and immune stimulatory function compared with DC in lymphoid tissue. Immature plasmacytoid (p)DC have been shown to induce graft prolongation and we have previously demonstrated that the microRNA, miR-181 is increased in pDC ($CD11c^+CD11b^-CD317^+$) as compared to conventional DC $CD11c^+CD11b^+CD317^-$).
Materials and Methods: BALB/c mice were pre-treated with hepatic C57Bl/6J (wild-type;WT) pDC (n=5) or hepatic C57Bl/6J miR-181a1b1$^{-/-}$ (KO) pDC (n=3) seven days before performing allogeneic (C57BL/6) vascularized heterotopic heart transplantation and graft survival followed. To determine the mechanism of graft prolongation, splenocytes were obtained at Day 7 post-transplantation and cytometry by time-of-flight (CyTOF, mass cytometry) was utilized to comprehensively characterize the immune response (on the basis of the expression of 17 surface and three intracellular markers). Correlation analyses of molecular features derived from mass cytometry data were performed using Citrus, a method for unsupervised identification of significant cellular populations.
Results: Allograft recipients pre-treated with hepatic pDC (n=5) had significantly prolonged allograft survival to day 17.6 ± 1.4 days as compared to the control group (n=4) which were not treated with pDC and rejected their allografts by day 7 (Mantel-Cox log rank for 2 groups, $p \leq 0.005$). However, recipients pre-treated with hepatic KO pDC (n=3), which lack expression of miR-181a1b1 rejected their allografts by day 8 ± 0.6 days (Mantel-Cox log rank for 3 groups, $p \leq 0.005$). Splenocytes were analyzed by mass cytometry and it was determined that a B cell population was elevated in the rejecting KO group (WT 0.99±0.18% vs. KO 2.76±0.11%, $p \leq 0.0005$). Further analysis of B cell subsets revealed a significant increase in marginal zone B cells (2.18±0.14% vs. 3.31±0.56%; $p \leq 0.05$) and plasmablasts in (0.26±0.09% vs. 0.59±0.07%; $p \leq 0.05$) in the absence of miR-181a1b1 (KO group) and a significant ($p \leq 0.01$) upregulation in IgG1 subclass antibodies as compared to the recipients that received miR-181 expressing pDC and had prolonged graft survival.
Conclusions: Our findings suggest that miR-181 expressing pDC prolong graft survival by limiting B cell activation and antibody production. Further studies are necessary to determine if, pDC and miR-181 can prevent donor specific antibody formation. Further, our findings demonstrate that CyTOF is a powerful new technology to identify immune cell populations that alter outcomes post-transplant.

557.6

Molecular landscape of allograft rejection: definitive mapping of shared and selective molecules for T cell-mediated rejection and antibody-mediated rejection

Philip Halloran[1,2], Jeffery Venner[2], Konrad Famulski[1,2].
[1]University of Alberta, Edmonton, AB, Canada; [2]Alberta Transplant Applied Genomics Centre, Edmonton, AB, Canada.

While the molecules selective for T cell-mediated rejection (TCMR) and antibody-mediated rejection (ABMR) are important, understanding the complete molecular phenotype requires that we also define the molecules shared by ABMR and TCMR. The present analysis mapped the shared and selective features in microarray results from 703 kidney transplant indication biopsies (Clinicaltrials.gov NCT 01299168).
First we mapped "Rejection Landscape" in a comparison between two classes: all rejection (TCMR, ABMR, and mixed) and all other biopsies (Figure 1), plotting association strength (p value; x axis) vs. fold change (y axis). Of the top 30 rejection-associated transcripts, 27/30 were IFNG-inducible molecules (e.g. chemokines CXCL9,10,11; guanylate-binding proteins GBP1,4,5; enzymes IDO and WARS) and three were shared by NK cells and effector T cells (CCL4, KLRD1, and PRF1). Many of those were used by a Rejection classifier to assign a Rejection probability score to each biopsy. The Rejection score was high in biopsies with histologic ABMR and TCMR, and correlated with the defining histologic lesions of both. TCMR had high Rejection and TCMR scores, and ABMR had high Rejection and ABMR scores.

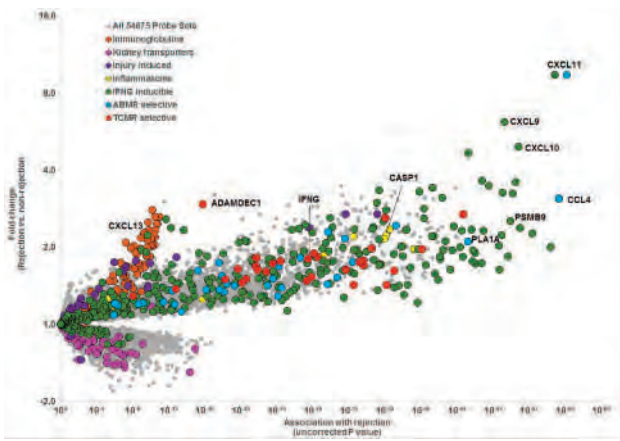

Table 1. "Top molecules"
Features most strongly associated (p value) with rejection syndromes

		Algorithm	Top genes	Examples
#1	All rejection vs. Others	ABMR vs. EE*	IFNG-induced; shared T/NK	CXCL9, 10, 11; IDO, WARS; CCL4, KLRD1
#2	ABMR vs. Other except TCMR	ABMR vs. EE, no TCMR	IFNG-induced; T/NK	Combined 1 and 3 features
#3	ABMR-selective vs. All others including TCMR	ABMR vs. EE; incl.* TCMR	NK and endothelial activation; selective IFNG effects	SH2D1B; ROBO4; PLA1A
#4	TCMR vs. Other except ABMR	TCMR vs. EE, no ABMR	T, DC, macrophage activation	Combined 1 and 5 features
#5	TCMR-selective vs. All others including ABMR	TCMR vs. EE, incl. ABMR	T, DC, macrophage activation; selective IFNG effects	CTLA4, SLAMF8; IFNG, ADAMDEC1, ANKRD22

*EE=everything else; incl. = including

Next, we assembled a complete list of Rejection, ABMR, and TCMR molecules using five algorithms - various combinations of ABMR,

TCMR, and all others ("everything else", EE) (#1-#5: Table 1). The selection of top transcripts was highly dependent on the details of the class comparison algorithm, and whether rejection-processes were included or excluded from the comparator. Many of the top shared molecules reflect elements conserved between the cognate recognition/signaling systems: for TCMR, T cell receptor-MHC-antigen presenting cells; and for ABMR, NK CD16a-IgG-MHC-endothelium, both triggering IFNG release.
The principle is that rejection mechanisms mapped by gene expression must use multiple algorithms to identify disease-selective and shared features to map the complete phenotype. "Top rejection gene" lists will always be some variation of the lists generated by these 5 algorithms, dependent on case mix in the positive and negative classes compared. These changes have been validated in new biopsy sets, and class comparisons in hearts transplants (clinicaltrials.gov NCT02670408) suggesting that the molecular phenotype of rejection will be similar in all organ transplants.

557.7

Exosomes released into the circulation following lung and heart transplantation: Composition and role in allograft rejection

Thalachallour Mohanakumar[1,2], Muthukumar Gunasekaran[1,2], Monal Sharma[1,2], Zhongping Xu[1,2], Deepak Nayak[1,2], Wei Liu[1,2], Nancy Steward[2], Nicholas Benshoff[2], Ramsey Hachem[3], Rajat Walia[1], Michael Smith[1], Ross Bremner[1].
[1]Norton Thoracic Institute, St. Joseph's Hospital and Medical Center, Phoenix, United States; [2]Surgery, Washington University School of Medicine, St. Louis, United States; [3]Medicine, Washington University School of Medicine, St. Louis, United States.

Introduction: Exosomes are nano-vesicles (40-100nm in diameter) often released into the circulation by stressed cells. The goals of this study are to determine whether exosomes are released into circulation following human lung and heart transplants, define the kinetics of release towards its use as a biomarker for rejection, and characterize the composition using both clinical specimens and murine models of allograft rejection.
Materials and Methods: Exosomes were isolated from sera and broncho-alveolar lavage (BAL) by ultra-centrifugation method from human lung transplant recipients (LTxR) and cardiac allograft recipients diagnosed with coronary artery vasculopathy (CAV). Purity of the isolated exosomes was determined by flow cytometry using CD63 and by western blot by Annexin-V. Expression of surface antigens were determined including HLA and tissue restricted self-antigens (Collagen-V and K-alpha 1 tubulin for lung, cardiac myosin and Vimentin for heart) by flow cytometry and electron microscopy. Micro-RNA (miRNA) content was determined by Affymetrix array and pathway analysis with DIANA-mirpath. Quantitative RT-PCR was performed for differentially regulated miRNA validated in independent cohorts. Murine models of chronic rejection of lungs and hearts were also analyzed for exosome formation and role in rejection.
Results and Discussion: Exosomes containing mismatched donor HLA and lung self-antigens were detected from sera and BAL from LTxR (10 patients each) diagnosed with acute rejection (AR) and chronic rejection (Brochiolitis Obliterans Syndrome (BOS)) 3 months before the diagnosis of AR and 6 months prior to BOS suggesting its use as a biomarker for rejection. Exosomes from 10 stable LTxR did not express donor HLA nor lung self-antigens. Five human cardiac transplant recipients with CAV had circulating antibodies to myosin and vimentin, and exosomes expressing the self-antigens were also detected. Exosomes isolated from both lung and cardiac transplant recipients were validated with independent cohorts contained several immune-regulatory miRNAs (miR-92a, 182, 155, 21 and 31). In a murine model of anti-MHC induced obliterative airway disease as well as anti-cardiac myosin induced cardiac rejection, exosomes were released into circulation prior to rejection expressing tissue restricted self-antigens and miRNAs.
Conclusions: We conclude that exosomes are released into the circulation both in human and animal models of acute and chronic rejection expressing donor mismatched HLA as well as tissue restricted self-antigens prior to clinical diagnosis of rejection suggesting that isolated exosomes with self-antigens can be a non-invasive biomarker for impending rejection. Further, exosomes may play an important role in the pathogenesis of rejection due to their surface antigenic and miRNA composition which may facilitate the spread of immune responses against donor MHC and self-antigens.

NK cells are required in B-cell dependent antibody mediated islet transplant tolerance

Christian Schuetz, Kang Mi Lee, Lisa Kojima, Laura Washburn, Liye Liu, Wei-Hui Liu, James Kim, James F.Markmann.
Transplant Surgery, Massachusetts General Hospital, Boston, MA, United States.

Immunologic tolerance to solid organ and cell grafts has been achieved in various rodent models using antibodies directed at CD45RB and Tim-1. We have shown that this tolerance mechanism is B lymphocyte dependent, presumably requiring immune regulatory function. In contrast to other models such as autoimmunity, the regulatory B cells (Breg) in our model do not depend on IL-10 and may therefore represent a yet to be characterized subpopulation of Bregs. In an effort to elucidate the mechanism of B cell induced tolerance we investigated the requirement of NK and NKT cells in vitro and in vivo. Murine islets (200-300 Islets/recipient), isolated from male Balb/c mice, were transplanted under the kidney capsule of STZ treated (200 mg/kg) C57bl/6 (B6), CD1d-/- and Lystbg/J (beige) mice. Tolerance was induced by intraperitoneal injection of 100 µg anti-mouse CD45RB (Bio X cell) on days 0, 1, 3, 5, and 7 following transplantation and 500 µg anti-mouse TIM-1 (Bio X cell, RMT1–10) i.p. on the day before transplant, and 300 µg on days 0 and 5 post-transplant. Blood glucose levels were monitored for a minimum of 2 weeks up to the time of rejection or 100 days post-transplant. One group of B6 recipients received 3 doses of NK1.1 Antibody i.p. (200 µg, days -7, 1 and 8) to deplete NK and NKT cells. This NK/NKT cell depletion resulted in the near absolute abrogation of the tolerizing effect of dual antibody treatment (anti CD45RB/Tim-1) as only 3/14 islet recipients treated with Nk1.1 antibody remained normoglycemic after 100 days. In the control group, 10/11 B6 recipients remained normoglycemic 100 days post islet transplant. In comparison, recipients that are deficient in NKT cells (CD1d-/-) demonstrated comparable long term graft survival rates at 100 days (4/5 CD1d-/- vs. 4/4 wt B6). Islet grafts were rejected between post-transplant day 14 and 20 in 4/4 beige recipient mice, treated with dual Antibody.In summary, these result point towards a crucial role of NK cells but not NKT cells in the maintenance of immune transplant tolerance induced by combined anti-CD45RB/anti-Tim-1 Antibody treatment. The mechanistic role played by NK cells and the potential interaction with Bregs, is under current investigation.

Short-term vascularized bone marrow transplant is sufficient to induced and maintained skin allograft tolerance in a mouse model

Cheng-Hung Lin[1], Madonna Rica Anggelia[1], Hui-Yun Cheng[1], Yen-Ling Wang[1], Wen-Yu Chuang[1], Chih-Hung Lin[1], Gerald Brandacher[2].
[1]Center for VCA,Department of Plastic and Reconstructive Surgery, Chang Gung Memorial Hospital, Taoyuan, Taiwan; [2]Department of Plastic and Reconstructive Surgery, VCA Laboratory, Johns Hopkins University School of Medicine, Baltimore, MD, United States.

Background: Accumulating evidences indicate that vascularized bone marrow transplantation (VBMT) plays a critical role in inducing tolerance of vascularized composite allografts (VCA). Recipients with long-term surviving allografts show a higher degree of cell trafficking between donor and recipient. We hypothesize that short-term existence of VBMT may promote engraftment the donor cells and induce allograft tolerance.
Methods: Osteomyocutaneous (OMC) allografts from Balb/c were transplanted onto C57BL/6 mice and 1 mg anti-CD154 (POD 0), 0.5 mg CTLA4Ig (POD 2), and 3mg/kg/day for 7 days every other day for 3 weeks of rapamycin were administered. Transplanted mice combined with skin graft were divided into 4 groups: Group 1, OMC + skin graft (n=4); Group 2, OMC removed at POD 30 + skin graft (n=4); Group 3, OMC removed at POD 60 + skin graft (n=4); Group 4, OMC removed at POD 120 + skin graft (n=4).
Results: Sixteen of 20 mice receiving OMC allografts achieved long-term graft survival (>120 days). In animals with long-term allograft survival, peripheral blood analysis showed that cellular and humoral responses (IgG and IgM) as well as proinflammatory cytokines (IL-1β, IL-21, IL-22, IL-31, IL-33, IFNγ, TNFα, CD40L) were suppressed. Peripheral and central tolerance were showed by a significant deletion of $Vb5^+$ $CD4^+$ cells in peripheral blood and thymus in tolerated allograft animals, but not in rejected mice ($p<0.05$). Interestingly, transplanted animals which OMC allografts were removed at POD 30 were able to achieve long-term skin allograft survival with (>60 days). It was consistent with the data that showed animals before OMC removed versus after OMC removed showed no significantly elevated immune response. Additional group using $Rag2^{-/-}$ mice, skin paddle of OMC allograft was able to delay rejection after $5x10^6$ Teff cell donor specific injection in comparison with control skin graft (MST=47 vs 33.5) (Figure 1). The percentage of $CD8^+$ T cells in the animals was slightly lower than control skin graft at 30 days post injection.
Conclusions: Efficacy of VBMT to promote long-term allograft survival has been shown in this study. The data also suggest that intra- and extrathymic clonal deletion is one of mechanisms contribute to maintenance of tolerance.

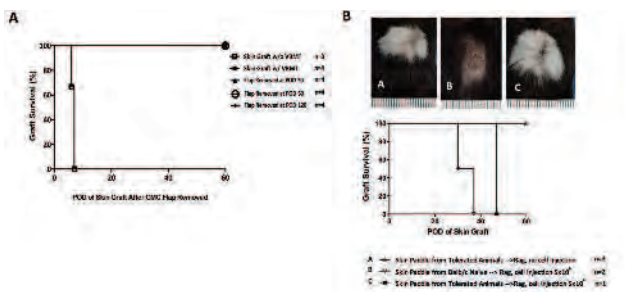

Figure 1. Skin allograft survival after VBMT removed in transplanted wild type animals (A) and skin paddle skin allograft survival in Rag 2 / animals treated with Teff adoptive transfer (B).

558.1

Human endothelial-like cells transdifferentiated from monocytes suppress allo-reactive T cells

Yuka Tanaka, Hideki Ohdan.
Gastroenterological and Transplant Surgery, Hiroshima University, Hiroshima, Japan.

Introduction: Although it is well known that liver allografts are often accepted by recipients, leading to donor-specific tolerance of further organ transplants, the underlying mechanisms remain unclear. We had previously showed that mouse liver sinusoidal endothelial cells (LSECs) had been proven capable of suppressing T-cells with cognate specificity for LSECs through programmed death (PD) 1/PD-L1 pathway in both of in vitro and in vivo models. Such immune-regulatory functions of LSECs have not been extensively investigated in human because of the limited availability of appropriate human samples. In the present study, we have determined immune-regulatory properties of human LSECs on allogeneic T cells. We have also proven that endothelial-like cells, phenotypically and functionally resembling LSECs, can be transdifferentiated from human peripheral blood monocytes.
Materials and Methods: The liver tissues were obtained from patients undergoing surgical resection of either hepatocellular carcinoma or colorectal liver metastasis. Human LSECs were isolated from the disaggregated liver tissues. Human CD14+ cells were isolated from peripheral mononuclear cells by using magnetic sorting and cultured in EGM2 medium supplemented with GM-CSF, IL-4, VEGF, hFGF-B, R3-IGF-1,and LPS for 14 days. The morphologic observations of the isolated/cultivated cells were carried out in a phase contrast microscope. The phenotype of those cells was analyzed by flow cytometry. In addition, we analyzed suppressive activity of those cells on allogeneic T cells by using a multiparameter MLR assay using CFSE labeling technique.
Results: Naïve human LSECs constitutively express molecules necessary for antigen presentation, i.e., freshly isolated CD105+ LSECs express MHC-class II, CD40, CD80, and CD86 together with PD-L1. The transdifferentiated cells from the CD14+ cells morphologically appeared endothelial-like cells and phenotypically resembled LSECs, i.e., they were MHC-class II+, CD40low, CD80low, CD86low, CD105+, PDL-1+. Allo-immune responses of both of CD4+ and CD8+ T cells in the MLR assays were significantly suppressed by subsequently adding the stimulator-type transdifferentiated endothelial-like cells. The proportion of CD25highCD4+ cells among the final products of the MLR assays with the endothelial-like cells was increased with propagated cells.
Conclusion: We have proven that human endothelial-like cells transdifferentiated from monocytes phenotypically resemble LSECs and suppress alloreactive T cells probably through PD-1/PD-L1 pathway. These findings raise a novel concept to induce hyporesponsiveness of alloreactive T cells by inoculating donor-derived those cells even in transplantation of organs other than liver.

Interaction between microchimerism-derived exosomes and host dendritic cells generates split tolerance.

William Bracamonte-Baran[1], Jonathan Flortentin[1], Ying Zhou[1], Ewa Jankowska-Gan [1], W. John Haynes[1], Todd Brennan[2], Arend Mulder[3], Frans Claas[3], Todd van Rood[3], WilliamJ. Burlingham[1].
[1]Surgery, University of Wisconsin-Madison, School of Medicine and Public Health, Madison, WI, United States; [2]Surgery, Duke University Medical Center, Durham, NC, United States; [3]Department of Immunohaematology and Blood Transfusion, Leiden University Medical Center, Leiden, Netherlands.

Maternal microchimerism (MMc) has been associated with development of allo-specific transplant tolerance, anti-tumor immunity, and cross-generational reproductive fitness, but its mode of action is unknown. We found in a murine model that MMc caused exposure to the non-inherited maternal antigens in all offspring, but in some, MMc caused membrane allo-antigen acquisition (mAAQ; "cross-dressing") of host dendritic cells (DC). Exosomes from serum of mAAQ+, but not mAAQ-, mice reproduced the DC cross-dressing phenomenon in vitro. In vivo, mAAQ was associated with increased expression of immune modulators PD-L1 and CD86 by myeloid (m)DC, and decreased presentation of allopeptide+self MHC complexes, along with increased PD-L1, on plasmacytoid (p)DC. Remarkably, membrane microdomains containing the acquired MHC alloantigens included CD86, but completely excluded PD-L1. In contrast, microdomains containing allopeptide+self MHC did not exclude PD-L1. Both findings were consistent with Western blot analysis of serum exosomes. Adoptive transfer of allo-specific transgenic CD4 T cells revealed a "split tolerance" status in mAAQ+ mice: T cells responding to acquired MHC alloantigens proliferated, while those responding to allopeptide+self MHC did not. Using isolated pDC and mDC for in vitro culture with allopeptide+ self MHC-specific CD4 T cells, we could replicate their normal activation in mAAQneg mice, and PD-L1-dependent anergy in mAAQ+ hosts. Finally, we found mAAQ+ mDC, and plasma exosomes capable of DC cross-dressing, in peripheral blood from a long-term microchimeric sibling kidney transplant recipient. We propose that exosomes provide a physiologic link between microchimerism and "split" tolerance, with implications for tumor immunity, transplantation, autoimmunity, and reproductive success.

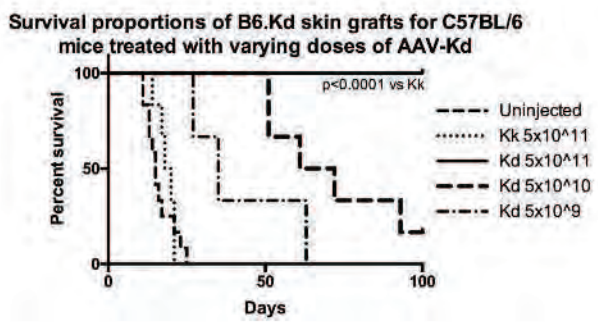
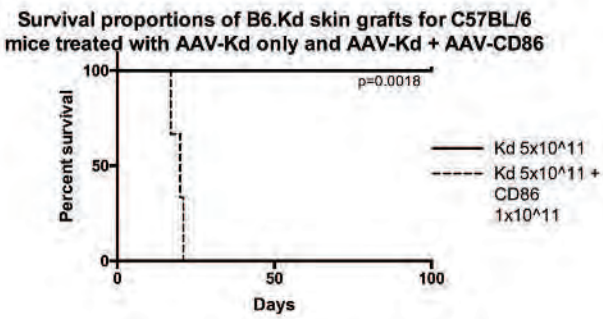
High-level co-expression of CD86 in recipient hepatocytes transduced with AAV-Kd breaks tolerance to Kd-bearing skin grafts

Mario Leong[1], Moumita Paul[1], Mamdoh Mouawadh[1], Eithne Cunningham[1], Szun Szun Tay[2], Chuanmin Wang[1], Patrick Bertolino[2], Alex Bishop[1], Ian Alexander[3], David Bowen[1,2], Alexandra Sharland[1]. [1]Collaborative Transplant Research Group, Central Clinical School, The University of Sydney, Sydney, Australia; [2]Liver Immunology Group, Centenary Institute, Sydney, Australia; [3]Gene Therapy Research Unit, Children's Medical Research Institute, Sydney, Australia.

Introduction: Allogeneic MHC class I expression by recipient hepatocytes following inoculation with liver specific AAV vectors results in tolerance to subsequent skin grafts expressing the same mismatched MHC allele[1]. Absence of CD86 expression by allo MHC-transduced hepatocytes may determine their ability to induce tolerance in alloreactive CD8+ T-cells.

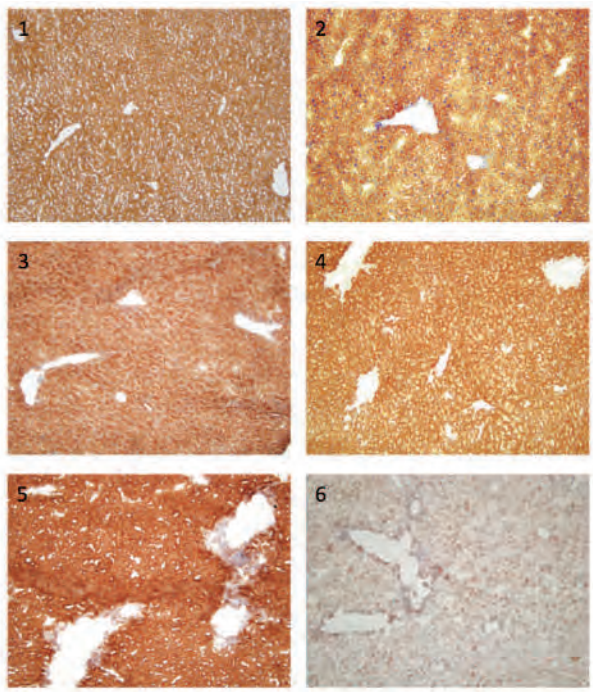
Methods: C57BL/6 mice were inoculated with AAV-Kd at doses $5x10^9$ to $5x10^{11}$vgc. A second cohort of mice were treated with AAV-CD86 at doses $1x10^{10}$ or $1x10^{11}$vgc in addition to AAV-Kd $5x10^{11}$vgc. AAV-Kk was the third-party control. Some mice received Kd-bearing skin grafts from B6.Kd mice at d7 post-inoculation. Graft survival, liver inflammation and Kd expression were monitored.





Results: Dose-dependent survival prolongation of Kd-bearing skin grafts in mice treated with AAV-Kd alone, but not control vector, culminated in indefinite survival of all grafts at $5x10^{11}$vgc ($p<0.0001$). Co-expression of high dose CD86 in conjunction with Kd produced significant liver inflammation, with transaminitis (ALT 1140-1570U/L), and heavy infiltration with CD8+ T cells (>2500 cells/hpf) and neutrophils (552 ± 21 cells/hpf) on d7. Livers transduced with Kd alone contained 5 CD8+ and 47 CD4+ T cells/hpf and ALTs of <50 U/L on d7. Rapid clearance of Kd-expressing hepatocytes was noted in mice receiving high-dose CD86. Whereas initial expression of Kd in these mice was strong and widespread (90% of the liver area expressed Kd on d7), by d14 post-inoculation, only 12.5% of the liver area expressed Kd, compared with 82% in mice inoculated with Kd alone. Concomitant expression of high-dose CD86 with Kd abrogates tolerance to B6.Kd skin grafts (MST 20 days vs >100 days) ($p=0.0018$). In contrast, co-administration of low dose CD86 with Kd resulted in mild elevation of ALT (88-120 U/L on d7), and a relatively sparse lymphocytic infiltrate where CD8+ T cells (46 ± 28 cells/hpf) were outnumbered by CD4+ T cells (117 ± 18 cells/hpf) in a ratio of 2.5:1. Kd expression in hepatocytes was maintained through d14 in mice also treated with low-dose CD86 (89-92% Kd-positive liver area, comparable to the AAV-Kd only group). Survival of B6.Kd skin grafts in mice inoculated with AAV-Kd and low dose AAV-CD86 is ongoing at the time of submission.

Discussion and Conclusions: Indefinite survival of Kd-mismatched skin grafts was achieved by administration of 5×10^{11} vgc AAV-Kd to C57BL/6 mice. High levels of CD86 co-expression in hepatocytes resulted in an intense inflammatory response within the liver, loss of expression of the Kd transgene, and abrogation of skin graft tolerance. Low dose CD86 produced mild inflammation and modest perturbation of liver function. CD4+ T cells predominate within the liver infiltrate of low-dose mice and may include Tregs; further characterization of these cells is in progress. Kd expression in hepatocytes was preserved in mice receiving low-dose CD86 at a time when it had been largely eliminated from mice treated with high-dose CD86. Absent or low expression of costimulatory molecules by hepatocytes is a requirement for tolerance induction by MHC I gene transfer.



IHC staining for Kd in: **1**-C57BL/6 mouse liver d7 post inoculation with AAV-Kd $5x10^{11}$ **2**-C57BL/6 mouse liver d14 post inoculation with AAV-Kd $5x10^{11}$ **3**-C57BL/6 mouse liver d7 post inoculation with AAV-Kd $5x10^{11}$ + AAV-CD86 $1x10^{10}$ **4**-C57BL/6 mouse liver d14 post inoculation with AAV-Kd $5x10^{11}$ + AAV-CD86 $1x10^{10}$ **5**-C57BL/6 mouse liver d7 post inoculation with AAV-Kd $5x10^{11}$ + AAV-CD86 $1x10^{11}$ **6**-C57BL/6 mouse liver d14 post inoculation with AAV-Kd $5x10^{11}$ + AAV-CD86 $1x10^{11}$

A comparison of anti-CD28 (FR104) and anti-B7 (belatacept) immunotherapy in monkey cardiac allograft transplantation

Tianshu Zhang, Natalie A.O'Neill, Dawn Parsell, Siamak Dahi, Natalia Kubicki, Jhade Woodall, Mehmet C.Uluer, Lars Burdorf, Ivan Tatarov, Katherine Thomas, Elizabeth Kang, Alena Hershfeld, Agnes M.Azimzadeh, Richard NPierson.
Department of Surgery, University of Maryland, Baltimore, MD, United States.

Aims: Therapeutic targeting of the CD28/B7 costimulatory pathway with CD28-specific agents might offer advantage over B7 blockade by favoring B7-mediated immune regulatory signals to T cells through CTLA-4 and PD-L1. Here we compare the immunosuppressive effects between FR104 (a humanized pegylated anti-CD28 Fab fragment) and belatacept in a cynomolgus monkey heterotopic heart transplant model.
Methods: Cynomolgus monkey heterotopic cardiac allograft recipients received FR104 (5 mg/kg, n=4; 10 mg/kg, n=3) or belatacept (5mg/kg, n=2; 10 mg/kg n=2) on days 0, 4, 7, 14, 21, 28, 42, 56, 70 and 84. Postoperatively, graft function (electrocardiogram; left ventricular systolic and diastolic pressure; heart rate) and core temperature were monitored daily by implanted telemetry device. Grafts were explanted at graft failure. Protocol biopsies and graft explants were analyzed for ISHLT AR grade and mean CAV score (0, 0%; 1, 1-10%; 2, 11-50%; 3, >50% occlusion).
Results: Median graft survival time (MST) with FR104 (5 mg/kg), FR104 (10 mg/kg), and belatacept (10mg/kg) was 122, 167, and 123 days, respectively. With low dose belatacept (5 mg/kg), one allograft experienced acute rejection on day 8, and to date the other graft continues to function (>8 days). On post-operative days 90-150, ISHLT/CAV scores of protocol biopsy and explanted allografts were found to have ISHLT/CAV scores of 0.6±0.4 and 0.5±0.3 for FR104 (5 mg/kg, long-term surviving grafts), 0.5±0.4 and 0.7±0.3 for FR104 (10 mg/kg, long-term surviving grafts), and 1.8±1.4 and 1.3±1.0 for belatacept (10 mg/kg) treatment groups, respectively.
Conclusions: Anti-CD28 blockade by FR104 prolongs cardiac allograft survival and attenuates CAV compared to belatacept. This preliminary data suggest that FR104 may be superior in modulating alloimmunity in cynomologus monkeys.

Selective blockade of CD28 costimulation prevented human allo-skin graft rejection in a humanised mouse model

Masaaki Zaitsu[1,2], Fadi Issa[2], Joanna Hester[2], Kate Milward[2], Bernard Vanhove[3], Kathryn Wood[2].
[1]Department of Gastroenterological Surgery I, Hokkaido University Graduate School of Medicine, Sapporo, Japan; [2]Transplantation Research Immunology Group, Nuffield Department of Surgical Sciences, University of Oxford, Oxford, United Kingdom; [3]INSERM UMR643, University of Nantes, Nantes, France.

Background: T cells are central to the detrimental alloresponses that develop after transplantation. Targeting the CD28-CD80/86 pathway with CTLA-4Ig reagents is a promising alternative to current immunosuppressive treatments. However, the CD80/86 blocking strategies that use CTLA-4Ig also inhibit the co-inhibitory CTLA-4 signal that is crucial to the regulation of T cell activation. In order to preserve the regulatory function of the immune system, selective blockade of the CD28 signal is theoretically advantageous as it would preserve coinhibitory signals that are facilitative for the development of a tolerant state. Importantly, costimulatory signals affect regulatory T cell homeostatic proliferation and regulatory function independently of their effects on effector T cells. In the current study, we have investigated the effects of selective blockade of the CD28 signal by a non-activating monovalent antibody in humanised mouse model.
Methods: Human skin grafts were transplanted to immunodeficient BALB/c.Rag2$^{-/-}$.cϒ$^{-/-}$ mice and were allowed to heal for 35 days before adoptive transfer of 10x10^6 human peripheral blood mononuclear cells (PBMCs) intraperitoneally. Groups of mice were treated with selective CD28 antibody: FR104 (5mg/kg), CTLA-4Ig (10mg/kg) or saline control intravenously twice a week for three weeks. All mice were started on the treatment regimen three weeks post-adoptive transfer of allogeneic human PBMCs to ensure adequate levels of human leukocyte chimerism in recipient mice.
Results: In this human skin transplantation model, prolongation of skin graft survival was observed in FR104 treated group, but not in CTLA-4Ig or saline treated recipients (median survival time, MST=63 vs. CTLA-4Ig (MST=31) or Saline (MST=31), ($p<0.05$)). While FR104 treatment significantly affected the level of human leukocyte chimerism in the peripheral blood, it remained above the required reconstitution level known to induce skin rejection. FR104 treatment significantly reduces the number of graft infiltrating CD4$^+$ cells (47.8±24.8 vs 83.3±5.1 cells/HPF, $P<0.02$) and CD8$^+$ cells (50.0±11.9 vs 111±34.0 cells/HPF, $P<0.04$) as compared to CTLA-4Ig treatment. No differences were noted in the number of graft infiltrating FOXP3$^+$ cells between FR104 and CTLA-4Ig groups although FR104 significantly reduces CD4 infiltration into skin grafts.
Conclusion: Short term selective blockade of CD28 costimulation preserves regulatory T cells and inhibits alloresponses. Selective CD28 blocking strategies might offer a strategy for reversing on-going acute rejection.

558.6

Modulation of influenza-specific humoral responses by selective CD28 blockade

Elizabeth Kang, Siamak Dahi , Tianshu Zhang, Natalie O'Neill, Evelyn Sievert, Elana Rybak, Ivan Tatarov, Richard N. Pierson, Agnes M. Azimzadeh.
Department of Surgery, University of Maryland School of Medicine and Baltimore VAMC, Baltimore, MD, United States.

Background: Current methods of immunosuppression are broadly inhibitory and thus associated with an increased risk of opportunistic infections. Immunization against bacterial and viral pathogens is a key preventative therapy clinically however immunosuppressed individuals are known to have impaired responses to immunization. We have shown previously that of a novel humanized peggylated αCD28 Fab Ab fragment (FR104) induces long-term survival of cynomolgus monkey cardiac allografts in association with decreased chronic rejection. Here we evaluate antibody responses to influenza vaccinations in the same FR104-treated animals.
Methods: Seven monkeys received a cardiac allograft and immunomodulation with FR104 at 10mg/kg (hi) or 5mg/kg (lo) (D0,4,7,14,21,28,42,56,70,84). Influenza vaccination was administered at d42 and 14d post graft explantation, with an additional vaccination at d150 in long survivors. Eight control cynomologus monkeys were primary and secondarily immunized with influenza vaccine in the absence of immunosuppression. (Results from four additional monkeys primary immunized with vaccine in presence of calcineurin inhibitor (CsA) and boosted in absence of immunosuppression are in progress.) Antibody levels were measured by ELISA and expressed as fold increase on d7, 14, 21 and 28 vs. pre-immunization levels. A 1.4- (IgM) or 2- (IgG) fold or greater increase was defined as a "detectable" response; > 5(IgM)/10(IgG)-fold responses were considered "robust".
Results: Graft survival time was not significantly different between FR104 lo (50,167, 178d) and FR104 hi (57,80,164,178d) groups. All control non-transplanted animals receiving no immunosuppression mounted a detectable 1° IgM (8/8, 2 robust), 6/8 developed 2° IgM (1 robust) and 7/8 developed 1° IgG (2 robust) and 2° IgG (4 robust) IgG responses. In contrast, only 3/7 transplanted animals receiving FR104 showed detectable 1° IgM and none developed 1° IgG responses during therapy. Secondary IgM and IgG responses were inhibited in early rejectors still exposed to FR104 (0/2), whereas while 2° IgM (4/4 detectable, 1 robust) and some IgG (2/4) were detectable observed during weaning of theas drug FR104 levels became undetectable aroundat d150. No tertiary responses were detectable in long survivors despite absence of drug exposure by ELISA and CD28 receptor occupancy assay (0/4).
Conclusions: Relative to no immunosuppression, αCD28 strongly suppressed primary and secondary responses and class-switching during therapy. Absence of tertiary responses after removal of long surviving grafts suggests long-term modulation (regulation) of immunity to viral antigens (antigen-specific immunoregulation, or tolerance) is induced by FR104, as previously described for αCD154 and influenza viral antigens (Crowe J AJT 2003). Additional studies will determine if αCD28 induces a unique profile compared to conventional immunosuppression with calcineurin inhibitors or B7-targeting agents inhibition with respect to protective immunity against common pathogens, and tolerogenic potential.

Modulation of the immune system by secretome-deficient mesenchymal stem cells

Franka Luk[1], Samantha F.H.de Witte[1], Sander S.Korevaar[1], Marieke Roemeling-van Rhijn[3], Marcella Franquesa[1], Tanja Strini[1], Sandra van den Engel[2], Madhusudhana Gargesha[4], Debashish Roy[4], Frank J.M.F.Dor[2], Edwin M.Horwitz[5], Ron W.F.de Bruin[2], Michiel G.H.Betjes [1], Carla C.Baan[1], Martin J.Hoogduijn[1].
[1]Nephrology and Transplantation, Dept. of Internal Medicine, Erasmus MC-University Medical Center, Rotterdam, Netherlands; [2]Transplant Surgery, Dept. of Surgery, Erasmus MC-University Medical Center, Rotterdam, Netherlands; [3]Dept. of Internal Medicine, University Medical Center Groningen, Groningen, Netherlands; [4]BioInVision Inc., Mayfield Village, OH, United States; [5]Dept. of Hematology/Oncology/BMT, Nationwide Children's Hospital, Colombus, OH, United States.

Mesenchymal stem cells (MSC) are widely studied as a cell therapeutic agent after solid organ transplantation. However, therapy with living culture-expanded cells comes with safety concerns. Furthermore, the development of effective MSC immune therapy is hampered by a lack of knowledge of the mechanisms of action and the therapeutic components of MSC. Such knowledge would allow better identification of diseases that are responsive to MSC treatment, appropriate timing of MSC therapy, optimization of the MSC product, and development of therapy based on functional components of MSC.
To close in on the components that carry the therapeutic immunomodulatory activity of MSC, we generated MSC that were unable to respond to inflammatory signals or secrete immunomodulatory factors but preserved their cellular integrity by heating the cells for 30 minutes at 50 °C. (HI-MSC). Secretome deficient HI-MSC and control MSC showed the same bio-distribution and persistence after infusion in mice with ischemic kidney injury. Both control and HI-MSC induced mild inflammatory responses in healthy mice, and, moreover, induced dramatic increases in IL-10 and reductions in IFN-γ levels in sepsis mice. In vitro experiments showed that in contrast to control MSC, HI-MSC lacked the capability to suppress T cell proliferation or induce regulatory B cell formation. However, both HI-MSC and control MSC modulated monocyte phenotype and their response to LPS.
The results of this study demonstrate that, in particular disease models, the immunomodulatory effect of MSC does not depend on their secretome or active cross-talk with immune cells but on the recognition of MSC by monocytic cells. These findings provide a new view on MSC-induced immunomodulation and help identify key components of the therapeutic effects of MSC.

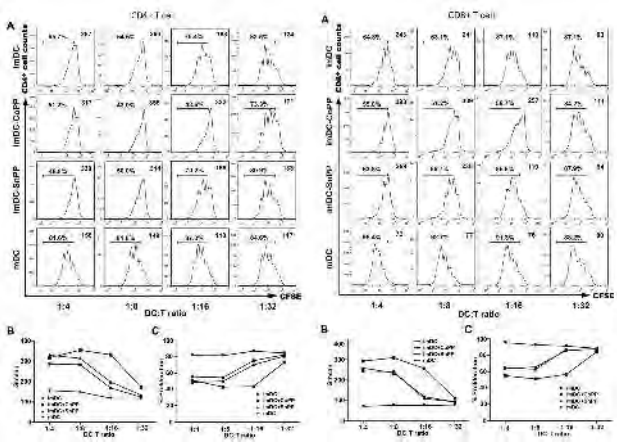
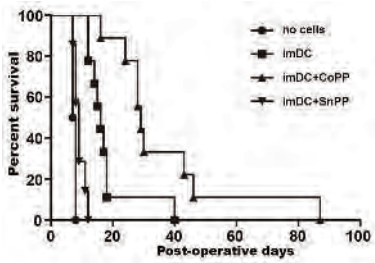
Upregulation of heme oxygenase-1 in immature dendritic cells improves their tolerogenic capacity in allotransplantation

Yu Jia, Gang Chen, Yue Zhao, Lu Wang, Song Chen , Xia Huang, Lan Zhu.
Institute of Organ Transplantation, Tongji Hospital, Huazhong University of Science and Technology, Wuhan, People's Republic of China.

Background: It has been reported that heme oxygenase-1 (HO-1) is critical for tolerogenic dendritic cells (tolDCs) to suppress T cell responses and tolDCs will lost their immunoregulatory effects when HO-1 is blocked. Therefore, significant upregulation of HO-1 may markedly improve the tolerogenic capacity of tolDCs.
Methods: Bone marrow-derived DCs (BMDCs) were generated from Balb/c mice with low doses of GM-CSF and IL-4. The adherent immature BMDCs were obtained as TolDCs. Upregulation of HO-1 in TolDCs (HO-1hi-TolDCs) was achieved by CoPP treatment. SnPP-treated TolDCs served as control cells. LPS was used to induce DC maturation. T cell proliferation was stimulated by anti-CD3/CD28 antibodies. Adoptive transfer of Balb/c donor-derived DCs (5×106) to C57BL/6 recipient mice was performed 7 days prior to cardiac transplantation. To study the distribution and location of adoptively transferred donor DCs in recipient mice, these cells were labeled with cellvue claret in advance.





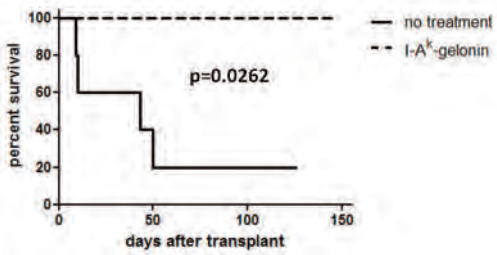
Results: CoPP treatment dramatically increased HO-1 expression in TolDCs, which rendered TolDCs refractory to LPS-induced maturation, enhanced their capability to suppress both CD4+ and CD8+ T cell proliferation stimulated by anti-CD3/CD28 antibodies (Fig.1), as well as induce more allogenic regulatory T cells (Tregs) in vitro after the coculture with naïve CD4+ T cells from C57BL/6 mice. Adoptive transfer of donor-derived untreated TolDCs significantly prolonged cardiac allograft survival compared to untreated control group (18.000±2.853 vs. 7.500±0.289 days). Interestingly, adoptive transfer of CoPP-treated TolDCs further extended the prolongation of allograft survival (36.778±6.974 days) (P<0.01, vs. untreated TolDCs group). In contrast, adoptive transfer of SnPP-treated TolDCs almost had no effects on the allograft survival (9.143±0.670 days) (Fig.2). Furthermore, adoptively transferred TolDCs were found to be mainly distributed in the recipient spleens. CoPP-treated donor TolDCs were found to be able to keep high levels of HO-1 expression and can survive longer than untreated TolDCs after adoptive transfer. In addition, alloreactive T cell response was significantly inhibited in CoPP-treated TolDCs group at day 7 after transplantation.
Conclusion: In vitro generated HO-1hi-TolDCs have enhanced tolerogenic capacity to modulate alloimmune responses both in vitro and in vivo, thus may provide an antigen-specific and cost-effective novel strategy to induce transplant tolerance.

558.9

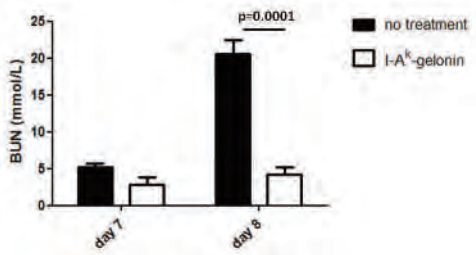
Indefinite survival of murine kidney allografts induced by depletion of donor passenger leukocytes

Kathryn Brown, Anna K.Nowocin, Lucy Meader, Lindsey A.Edwards, Richard A.Smith, Wilson Wong.
MRC Centre for Transplantation, King's College London, London, United Kingdom.

Introduction: While modern anti-rejection treatments have concentrated on modifying the immune system of the recipient, relatively less work has been done on modifying that of the donor. Rejection of donor organs depends on the trafficking of donor passenger leukocytes to the secondary lymphoid organs of the recipient to elicit an immune response. Therefore, the depletion of passenger leukocytes may be clinically applicable as a strategy to improve graft survival.
Materials and Methods: The F(ab')2 fragment of a monoclonal antibody against the donor MHC class II molecule I-Ak was conjugated with the plant-derived ribosomal inactivating protein gelonin to form an immunotoxin. After confirmation that the immunotoxin depleted target cells specifically *in vitro* and *in vivo*, it was administered to FVB recipients of target antigen-expressing, fully allogeneic C57BL/6 x CBA F1 kidneys.
Results: Treatment with immunotoxin resulted in indefinite survival of kidney allografts, compared with control allografts which had a median survival time of 43 days (p=0.0262).



Kidney function in the immunotoxin-treated group was also improved, with blood urea nitrogen at 4.2±1.03mmol/L at day 8 post transplant, compared with 20.64±1.77mmol/L in the control group (p=0.0001).



Immunotoxin-treated kidneys showed well preserved architecture and the presence of Foxp3+ cells, and recipients also displayed diminished donor-specific antibody formation and delayed rejection of subsequent donor type skin grafts.
Discussion: Our data suggest that depletion of donor passenger leukocytes, resulting in indefinite graft survival, can be achieved with a single treatment of an anti-donor MHC class II immunotoxin. The presence of an immune response against the graft, in the form of alloantibody generation and the rejection of challenge skin grafts, means that, if translated to the clinic, immunotoxin treatment would not induce indefinite graft survival, but may be a useful adjuvant to prevent rejection.
Conclusion: Current anti-rejection treatment is almost exclusively directed against the recipient's immune response. The approach described here, directed against donor cells, opens a new, simple and safe therapeutic avenue that can be used in conjunction with conventional therapy.

559.1

Immunoglobulin M therapy prevents development of type 1 diabetes by modulating the expression of dysregulated pancreatic microRNAs associated with disease pathogenesis

Preeti Chhabra, Ricardo Gehrau, Katherine Schiermeyer, Valeria Mas, Kenneth Brayman.
Surgery - Transplantation Division, University of Virginia, Charlottesville, United States.

Goal: Type 1 Diabetes (T1D) is hallmarked by beta-cell destruction. Our goal was to identify specific pancreatic microRNAs (miRNA) as potential biomarkers for T1D risk prediction and diagnosis, and to study the efficacy of Immunoglobulin M (IgM) therapy.
Background: At diagnosis, 80–90% of the beta-cells have already been destroyed. Current use of autoantibodies against islet antigens as biomarkers for disease prediction is unreliable. Therefore, identifying novel pancreatic miRNA biomarkers that predict the risk of T1D as well as its recurrence following pancreas or islet transplantation remains an important goal. IgM therapy prevents onset of T1D and studying its effect on the diabetic miRNA profile has immense therapeutic significance.
Methods: Female non-obese diabetic (NOD) mice (n=39) were used to identify differentially-expressed pancreatic miRNAs at various developmental stages of T1D. NOD mice were treated with IgM (n=15) or Saline (n=24) intraperitoneal and underwent pancreatectomy at 5-weeks (n=10), 14-weeks (n=15), and 21-weeks (n=14). T1D progression was categorized by blood glucose: normal (≤120mg/dL), prehyperglycemia (120-250mg/dL), and diabetes (≥250mg/dL). Labeled total pancreatic RNA was used for GeneChip miRNA v3.0 array hybridization and expression summaries obtained using RMA algorithm. Pairwise comparison was performed using two-sample t-test and P≤0.01 considered significant. IPA tool was used for biological analyses. Significant biologically relevant miRNAs were validated by RT-PCR.
Results: In non-treated mice, there was a significant increase in glycaemia at 14wk (p=0.005) and 21wk (p>0.001). In contrast, glycaemia in IgM-treated mice remained similar at 5wk (135mg/dL), 14wk (114mg/dL) and 21wk (113mg/dL). In non-treated mice, onset of diabetes occurred at 14 weeks. In total, 39 miRNAs were differentially expressed when comparing 5wk vs. 21wk. Differentially-expressed miRNA profiles were identified in non-treated (39 miRNAs) and IgM-treated (42 miRNAs) mice between 5wk and 21wk. A comparison between profiles identified 17 miRNAs specific for T1D and 30 miRNAs specific for IgM-treated mice. Downregulated T1D-specific miRNAs (miR-17-5p, -31-5p, -103-3p, and -379-5p) were related to pancreatic disorders and hyperglycemia. Upregulated IgM-treatment specific miRNAs (miR-155-5p, -21-5p, 16-5p, and 10a-5p) were associated with induction of monocytic and polymorphonuclear myeloid derived suppression cells and immunomodulation. Four miRNAs (miR-1224, -130b, -150, and -29a) overlapped between groups. The differential expression of miR-150 (which modulates B and T cells) was 7.6-fold higher in IgM-treated mice. Selected miRNAs (n=11) including miR-29a, -150, -31, and -103 were validated.
Conclusion: IgM therapy promoted normal glycaemia and upregulated immunomodulatory miRNAs in T1D compromised mice. This finding may be the basis for new therapeutic strategies for individuals at risk for T1D and patients undergoing transplantation.

The role of calcineurin inhibition in the dendritic cell response to Aspergillus fumigatus infection in lung transplant recipients

Amit Adlakha[1,2], Darius P. H. Armstrong-James[2], Boris Lenhard[1].
[1]MRC Clinical Sciences Centre, Imperial College, London, United Kingdom; [2]National Heart and Lung Institute, Imperial College, London, United Kingdom.

Background: Invasive aspergillosis caused by *Aspergillus fumigatus* has high morbidity and mortality in the setting of lung transplant immunosuppression. The calcineurin inhibitor FK506 inhibits the calcineurin–NFAT axis in immune cells, and has been shown to impair fungal killing, phagocytosis and TNF-α production in recipient alveolar macrophages[1]. Pulmonary dendritic cells play a crucial immune signalling role by phagocytosing antigen, maturing, secreting cytokines and stimulating T-cell immunity[2]. We used transcriptomics, cytokine profiling and cell surface marker analysis to investigate the mechanisms by which the dendritic cell-mediated fungal response is impaired by FK506 treatment.

Methods: Healthy volunteer monocytes were differentiated into monocyte-derived dendritic cells (moDC's) in cell culture with GM-CSF and IL-4 for 7 days. MoDC's were matured with interferon-gamma before treatment with FK506 +/- inoculation with *A .fumigatus* swollen conidia. Anti-CD83 (a late maturation marker) and anti-CD209 (a DC-specific marker) stained cells were analysed with the ImageStream imaging flow cytometer (Amnis). IL-2 and IL-10 in cell culture supernatant were quantified by sandwich ELISA. RNA-Sequencing - total-RNA was extracted using phenol/chloroform, poly-A +ve mRNA was selected and cDNA libraries were sequenced on the Illumina HiSeq 2500. Post-sequencing read quantification, alignment and differential expression were performed with open source C++/R software (kallisto[3], edgeR[4] and RTN[5]).

Results and Discussion: *Imaging flow cytomtery:* 5000 cells per condition were analysed. MoDCs were identified by gating for CD209. We observed upregulation of CD83 with infection of both immature moDCs (29,888 mean fluorescence units [SEM 1,393] vs 12,534 [799]; p<0·0001), and IFNγ-matured moDCs (36,778 [1,356] vs 26,228 [1,462]; p<0·0001).

CD83 mean fluorescence intensity was reduced with FK506 treatment of both infected immature moDCs (29,888 [1,393] vs 24,289 [1,253], p=0·0028) and infected, IFNγ-matured moDCs (36,778 [1,356] vs 30,159 [1.279], p=0·0004), but unchanged for uninfected moDCs (12,534 [799] vs 11,942 [762], p=0·5921).

ELISA: the upregulation of IL-2 in response to infection (median 16.8 vs 13.5pg/ml; p<0.01) was impaired by FK506 (median 16.8 vs 12.8pg/ml; p<0.01). IL-10 increased with infection in FK506-treated cells (median 146.4 vs 246.9pg/ml; p<0.01), but not in untreated cells (median 106.6 vs 101.8pg/ml; p<0.01).

RNA-Seq: 19 genes were differentially expressed in untreated moDCs +/- infection and 17 in FK506-treated moDC's +/- infection. Treatment-effect analysis revealed 74 genes under FK506-control. Co-expression analysis of these genes revealed strong correlation with 3 transcription factors - Oct-4, pod-1 and FOXF2.

Conclusion: *Aspergillus fumigatus* infection stimulates phenotypic maturation of moDCs and FK506 treatment inhibits this maturation. FK506 also impairs IL-2 release by moDCs in response to infection and is required for IL-10 release during infection – this is consistent with IL-10's known inhibitory action on IL-2, though the significance of the FK506-dependence of this response is unclear. Both these findings suggest an inhibitory role of FK506 on dendritic cell signaling to the adaptive immune system. Our transcriptomic co-expression analysis has identified targets to investigate regulatory transcriptional factor control by ChIP-Sequencing and hence elucidate the gene regulatory mechanisms by which FK506 exerts its inhibitory effect on the DC response to aspergillosis in lung transplants recipients.

Human B cell cytokines predict renal allograft rejection and early transplant outcomes

Aravind Cherukuri, Rajil Mehta, Sunday Ogunde, Sundaram Hariharan, David Rothstein.
Thomas E. Starzl Transplantation Institute, University of Pittsburgh, Pittsburgh, PA, United States.

Introduction: In renal transplantation, non-invasive predictive biomarkers that allow for early intervention are limited. We have previously shown that Breg activity in human peripheral blood is best defined by the ratio of IL-10:TNFa expression, and that this ratio falls in renal allograft rejection. Here we report findings from a prospective longitudinal study using these B cell cytokines as a biomarker in renal transplant recipients to predict rejection and outcome.
Methods: 164/374 patients transplanted between dates 1/13-12/14 having serial biopsies (for-cause, and protocol at 3 and 12 months) and blood drawn at 0, 1, 3, 6 and 12 months, were examined (315 biopsies and 534 PBMC samples). We assessed the ratio of B cell IL-10:TNFa expression (after in vitro stimulation with CD40L & CpG X24h) as a biomarker for transplant outcomes.
Results: Patients received thymoglobulin induction with rapid steroid withdrawal and were maintained on tacrolimus and mycophenolate. 37% of the patients had acute rejection (AR) within the first year (all ACR and 3 ACR&ABMR; 21% subclinical, 16% clinical). Of patients with AR: 35% had early AR (≤3mos) that responded to therapy (no recurrence), 27% had early AR with persistence/recurrence at 12mos despite initial treatment, and 38% had late AR (6-12mos) despite a normal early biopsy. The utility of 3-month histology and currently available markers like creatinine or DSA was limited in that they were not predictive of response to treatment or late AR.
At every time-point, patients with AR (clinical or subclinical) had a significantly lower IL-10:TNFα ratio within all B cell subsets, especially within the T1 transitional subset (T1B). The T1B IL-10:TNFα ratio at 3 months was independently associated with rejection (OR 0.31 per increase in ratio by 1; p=0.0001) and predicted AR at any time (ROC AUC 0.88, Sensitivity 85%, Specificity 86%, p<0.0001). At 3months, even in patients with normal protocol biopsy, a low T1B IL-10:TNFα ratio predicted subsequent rejection with a sensitivity of 88% and specificity of 81% (AUC 0.86, p<0.0001). Moreover, in patients treated for early AR, the T1B cytokine ratio at 3mos was strongly predictive of response to therapy vs. persistent/recurrent AR (ROC AUC 0.79, Sensitivity 78%, Specificity 80%, p=0.004). Importantly, patients with a low T1B IL-10:TNFα (<1.26, determined by ROC analysis) ratio had significantly worse creatinine at 18 and 24 months post-transplant and this was independently associated with interstitial fibrosis with inflammation (IF+i) on 12 months biopsy (OR 0.31, p=0.03).
Importantly, this biomarker is not confounded by "inflammation" due to infection. Patients with BK or CMV viremia had significantly higher T1B IL-10:TNFa ratio compared to those with AR (4.9 vs. 0.97, P=0.02). Moreover, Tacrolimus trough levels and the total Mycophenolate dosage were comparable between the groups with high and low cytokine ratio.
Conclusion: T1B IL-10:TNFα ratio at 3 months appears to be a strong and a specific biomarker for the prediction and course of renal allograft rejection, and possibly long–term outcome. If confirmed, it may help inform individualized therapeutic intervention.

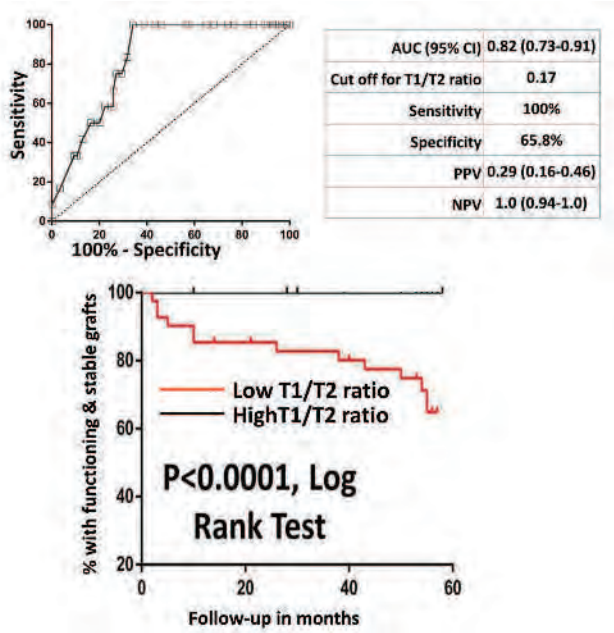
Transitional B cell T1/T2 ratio is a prognostic marker for human renal allograft deterioration

Aravind Cherukuri[1], Richard Baker[2], David Rothstein[1].
[1]Thomas E. Starzl Transplantation Institute, University of Pittsburgh, Pittsburgh, PA, United States; [2]Leeds Transplant Centre, Leeds Teaching Hospitals NHS, Leeds, United Kingdom.

Introduction: Human transitional B cells (TrB) play a significant role in auto and alloimmune disease. We showed that TrB express a high IL-10:TNFα ratio and this falls in the presence of renal allograft rejection. TrB are comprised of less mature T1 and more mature T2 cells. We characterized the cytokine expression of T1 vs. T2 cells and investigated the utility of T1/T2 ratio as a biomarker for allograft deterioration.
Methods: Various B subsets were defined as described previously. Specifically T1 and T2 cells were differentiated by the level of expression of CD24 and CD38 and cytokine expression analysed after in vitro stimulation (CpG+CD40L X48hrs). In a training set, TrB were analysed in 84 patients (45 patients at time of for-cause biopsy for allograft dysfunction and 39 patients with stable allograft function) and followed for an additional 5 years. In a validation set, we also examined T1 and T2 cells 2 years post-transplant in 97 stable patients who were participating in a RCT comparing alemtuzumab (n=51) or basiliximab induction (n=46). The clinical outcome in both training and validation sets was a composite of graft loss or doubling of serum creatinine over a five year follow-up from the time of B cell analysis.
Results: While both T1 and T2 cells expressed similar IL-10, T1 cells expressed significantly less TNFα, resulting in a higher IL10:TNFα ratio. Thus, T1 cells are the B subset with the most anti-inflammatory profile. The number of T1 cells was found to fall in rejection (resulting in lower T1/T2 ratio), and this contributed to the low IL-10:TNFα ratio in this setting.



Training set: In 84 patients (with either prior graft dysfunction or stable baseline function), a low T1/T2 ratio was a strong predictor of allograft deterioration over 5 years (ROC AUC 0.84, P<0.001) and was independently associated with allograft deterioration (per increase in the ratio by 1: HR 0.9, P=0.007). The association remained statistically significant when the analysis was only included patients with prior graft dysfunction.

Validation set: T1/T2 ratio measured 2-years post-transplant in stable patients was a strong predictor of outcome over the subsequent 5 years (ROC AUC 0.82, P<0.001) and was independently associated with allograft deterioration (HR 0.88, P=0.02). Thus, the T1/T2 ratio can segregate clinically quiescent patients into two halves. Those with a high ratio had entirely stable function, whereas in the group with a low ratio, ~35% had allograft deterioration over the ensuing five years (Fig1).
In both the test and validation sets, the T1/T2 ratio was a much stronger predictor of graft deterioration than traditional markers like eGFR (test set, eGFR ROC AUC 0.76 vs. T1/T2 ratio 0.84; validation set, eGFR AUC 0.64 vs. T1/T2 0.82), or DSA (test set, DSA ROC AUC 0.68 vs. T1/T2 ratio 0.84; validation set, DSA AUC 0.66 vs. T1/T2 0.82).
Conclusion: We demonstrate that the T1 subset of TrB expresses a strongly anti-inflammatory cytokine profile. A decrease in T1:T2 ratio (due to selective loss of T1 cells) is a strong prognostic biomarker for subsequent renal allograft deterioration.

The unholy triad of inflammation, infection and immune rejection of the kidney allograft- partners in crime?

Franco B.Mueller, Hua Yang, Carol Li, Catherine Snopkowski, Liana Perry, Elly Varma, John Lee, Darshana Dadhania, Manikkam Suthanthiran, Thangamani Muthukumar.
Department of Medicine and Transplantation Medicine, Weill Cornell Medicine, New York, United States.

Introduction: The role of inflammation and infection in acute allograft rejection is emerging. Inflammsomes are multiprotein molecular complexes that are critical players regulating inflammation. DAMPs (Damage-Associated Molecular Pattern molecules) are host molecules that can initiate/perpetuate inflammation. PAMPs (Pathogen-Associated Molecular patterns) are molecules associated with pathogens that are recognized by the innate immune system. Thus, while cellular rejection of allograft is primarily driven by T-cells in response to alloantigens, infection and tissue damage in pre-clinical models trigger the activation of inflammasomes and shape the adaptive immune response (reviewed by Chong and Bromberg, Literature Watch, AJT 2013). Their role in rejection of human allograft has not been well characterized. We tested the hypothesis that inflmmasomes, DAMPs and PAMPs are hyperexpressed during acute rejection in human kidney allografts.
Methods: We studied 12 kidney transplant biopsies from 12 kidney recipients; 7 were for-cause biopsies categorized as Banff acute cell mediated rejection (ACR) and the remaining 5 were protocol/surveillance biopsies categorized as normal (Protocol/Normal). RNA from these biopsies was sequenced in Illumina HiSeq platform. The sequencing data analysis workflow using Galaxy consisted of FASTQC for read quality control, mapping of reads to reference genome assembly: Feb 2009 GRCh37.75/hg19, read alignment with TopHat2, generation of the raw counts with HTSeq, normalization with Cufflinks and differential gene expression analysis using the Bioconductor R package edgeR. We used KEGG and NCBI databases to identify genes implicated in inflammasomes, DAMPs and PAMPs.
Results: The mean (SD) age of recipients in the ACR group was 48 (14) years and was 45 (12) years in Protocol/Normal biopsy group. There were 3 women, 1 Black and 2 deceased donor transplants in ACR group and 3 women, 0 Blacks and 2 deceased donor transplants in Protocol/Normal group. Median time from transplant to biopsy: 12 months (ACR) and 6 months (Protocol/Normal). Median serum creatinine at biopsy: 2.63 (ACR) and 1.20 (Protocol/Normal). Median RIN (RNA integrity number) value: 7.2 (both groups). Single end reads per sample: >36 million. We identified 26 key inflammasome genes, 17 key DAMP genes and 33 key PAMP genes in KEGG and NCBI databases of which 16, 17 and 29, respectively, had >1 cpm in at least 1 biopsy sample. Among these, 9 inflammasome genes, 5 DAMP genes and 11 PAMP genes were differentially expressed (figure-1–genes overlapping among the categories are shown only once).

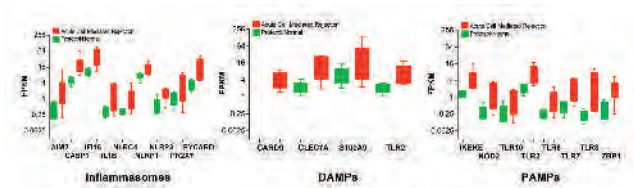

Figure-2 below shows the fold change of transcripts (ACR vs. Protocol/Normal).

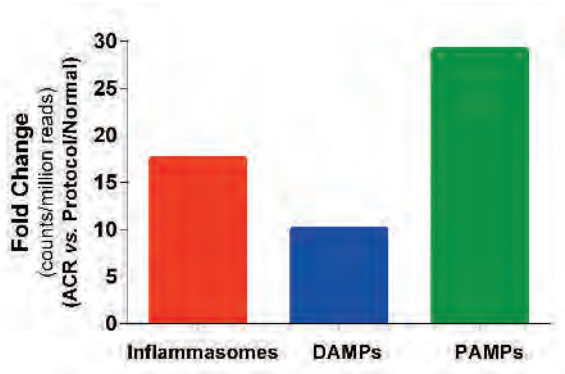

Conclusion: Our RNA-Seq and bioinformatics analyses have discovered that Inflammsomes, DAMPs and PAMPs are all hyperexpressed during ACR in the human kidney allograft suggest a possible causal link between inflammation, infection and immune rejection, and the need to target each of these components contributing to allograft damage and failure.

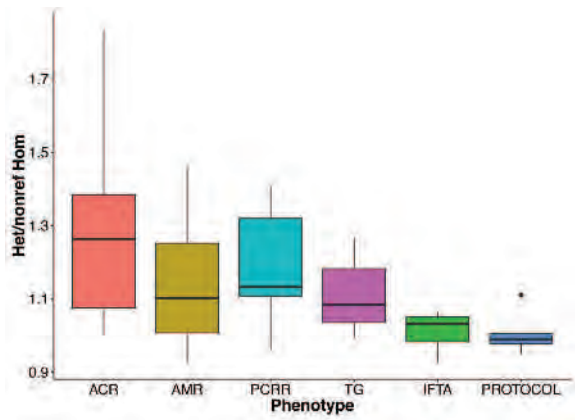
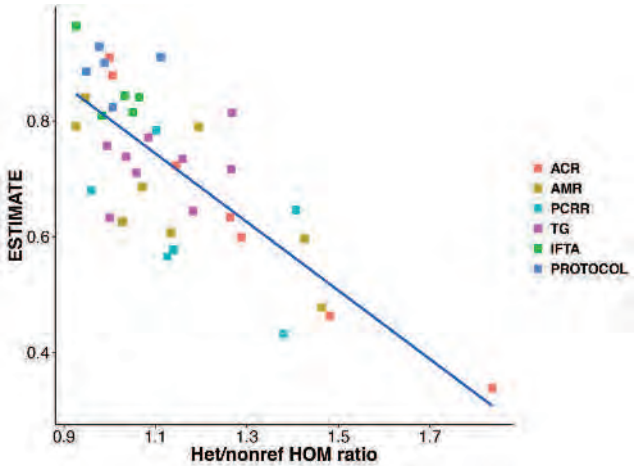
The Het/Hom ratio calculated from RNA-Seq data: a universal and unbiased quantitative measure of immune cell invasion into human allografts

Gaurav Thareja[1], Hua Yang[2], Shahina Hayat[1], Carol Li[2], Catherine Snopkowski[2], Liana Perry[2], Elly Varma[2], Mohamad Alkadi[2], John Lee[2], Darshana Dadhania[2], Karsten Suhre[1], Manikkam Suthanthiran[2], Thangamani Muthukumar[2].
[1]Physiology and Biophysics, Weill Cornell Medicine-Qatar, Doha, Qatar; [2]Department of Medicine and Transplantation Medicine, Weill Cornell Medicine-Qatar, New York, United States.

Introduction: Immune rejection continues to remain the Achilles heal of organ transplantation. The advent of RNA sequencing technology at affordable costs has brought this powerful tool to the bedside and has paved the way for personalized medicine. Newer bioinformatics approaches are being developed to analyze the sequencing data in order to better understand the mechanistic basis of rejection. However standard RNA sequencing analysis does not account for the invasion of the host immune cells into the allograft and the fact that the RNA sequences are generated from two different sets of DNA. The Het/Hom ratio, defined as the ratio of heterozygous to non-reference homozygous variant calls, has been traditionally used as a quality measure to identify contamination in variant calls using DNA sequencing data. RNA obtained from the allograft biopsies provides a classic example of "sample mix-up", as the allograft and immune cells on the allograft are from two different individuals. Herein, we propose the use of the Het/Hom ratio from the RNA sequencing data of the transplant kidney biopsies to resolve immune cell invasion into the allograft.
Methods: We studied 40 human kidney allograft biopsies, 35 showing abnormal findings based on the Banff classification, including acute cellular rejection (ACR, n=7), acute antibody mediated rejection (AMR, n=8), plasma cell rich acute rejection (PCRR, n=6), fibrosis (IFTA, n-=5), transplant glomerulopathy (TG, n=9) and 5 surveillance/protocol biopsies showing no abnormalities (Protocol). We isolated total RNA and sequenced using the Illumina HiSeq platform at high coverage (>36 million single ended reads per sample). Data was processed following GATK best practice protocols for RNA seq variant calling using the iGenome human Ensembl gene annotation. Individual Het/Hom ratios were calculated using an in-house python script. We used ESTIMATE software to infer the admixture of immune and donor kidney cells. These admixture fractions were converted into purity scores and a score of 1.0 describes no admixture of cells the biopsy.
Results: The median Het/Hom ratio of protocol biopsies, which have no/minimal invasion of immune cells, was 0.989. This observed Het/Hom ratio was lower compared to all rejection biopsy groups. The highest ratio of 1.263 was found in the ACR group.



The Het/Hom ratio was strongly correlated with the purity score from ESTIMATE (r=-0.77; p-value=5.3x10-9).



Conclusion: In the first of its kind study in kidney transplantation, we show the feasibility of using Het/Hom ratio as a measure of immune cell invasion into the kidney allograft. The Het/Hom ratio was significantly associated with fractional admixture of recipient immune and donor kidney cells in the allograft biopsies. Our results suggest that the Het/Hom ratio is an unbiased and universal biomarker for recipient immune cell invasion estimates in any type of allografts.

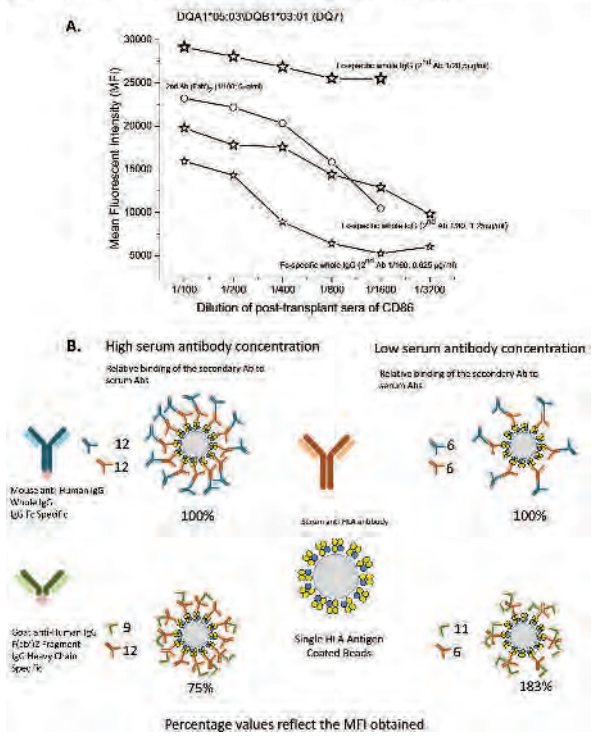
Importance of the nature and binding specificity of the secondary antibody used in Luminex single antigen bead assays for monitoring clinically relevant HLA IgG antibodies in pre- and post-transplant patients

Mepur H. Ravindranath, Vadim Jucaud, Nubia Banuelos, Anh Nguyen, Mathew Everly, Junchao Cai, Paul I.Terasaki.
HLA Immunology, Terasaki Foundation Laboratory, Los Angeles, CA, United States.

Antibodies (Abs) to HLA antigens are monitored to guide donor selection and kidney paired exchange programs, to assess de novo Ab-mediated rejection and to monitor desensitization therapies. Efforts have been made to provide insight into the sources of variability caused by commercially available HLA antibody testing kits. The PE-conjugated secondary antibody (2nd Ab) is least recognized as a factor that can influence the reproducibility and reliability of the assay.
In the 1960s, polyclonal (Fab')2 of IgG was developed as a 2nd-Ab for monitoring antigens on cell surfaces, tissue sections and Western blots, since its binding to multiple epitopes on the primary antibody promotes signal amplification when multiple (Fab')2 bind to antigen-bound antibody. For monitoring HLA-Abs, a dual-laser flow based detection flow cytometer (Luminex) is used with single antigen bead (SAB) assays, which defines the second laser as the one that "determines the magnitude of the PE-derived signal, which is in direct proportion to the amount of bound analyte" [1]. Fc-specific Abs are considered critical "for the quantitation of the heavy chain antibody only in samples containing other immune-globulins and proteins such as serum or tissue culture media"[2]. This implies that the signal amplification by multiple Fab or (Fab')2 may not be directly proportional to the HLA-bound antibodies on SAB, and hence not reliable or reproducible for monitoring the level of HLA-Abs.

Figure 1 **A.** Box titration (Primary Ab dilution X 2nd Ab dilution) profile of a *de novo* donor specific DQ antibody in a patient (CD86), examined with polyclonal $(Fab')_2$ 2nd Ab and monoclonal Fc-specific IgG 2nd Ab. Note the dilution of 2nd Ab required for titration. **B.** Theoretical model validates the hypothesis and illustrates the differences in the binding of $(Fab')_2$ *versus* Fc-specific IgG to high and low concentrations of the serum Ab. The superiority and reliability of the monoclonal Fc specific IgG 2nd Ab for monitoring high and low concentration primary Ab is indicated.



To test this hypothesis, the Mean Fluorescent Intensities (MFI) of HLA-Abs in the sera of healthy donors (n =13) and renal allograft recipients (n = 10) obtained with "constant heavy chain (CH)-binding" polyclonal PE-(Fab')2 and "Fc-specific" monoclonal PE-IgG (whole) as 2nd Ab in a Luminex SAB assay, are compared. IgG Isotype specific 2nd Abs were also employed. The 2-tailed paired-sample T-test was used to assess the significant differences.

Table 1 shows the number of HLA antigens reacting with (Fab')2 is higher than that with monoclonal Fc-specific IgG for both healthy and allograft recipients. For healthy donors, this difference is significant for all loci (1A). Among allograft recipients, significant difference is seen for HLA-B and HLA-DRB loci (1B). For both, the number of anti-HLA IgG isotypes are also lower than those recognized by (Fab')2 2nd Ab. Perhaps the reported prevalence of high numbers of "non-donor specific HLA antibodies" and even "pre-existing DSA" is a consequence of using (Fab')2 as the 2nd Ab. Strikingly, the MFIs (even titers) obtained for de novo DSA in allograft recipients are markedly higher with Fc-specific whole IgG than those obtained with (Fab')2 as 2nd Ab. An example and the mechanism underlying the differential binding of (Fab')2 and Fc-specific whole IgG as 2nd Ab are shown in Figure 1. These findings suggest the superiority of Fc-specific IgG over CH-binding (Fab')2 as the 2 Ab for SAB assays.

Table 1. **A.** The number of HLA antigens reacting for each HLA Loci is significantly higher with polyclonal CH-binding (Fab')$_2$ than with monoclonal Fc-specific IgG as 2nd Ab. **B.** The number of HLA antigens reacting for each HLA Loci is higher with (Fab')$_2$ than with Fc-specific IgG .

De-novo donor specific antibodies (DSA) monitoring in living related transplantation

Raj Kumar Sharma, Sonia Mehrotra, Mahabaleshwar Mayya, Narayan Prasad, Amit Gupta, Anupama Kaul, Dharmendra S.Bhadauria.
Nephrology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India.

Introduction: Development of donor specific antibody (DSA) could have an adverse effect on graft survival due to immunologically mediated acute or chronic allograft failure. Single antigen bead assay(SAB) on luminex platform is the gold standard for detection of post-transplant DSA. There are no reports of new onset DSA detected by solid phase cross match luminex assay using donor lysate as marker of rejection after transplantation.

Material and Methods: Present study is comparison of two methods (single antigen bead assay and solid phase cross match luminex assay using donor lysate), their sensitivity and specificity.121 living donor kidney transplant recipients were prospectively evaluated after transplantation for development of de-novo DSA against Class I and Class II HLA antigens. All recipients were complement dependant cytotoxicity (CDC) cross match negative at room, warm and cold temperatures at the time of kidney transplant. Eighty seven recipients (72%) were given induction with either Basiliximab (62 recipients) or ATG (25 recipients) at the time of kidney transplant.

Result: Twenty six recipients (21.4%) out of 121 developed dn-DSA within one to three months post-transplant by solid phase cross match luminex assay using donor lysate. Out of patients who were dn-DSA+ive, 11 were given Basiliximab and 9 got ATG induction. Sixteen out of 26 dn-DSA positive recipients (61%) developed only Class II DSA and seven patients (27%) developed only Class I DSA positivity; while in three patients (12%), both Class I and Class II dn-DSA developed. Eight recipients(31%) developed acute rejection in positive group; six (75%) of these patients with acute rejection had evidence of antibody mediated rejection (ABMR) with glomerulitis (5 C4d–ve, one C4d +ve), while two patients (25%) had T cell mediated AR. In the DSA negative group (78.5%): 18 recipients out of 95 (19%) developed acute rejection. Twenty two(18.2%) recipients out of 121 were positive for dn-DSA by single antigen bead assay and ninety nine (81.8%) were negative. All acute rejection episodes in dn-DSA negative group were responsive to treatment. There was more use of ATG induction as compare to Basaliximab induction in d-DSA positive group. On comparison of these two methods; the sensitivity of lysate assay was 100% (95% confidence interval 84.56 % to 100%) and specificity was 95.96% (95% confidence interval 89.98% to 98.89%) against SAB assay.There was increased dn-DSA development with ATG induction (36%) as compared to Basiliximab (17.7%) and no induction (17.6%).

Conclusion: Development of de-novo DSA was associated with more acute rejection episodes (31%) in positive group vs 19% in negative group. dn-DSA positive group had more ABMR (75% of AR) while 33.3% of AR in dn-DSA negative group were ABMR. DSA detected by luminex solid phase cross match developed in 18 patients (5 Class I, 11 Class II, both class I and II in 2 patients) without clinical rejection. These patients would need to be followed up to assess significance of dn-DSA on graft outcome.Lysate based solid phase cross match with 100% sensitivity and 95.96% specificity which is cheaper than SAB assay can be useful for post-transplant DSA monitoring.

Evidence for structural variants within an individual HLA-I molecule coated on Luminex single antigen bead assays: impact on monitoring HLA antibodies for organ allocation and de novo DSA in transplant patients

Vadim Jucaud, Mepur H.Ravindranath, Paul I.Terasaki.
Terasaki Foundation Laboratory, Los Angeles, CA, United States.

Recombinant HLA-I (rHLA-I) molecules coated on the single antigen beads (SAB) are used to screen HLA-I antibodies for pre-transplant organ allocation and post-transplant monitoring of de novo DSA. While a HLA-I trimeric complex, comprised of a glycosylated HLA heavy chain (HC), β2-microglobulin (β2m), and a peptide, is expressed on the cell surface, every single rHLA-I molecules on SAB are structurally diversified as β2m-associated HLA HC (β2aHC) and β2m-free HLA HC (β2fHC)[1]. The conventional LabScreen® HLA-I beads (LS1A04, Lot# 8, One lambda, USA) does not distinguish anti-β2aHC from anti-β2fHC. iBeads (Lot#1, One Lambda) specifically express β2aHC, and acid treated HLA-I beads (expressing β2fHC only) help to resolve the nature of HLA-I antibodies in patients[2],[3]. In addition, peptide dissociation from HLA HC results in peptide-free (pepF)-β2aHC and β2fHC molecules (Figure 1A).

There is a need to evaluate the relative distribution of the variants of an individual HLA-I molecule on SAB. We used anti-HLA-I monoclonal antibodies (mAbs), targeting the structural variants of rHLA-I: W6/32 (specific for β2aHC); TFL-006[4],[5] and HC-10 (both specific for β2fHC) (Figure 1B). mAbs were tested at 10µg/mL, MFI cutoff >1000 for positivity. The percentage (%) of β2fHC, coated on SAB, is based on the MFI of W6/32 and TFL-006, as HC-10 binds to alleles on iBeads whereas TFL-006 does not, but both bind to the same alleles on acid treated beads. Table 1A shows the median % of β2fHC on SAB.

HC-10 can bind HLA-I HC in the presence of β2m as HC-10 recognizes alleles on iBeads. The arginine (R) at position 62 on the α1 domain of a HLA HC is critical for HC-10 binding[6], and R62 is masked in the presence of peptide in the groove[7]; perhaps HC-10 recognizes a pepF-β2aHC. iBeads may carry peptide-associated and pepF-β2aHC, whereas HLA-I beads carry peptide-associated and pepF-β2aHC, as well as β2fHC. Table 1A shows the median % of pepF-β2aHC coated on iBeads. Acid treatment results in a homogeneous entity of pepF-β2fHC for all HLA-I alleles. Based on the reactivity of the mAbs, it is possible to identify the alleles with no or minimal β2fHC on HLA-I beads, as well as the alleles with β2fHC and pepF-β2aHC on iBeads (Table 1B).

HC-10	-	+	-?	+++

The structural variants of any single HLA-I allele (presence and absence of β2m and a peptide in the groove), on HLA-I beads or iBeads, creates an awareness of similar variants in the binding specificities of de novo DSA or non-DSA, and also provides an explanation for reports on DSA associated with negative Flow-XM[8],[9]. Anti-β2fHC are found in non-alloimmunized healthy males[10], and are highly prevalent in HLA-sensitized patients awaiting donor organs[2]. The clinical evaluation of pre- or post-transplant DSA (using allele-specific MFI cutoff based on TFL-006 reactivity against HLA-I beads and HC-10 reactivity against iBeads) may improve the organ allocation for patients awaiting a transplant and the management of post-transplant patients, by discriminating β2fHC HLA-I DSA.

Table 1. A. Median Percentage of β2fHC coated on SAB. Median Percentage of peptide-free β2aHC coated on iBeads. **B.** Percentage of β2fHC on HLA-ClassI beads, iBeads, and percentage of peptide-free β2aHC on iBeads.

Evaluation of PK profile and clinical outcomes with Hexal® versus Prograf® in de novo renal transplant recipients: Results from SparTacus - a multicentre, prospective randomized study

Wolfgang Arns[1], Andrea Huppertz[1], Thomas Rath[1], Stephan Ziefle[1], Lars C.Rump[1], Anita Hansen[1], Daniel Baeumer[2], Klemens Budde[1], Lukas J.Lehner[1], Thomas Klein[1], Peter Schenker[1].
[1]Spartacus Study Group, Koln, Germany; [2]Novartis Pharma GmbH, Nuernberg, Germany.

Background: Little data exists for pharmacokinetic (PK) profile and safety and efficacy of generic Tacrolimus (TAC) vs the reference drug in renal transplant recipients (RTxR). SparTacus (NCT01649427) study was designed to compare PK profile of Tacrolimus Hexal® with Prograf® in RTxR and to evaluate whether the comparable exposure results in similar renal function.
Methods: Overall 76 *de novo* RTxR were randomized to this prospective two-phase open-label study, to receive TAC Hexal® (n = 35) or Prograf® (n = 41), with enteric-coated mycophenolate sodium + corticosteroids + basiliximab induction therapy. TAC was initiated at a dose of 0.15 mg/kg/day and further adjusted to target trough levels (C0) of 8–12 ng/mL from Tx to month (M) 1; 5–10 ng/mL up to M3; and 5–8 ng/mL up to M6. Primary objective of this phase I study was to demonstrate comparable PK at M1 post-Tx and non-inferior renal function (GFR, Nankivell) at M6 in TAC Hexal® vs Prograf®. Renal function was analyzed using ANCOVA model with treatment, donor status and center as factors and GFR at baseline as covariate. Incidences of efficacy and safety outcomes at M6 were also assessed.
Results: Overall 44 patients were included in PK analysis. At M1, PK parameters [dose-normalized TAC 12-h-AUC (h/10^{3}xL), Cmax (1/10^{3}xL) and mean 12 h TAC C0 (µg/L)] were comparable between TAC Hexal® vs Prograf® (Figure 1a). A total of 24 patients in the TAC Hexal® and 29 patients in Prograf® group were analyzed at M6. Renal function was better with TAC Hexal® vs Prograf® (unadjusted mean: 72.1 vs 63.0 mL/min). Mean GFR after adjusting (for the treatment, donor status and center, ANCOVA model) was also better with TAC Hexal® (47.9 mL/min) vs Prograf® (37.9 mL/min) and the between treatment difference of 10.0 mL/min (95% CI 1.10 – 18.90) was non-inferior (P = 0.004) and superior (P = 0.0285) in TAC Hexal® vs Prograf®. TAC Hexal® vs Prograf® had a comparable incidence of composite efficacy events and its individual components (Figure 1b). Incidence of adverse events (AEs) was comparable between TAC Hexal® vs Prograf® (AEs: 97.1 % vs 100%; serious AEs: 37.1% and 42.1%).
Conclusion: TAC Hexal® vs Prograf® had similar PK profile along with better renal function and comparable efficacy and safety in *de novo* RTxRs.

Reduced incidence of cytomegalovirus infection in kidney transplant recipients receiving everolimus: A cost-effectiveness analyses

Hélio Tedesco-Silva, Claudia Rosso Felipe, Alexandra Nicolau Ferreira, Marina Pontello Cristelli, Juliana Mansur Siliano, Mayara Ivani de Paula, Adrieli Barros Bessa, Priscila Ruiz Ruppel, José Medina - Pestana.
Nephrology Division, Hospital do Rim - UNIFESP, São Paulo, Brazil.

A cost-effectiveness analysis was performed using data from a prospective single center trial where de novo kidney transplant recipients received a single 3 mg/kg dose of rabbit antithymocyte globulin, tacrolimus, everolimus and prednisone (r-ATG/EVR, n=85); basiliximab, tacrolimus, everolimus and prednisone (BAS/EVR, n=102) or basiliximab, tacrolimus, mycophenolate and prednisone (BAS/MPS, n=101). This analysis was developed from the perspective of the Public Healthcare System. The clinical outcomes considered for this analysis were: acute rejection, CMV viremia/disease, graft dysfunction, surgery complications, graft loss and death. The economic outcomes contemplated in the analyses were direct medical costs, including: immunosuppression, treatment of adverse events and follow-up of patients. To estimate costs and outcomes for each treatment a Markov model was used to follow patients during 12 months after transplantation.
Compared to the standard of care regimen, r-ATG/EVR and BAS/EVR were associated with 36% and 15% reduction in costs. This was primarily due to lower costs associated with the management of adverse events as there were no significant differences in the costs of immunosuppressive drugs. Compared to the standard of care regimen, r-ATG/EVR showed higher effectiveness in all clinical outcomes while BAS/EVR showed higher effectiveness for the prevention of CMV infection and graft loss and comparable effectiveness for the other clinical outcomes. A probabilistic sensitive analysis with 1000 simulations, using ±20% variation in costs and beta distributions for transition probabilities, efficacy and safety data, confirmed these observations.
Conclusion: In this cohort of de novo kidney transplant recipients receiving tacrolimus and prednisone and no CMV pharmacological prophylaxis, everolimus containing regimens were dominant (cost-effective) compared to the standard of care regimen.

Abbreviated thymoglobulin and basiliximab induction therapy in patients undergoing kidney transplantation results in superior graft and patient survival with less infectious complications

Vaughn Whittaker, Angelika Gruessner, Rainer Gruessner.
Surgery, SUNY Upstate Medical University, Syracuse, United States.

Purpose: We report the two year outcomes from our single center experience with the novel induction regimen using Thymoglobulin (3 mg/kg) in divided doses given on the operative day (post operative day zero and post-operative day one and Basiliximab (20 mg) given on post operative day two, followed by steroid-free maintenance therapy for patients undergoing kidney transplantation.
Methods: We retrospectively reviewed 168 consecutive patients receiving thymoglobulin plus basiliximab induction therapy (cohort A) transplanted between August 2013 to December 2015 and compared outcomes against a prior five year series August of 2008 to August 2013 with 144 consecutive patients who received a basiliximab-based regimen followed by steroid maintenance (cohort B) for low immunologic risk patients PRA <20% and Thymoglobulin 6mg/kg for those with PRA >20%. The two groups were compared against the length of hospital stay, rejection events, infectious complications, graft failure, and death, for a period of up to 2 year.
Results: Patients receiving the thymoglobulin plus basiliximab induction therapy experienced shorter length of hospital stay compared to our historical cohort (mean 4.63 d vs. 6.25 d, median 4 d vs. 5 d). The biopsy proven rejection rate was similar between the two groups (11/168 (6.5%) vs. 14/144 (9.7%)), p <0.05. Infectious complications were similarly comparable between the two groups (42/168 (25%) vs. 59/144 (41.0%)), p<0.05. Graft failure rate (4/164 (2.38%) vs. 7/144 (4.86%)), p<0.05, and death rate for primary transplants (1/168) (0.59%) vs. 4/144 (2.7%)), p <0.05, in the thymoglobulin plus basiliximab group compared to our historical cohort. There were only rejection episode in the group with high immunologic risk PRA >20.
Conclusions: Two year results from utilizing a Thymoglobulin plus basiliximab for induction in kidney transplantation demonstrate that the combination is associated with decreased length of hospital stay, comparable infectious complication rates, and superior graft and patient survival. It may be associated with cost savings as well.

570.4

Comparison of mycophenolic acid (MPA) exposure after conversion from enteric-coated mycophenolate sodium (EC-MPS) twice-daily to once-daily in adult kidney transplant recipients

Eric Dailly[1], Claire Garandeau[2], Matthieu Grégoire[1], Guillaume Deslandes[1], Pascale Jolliet[1], Diego Cantarovich[2].
[1]Clinical and Pharmacological Department, Nantes University Hospital, Nantes, France; [2]Institute of Transplantation-Urology-Nephrology (ITUN), Nantes University Hospital, Nantes, France.

The variation of mycophenolic acid (MPA) exposure was investigated after the administration of the enteric coated formulation of mycophenolate sodium (EC-MPS), 720 mg twice-daily versus 1440 mg once-daily, in association with tacrolimus (Advagraf®) and prednisone, following adult kidney transplantation.
MPA full pharmacokinetic profiles were assessed 3 months after transplantation in 8 patients, before and after switching EC-MPS from 720 mg twice-daily to 1440 mg once-daily (morning intake). The pharmacokinetic parameters of MPA were calculated by a non-compartmental analysis. The log transformed values of MPA pharmacokinetic parameters were compared between periods using a paired t-test ($p < 0.05$ for significance).
No significant variations of MPA area under the plasma concentration–time curve from 0 to 24 h, plasma concentration at the end of the dosing interval, maximum observed drug concentration (Cmax) and apparent clearance were observed. Time to reach Cmax (Tmax) was significantly increased (3.29 h versus 2.16 h; p= 0.03) after administration of EC-MPS once-daily versus twice-daily.
The significant increase in Tmax but not Cmax when EC-MPS was given once-daily, confirmed the non-linear pharmacokinetic profile of MPA. This result could be explained by a saturable absorption of MPA and/or by a high inter-individual variability. EC-MPS once-daily (1440 mg) was well tolerated and seemed to be sufficient and efficacious as 720 mg twice-daily.

Impact of early red blood cell transfusion after kidney transplantation on de novo HLA sensitization in the setting of antithymocyte globulin induction

Thomas JOUVE[1,2], Guillaume Rigault[1,2], Benedicte Janbon[2], Rachel Tetaz[2], Nicolas Terrier[2], Dominique Masson[3], Lionel Rostaing[1,2], Paolo Malvezzi[2].
[1]Health department, Grenoble Alpes University, Grenoble, France; [2]Nephrology and kidney transplantation unit, Grenoble University Hospital, Grenoble, France; [3]HLA laboratory, Etablissement Francais du Sang, Grenoble, France.

Introduction: HLA specific antibodies detection (HSA) and that of Donor Specific Antibodies (DSA) were revolutionized by the introduction of solid phase assays (Luminex®), therefore making these antibodies a powerful biomarker for humoral injuries to the allograft. Determinants of HSA development entail non-adherence to immunosuppressive drugs but also allosensitizing events such as red blood cell (RBC) transfusions. Recent works showed a higher incidence of DSA in transplanted patients following RBC transfusion events, but no specific data exist for AntiThymocyte Globulin (ATG) induction.
This work aims at assessing whether peri-transplant RBC transfusion resulted in post-transplant HLA sensitization, in the setting of ATG induction therapy.
Patients and Methods: All consecutive patients benefiting from a first ATG-induced kidney allograft between 2004 and 2014 at our center with no history of HLA immunization were included retrospectively, provided transfusion history and HSA history were available. Our primary endpoint was immunization-free survival. Early transplantation was defined as a RBC transfusion within the first three months after transplantation. We defined de-novo HLA sensitization as at least one positive Luminex test post-transplantation (whether class I or II), without sensitization history before transplantation.
Results: Among the 1018 kidney transplants performed at our center, 432 patients corresponded to our inclusion criteria (82.7% of our patients received ATG induction). Of these, 152 (35%) received at least one RBC unit within the first three months after transplantation. With a median follow-up of 3.9 years, de-novo HLA sensitization occurred in 46 patients (16%) in the no early RBC transfusion group VS 34 patients (22%) in the early RBC transfusion group (chi-squared test: p=0.176, log-rank test: p=0.172, fig. 1). A multivariate Cox survival analysis (adjusting for recipient age, donor-status (living or brain-dead), pre-transplantation RBC transfusion and CNI use) shows that HSA development is not associated with early RBC transfusion (p=0.18).
Conclusion: We found that early RBC transfusion in the setting of ATG induction therapy does not result in HLA sensitization.

Evaluation of genetic variants in diabetes susceptibility genes and disposition-related genes as risk factors for the development of new-onset diabetes after transplantation in Singapore asian adult kidney transplant recipients

Wai-Ping Yau[1], Diana Chee-Siang Teh[1], Anantharaman Vathsala[2,3].
[1]Department of Pharmacy, Faculty of Science, National University of Singapore, Singapore, Singapore; [2]National University Centre for Organ Transplantation, National University Hospital, Singapore, Singapore; [3]Department of Medicine, Yong Loo Lin School of Medicine, National University of Singapore, Singapore, Singapore.

Introduction: New-onset diabetes after transplantation (NODAT) is a clinically significant metabolic complication of transplantation contributing to increased risks of graft failure and mortality. Previous studies suggest that specific genetic variants increase the risk of NODAT. This study aimed to evaluate 14 single nucleotide polymorphisms (SNPs) in 8 diabetes susceptibility genes and disposition-related genes as potential risk factors for NODAT development in Singapore Asian adult kidney transplant recipients on tacrolimus- or cyclosporine-based immunosuppression.
Materials and Methods: A nested case-control study was conducted at National University Centre for Organ Transplantation, Singapore. Cases included kidney transplant recipients without pre-existing diabetes who developed NODAT while controls included those who did not develop NODAT. Blood samples were collected from study participants and DNA was extracted for genotyping at the following SNPs: *KCNQ1* rs2237892 and rs2237895; *HHEX* rs1111875, rs5015480 and rs7923837; *CDKAL1* rs10946398 and rs7756992; *TCF7L2* rs4506565; *CCL5* rs2107538, rs2280789 and rs3817655; *ADIPOQ* rs2241766; *CYP3A5* rs776746 *(CYP3A5*3)*; and *ABCB1 (MDR-1)* rs1045642. Odds ratio (OR) and 95% confidence interval (CI) were calculated to estimate the risk of NODAT development with each evaluated SNP.
Results and Discussion: Of the 101 patients who received kidney transplants between 1994 and 2014 (79.2% Chinese, 11.9% Malays and 8.9% Indians), 53 (52.5%) received tacrolimus-based immunosuppression while 48 (47.5%) received cyclosporine-based immunosuppression. A total of 36 patients (35.6%) developed NODAT over a mean (± standard deviation) follow-up duration of 3.2 ± 3.7 years. NODAT generally occurred earlier in patients receiving tacrolimus (1.7 ± 2.3 years, n=17) than in those receiving cyclosporine (4.6 ± 4.2 years, n=19). Overall, NODAT patients (n=36) had a larger pre-transplantation body weight than non-NODAT patients (n=65) (66.5 ± 13.2 kg vs. 60.1 ± 12.3, p=0.044). Among the 14 SNPs evaluated, increased NODAT susceptibility was observed for the *KCNQ1* rs2237895 AC genotype as compared with the AA genotype in the overall population (OR: 2.56; 95% CI: 1.02 – 6.44). Though not statistically significant, the *CYP3A5**1/*3 genotype seemed to confer an increased risk of NODAT development as compared with the *CYP3A5**3/*3 genotype among patients receiving tacrolimus (OR: 3.81; 95% CI: 0.99 – 14.67).
Conclusion: Our data suggest that pre-transplantation body weight and the *KCNQ1* rs2237895 AC genotype are associated with an increased risk of NODAT development in Singapore Asian adult kidney transplant recipients on tacrolimus- or cyclosporine-based immunosuppression. While the *CYP3A5**1/*3 genotype was not found to be significantly associated with NODAT development, the observed trend suggests possible genetic predisposition to NODAT among patients on tacrolimus-based immunosuppression that warrants further evaluation in larger studies.

571.1

Management of humoral rejection in renal transplantation: Results of a single center

Ebru H.Ayvazoglu Soy, Mahir Kirnap, Murat Yilmaz, Gokhan Moray, Mehmet Haberal.
Transplantation Center, Baskent University, Ankara, Turkey.

Introduction: Humoral rejection (HR) following renal transplantation (RT) is still major concern for graft survival despite improvements in surgical technique and immunotherapy. We had various protocols for HR with various success rates. In this study we evaluated three different protocols according to effects on graft survival.
Materials and Methods: Between October 1985 and December 2015 we performed 2248 RT at our centers. We diagnosed humoral rejection by renal biopsy and confirmed with PRA levels, USG findings and C4d deposition ratio. The choice of HR treatment protocols are done according to the changes in Turkish government health insurance payment system. HR are grouped according to treatment protocols; pulse steroid followed by anti-thymocyte globulin (PS+ATG), plasmapheresis followed by intravenous immunoglobulin (PF+IVIG), plasmapheresis followed by rituximab (PF+RX). We evaluated all RT patients with preoperative and postoperative creatinine levels (at the 6th and 12th month of RT). RT patients with HR were evaluated with C4d deposition ratio, creatinine levels before and after HR treatment and also preoperative and postoperative creatinine levels (at the 6th and 12th month of RT).
Results: We detected HR in 574 RT patients (29.8%). We applied PS+ATG in 124 (21.7%), PF+IVIG in 206 (35.8%), and PF+RX in 244 (42.5%) RT patients. In PS+ATG group we had no PRA positivity; we detected PRA positivity in 33 (16%) patients in PF+IVIG group, 39 (16%) patients in PF+RX group (p=0,394). No statistically significance is detected between groups' responses to rejection therapy with respect to creatinine levels (before and after rejection therapy at the first week, at the 6th and 12th month of RT). In all groups creatinine levels are significantly decreased after HR therapy (p <0,001).
Conclusions: Current treatment protocols for humoral rejection following RT are developed with new agents. There was no difference in response to treatment between these different protocols.

Never events and hospital acquired conditions after kidney transplant

Zhobin Moghadamyeghaneh, Mahmoud Alameddine, George Burke, Gaetano Ciancio, Linda Chen.
Miami Transplant Institute, University of Miami/ Jackson Memorial Hospital, Miami, United States.

Introduction: Never Events (NE) and Hospital Acquired Conditions (HAC) after surgery have been designated as quality metrics in health care by the centers for Medicare and Medicaid Services (CMS).
Methods: The NIS database 2002-2012 was used to identify patients who underwent kidney transplant. Multivariate analysis using logistic regression was used to identify outcomes and risk factors of HAC and NE after transplant.
Results: Among 172,586 patients who underwent kidney transplant alone there were 48 Never Events, all of which were due to retained foreign bodies. Among HAC after surgery, falling was the most common (42%) followed by poor glycemic control (21%), vascular catheter-associated infection (19%), catheter-associated urinary tract infection (7%), stages III & IV pressure ulcers (3%), and ABO incompatible blood transfusion (2%)(Figure 1). HAC and NE after surgery lead to a significantly increased length of stay (13 days vs. 7 days, P<0.01), hospital charges ($233128 vs. $147312, P<0.01), mortality (AOR: 2.78, P<0.01), and a trend towards increased need for reoperation (AOR: 2.05, P<0.01). A significantly higher risk of HAC or NE events was seen for patients who were expected to have higher mortality (AOR: 1.51, P=0.01) and morbidity (AOR: 2.02, P<0.01) before operation.
Conclusions: HAC and NE after kidney transplant are uncommon, but they are associated with a significant increase in mortality, hospitalization length of stay, hospital charges, and reoperation of patients. Quality improvement initiatives should target HAC and NE in order to successfully reduce or prevent these events.

Clinical outcomes of percutaneous coronary intervention on patients with cardiac allograft vasculopathy

Raymond Fung, Katherine Y.Y.Fan, Man Hong Jim.
Cardiac Medical Unit, Grantham Hospital, Hong Kong, Hong Kong.

Introduction: Cardiac allograft vasculopathy (CAV) is the Achilles heel of heart transplant. CAV accounts for nearly 25% of all deaths between year 1 and 10[1]. Although retransplantation is the only definite treatment for CAV, due to limited donor pool, it is rarely performed in our locality[2]. Bypass surgeries were also not commonly performed because of the suboptimal results. Another treatment option is percutaneous coronary intervention (PCI). The effect of PCI on native coronary artery disease has been extensively studied. There were relatively few studies on the clinical effect of PCI on CAV patients[3]-[6]. Most of the studies only involved early generation devices. In this retrospective study, patients with either angiographically or intravascular ultransound diagnosed CAV treated with PCI (both old and newer generation devices) were included. The primary objective is to determine the incidence of major cardiac events after the procedure.

Table 1. Baseline , clinical and procedural characteristics

Baseline characteristics		
Age		51.4 ± 12.1
Male, gender n (%)		17 (87.5%)
Body weight, kg		61.5 ± 14.0
Body height, m		1.61 ± 0.06
Body mass index, kg / m^2		22.7 ± 3.23
Clinical characteristics		
Reasons for transplant	Ischaemic cardiomyopathy	6 (37.5%)
	Chronic rheumatic heart disease	4 (25%)
	Dilated Cardiomyopathy	3 (18.8%)
	Myocarditis	1 (6.3%)
	Tetralogy of fallot	1 (6.3%)
	Sarcoidosis	1 (6.3%)
Clinical presentations	Annual examination	11 (68.8%)
	ST elevation myocardial infarction	3 (18.8%)
	Stable angina	1 (6.3%)
	Congestive heart failure	1 (6.3%)
Cytomyegalovirus status	Positive	2 (12.5%)
Peripheral vascular disease		0 (0%)
Diabetes mellitus		6 (37.5%)
Hypertension		9 (56.3%)
Hyperlipidaemia		15 (93.8%)
Renal failure		2 (12.5%)
Old stroke		0 (0%)
Ejection fraction	> 55%	14 (87.5%)
	35-55%	2 (12.5%)
Smoking	Current smoker	2 (12.5%)
	Exsmoker	7 (43.8%)
	Nonsmoker	6 (37.5%)
	Unknown	1 (6.3%)
Aspirin		16 (100%)
Clopedogrel / Ticagrelor		16 (100%)
Beta-blocker		8 (50%)
Calcium channel blocker		5 (31.3%)
Angiotensin converting enzyme inhibitor		5 (31.3%)
Angiotensin II receptor blocker		3 (18.8%)
Statin		14 (87.5%)
Insulin		1 (6.3%)
Oral hypoglycaemic agents		5 (31.3%)
Calcineurin inhibitors	Tacrolimus	4 (25%)
	Cyclosporin	8 (50%)
Antimetabolites	Azathioprine	4 (25%)
	Mycophenolate mofetil	10 (62.5%)
Prednisolone		8 (50%)
Proliferative signal inhibitors	Everolimus	6 (37.5%)
Procedural characteristics		
Vessel(s)	Left main artery	1 (6.3%)
	Left anterior descending artery	13 (81.3%)
	Left circumflex artery	3 (18.8%)
	Right coronary artery	5 (31.3%)
Number of vessels	1	12 (75%)
	2	2 (12.5%)
	3	2 (12.5%)
Type of devices	Bare metal stents	2 (12.5%)
	First generation drug eluting stents	3 (18.8%)
	Second generation drug eluting stents	8 (50.1%)
	Second generation drug eluting stent + drug eluting balloon	1 (6.3%)
	Drug eluting balloon	1 (6.3%)
	Bioresorbable vascular scaffold	1 (6.3%)

Materials and Methods: Consecutive CAV patients treated with PCI in Grantham Hospital between 1 Jan 2005 and 31 Dec 2015 were included. Patients treated with medical therapy / CABG or retransplantation excluded. Methods of intervention and type of devices used were subjected to the discretion of operators. Clinical and procedural data were retrieved from the computer based electronic clinical records, PCI reports. The primary endpoint was the composite of cardiac death, target lesion revascularization (TLR), non-target lesion revascularization (nonTLR), congestive heart failure (CHF), acute

coronary syndrome (ACS) and stent thrombosis. Data were analyzed using SPSS software. Kaplan-Meier analysis was used to examine the major cardiac events.

Results and Discussions: A total of 16 patients were identified. Table 1 shows the baseline, clinical and procedural characteristics of the population. Most patients have CAV diagnosed during their annual examinations. Mean follow up duration was 5.14 ± 4.22 years. The mean time of PCI from transplant was 7.74 ± 3.88 years. The majority of patients were implanted with newer generation devices; eight (50.1%) patients had second generation drug eluting stents (DES), one (6.3%) patient had mixed second generation DES and drug eluting ballon (DEB), one (6.3%) patient had DEB and one (6.3%) patient had biosresorbable vascular scaffold . The incidence of major cardiac events was 9 (56.3%) (Fig 1). There were 1 (7.2%) cardiac deaths, 4 (25%) TLR, 3 (18.8%) nonTLR and 1 (6.3%) CHF. Mean time of cardiac event from PCI was 12.9 ± 3.8 years.

Conclusion: This study included patients implanted with newer generation devices. Despite improvement in interventional devices, CAV patients still have a high cardiac event rate (56.3%). The majority of the events were due to repeat revascularization which reflected progressive nature of the condition. There was only 1 death in our series. However this study is limited by its small sample size. The overall effect of PCI in CAV may be better shown in study with larger number of patients.
